Using the altimetry data, we detected a zonal band distribution of dominant high frequency oscillation in the world ocean. In any certain latitude it has a most significant frequency, from 1/30days in about 7°N(S) to 1/120days in about 28°N(S). This dominant frequency is well in agreed with the critical frequency in the latitude, which is derived from WOA01 data, according to the linear theory for the first baroclinic Rossby wave. Because the group velocity is zero for the Rossby wave with critical frequency, the wave energy will be trapped in the local area and do not propagate to anywhere. Considering the energy of other Rossby waves will propagate to the west (long wave) or the east (short wave) with the group velocity, the most significant oscillation in certain latitude could be expected from the Rossby wave with zero group velocity. Our result is a good illustration for the validity of linear wave theory in the World Ocean.

CELLULAR NITROGEN LEVELS REGULATE NITROGEN UPTAKE BY PRYMNESIUM PARVUM (HAPTOPHYTA) AND ITS INTERACTIONS WITH CO OCCURRING SPECIES.
A Baltic Sea plankton community was grown in mesocosm with dissolved organic matter concentrated from sewage or inorganic nitrogen. After 4 days the ichthyotoxic Prymnesium parvum, cultivated under nitrogen sufficient and deficient conditions, was added to both plankton communities. Uptake rates of 15N labeled dissolved inorganic (nitrate) and organic (urea, glycine and glutamic acid) nitrogen by P. parvum were measured in concentration gradients every 24h for three days. Prymnesium parvum was able to take up amino acids (AA) more efficiently than nitrate and urea at low concentrations. Nitrogen deficient cells had higher nitrate uptake rates (0.7-1.8 fg (g atom-N (cell h)^(-1)) than nitrogen sufficient cells (<0.5 fg (g atom-N (cell h)^(-1)). Incubation of nitrogen deficient P. parvum cells with the nitrate grown community lead to an increase of intracellular nitrogen and uptake rates of nitrate grown community lead to an increase of intracellular nitrogen and uptake rates of nitrate (0.7-1.8 fg (g atom-N (cell h)^(-1)) throughout the experiment. This dataset shows that nitrogen uptake by P. parvum are affected by intracellular nitrogen levels, availability of substrate and availability of prey.

DETAILED SPATIAL AND TEMPORAL MEASUREMENTS OF SPONGE EXCUSSION PLUMES MEASURED IN SITU UTILIZING THE AQUARIUS REEF BASED OBSERVATORY
Sponges on Caribbean coral reefs are a conspicuous group of abundant sessile organisms that play important roles in element cycling and reef ecology. Sponges, as a group, are thought to dump and filter large volumes of seawater, potentially altering the particulate and dissolved organic and inorganic composition of the seawater. Previous studies, mostly lab-based, reported pumping rates that are low compared to our in situ measurements (up to 110,000 liters of seawater filtered per liter of sponge tissue per day) for a broad range of sponge species. Initially, we used a dye-video technique to acquire “snap shots” of sponge pumping rates, and have since deployed advanced acoustic Doppler instruments during Aquarius missions to obtain high frequency measurements of sponge exhalent water velocities for multiple individuals over 48-72 hour periods. These data reveal that sponges have complex pumping behaviors, occasionally swinging between periods of high pumping to virtually no pumping over a 24 hour period. Rigorous, long-term pumping rate data are crucial for accurately determining sponge-mediated fluxes of various dissolved chemicals that potentially impact the health of coral reef ecosystems.

EVALUATING OCEANIC MODEL PARAMETERIZATIONS WITH TRANSIT TIME DISTRIBUTIONS
Transit time distributions (TTDs), or age spectra, provide a powerful conceptual framework for evaluating and interpreting the advective-diffusive transport properties of geophysical flows. We describe the results of computing global and regional TTDs in a global ocean GCM with 1 degree nominal resolution. We show how the results depend on different model parameterizations. We further compare them to computed spectra from an eddy resolving model and to constraints derived from observations.

A COMPARISON OF BIOLOGICAL TRENDS FROM FOUR NORTHERN HEMISPHERE MARINE ECOSYSTEMS
Major features of four marine ecosystems were analyzed based on a broad range of oceanographic, fisheries dependent and independent datasets. The ecosystems analyzed included the Gulf of Maine/Georges Bank in the Northwest Atlantic Ocean, the Norwegian/Barents Seas in the Northeast Atlantic Ocean, and the eastern Bering Sea and the Gulf of Alaska in the Northeast Pacific Ocean. We examined survey trends in major fish abundances, fishery catches, total system fish biomass, zooplankton biomasses, and measures of various species diversity indices. We standardized each time series and examined trends and anomalies over time, using both qualitative and statistical methods. We specifically compared dynamics of functionally analogous species from each of these four ecosystems. Major commonalities among ecosystems included a relatively stable amount of total fish biomass and the importance of large calanoid copepods, small pelagic fishes and gadids. Many of the peaks in these components were synchronous across ecosystems. Major differences between ecosystems included gradients in the magnitude of total fish biomass, differences in lower trophic level production, commercial fish biomass, and timing of major biological events. This work demonstrates the value of comparative analysis across a wide range of aquatic ecosystems, suggestive of common and broad-scale features across all northern hemisphere ocean systems.

A NEW CHEMICAL LEACH METHOD TO ASSESS THE FRACTION OF PARTICULATE IRON THAT IS AVAILABLE TO PHYTOPLANKTON
Identifying the sources and concentrations of biologically available trace metals in surface waters is fundamental to the distribution of oceanic plankton productivity. In addition
to the dissolved phase, the particulate trace metal pool is also an important source of microelements to phytoplankton. Accurate means of estimation of the fraction of the particulate trace metal phase that can be solubilized over the time frame of phytoplankton generation is necessary to understanding plankton productivity. A comparison of common leach methods was conducted on coastal and riverine suspended particulate matter to determine the differences between several operational definitions of the particulate trace metal fraction. Leachable trace metal concentrations were determined using HR-ICP-MS. A commonly used 25% acetic acid leach ("HAc") was shown to underestimate the labile fraction; in particular, it does not access intracellular trace metals. This study presents a modification of the HAc leach, "HAc+", with the addition of a heating step and reducing agent. Both leach methods (HAc and HAc+) were applied to surface transect samples from the Columbia River plume; HAc+ resulted in a more complete solubilization of the labile particulate iron.

ESTIMATING SUBSURFACE CROSS-SHORE FLOW FROM OBSERVATIONS OF SURFACE CURRENTS

Observations of nearshore circulation have traditionally been made with in situ arrays of current meters positioned within and very near the surf zone, or in vertical stacks at a few locations. Recent development of remote sensing instrumentation (Dopper radar and video-based PIV) allow for dense measurement of the flow field; however, only at the surface where the currents are generally substantially different than near-bottom flow, particularly in the cross-shore direction. In this work, a simple model is developed that allows for observation of mean surface currents to be used to estimate the cross-shore current. The method assumes that the alongshore gradient of the depth-averaged longshore current can be approximated by the mean surface value. Integrating the depth-averaged continuity equation from the shoreline to a given distance offshore allows an estimate of the depth-averaged mean cross-shore current to be found, provided the depth of the water depth is known. Subsurface mean cross-shore currents are found by assuming a saturated surf zone and vertical balance where the surface mass flux is balanced by a depth averaged mean return flow below the mean trough level (given as a constant fraction of the water depth). Mean cross-shore flows estimated from surface flow fields (obtained using video-PIV techniques) will be presented and compared with a vertical stack of electro-magnetic current meters during the 1997 SandyDuck experiment. This work was sponsored by ONR.

FERRYBOX MEASUREMENTS: A TOOL TO MONITOR AND ASSESS MESO-SCALE VARIABILITY (GULF OF FINLAND, BALTIC SEA)

External forcing as well as reaction of the pelagic ecosystem to external forcing may have very different temporal and spatial scales. In order to understand the transfer mechanisms between forcing and impact multi-scale monitoring methods with sufficient resolution, duration and extent have to be applied. The occurrence and intensity of meso-scale physical features (upwelling events, fronts etc), which are known to be determinant for biological production, retention and transport, can be estimated using Ferrybox measurements carried out in the Gulf of Finland (Baltic Sea) in a regular basis since 1997. An upwelling intensity index is developed and applied and behavior of a quasi-permanent front is described by means of statistical analysis of collected cross-gulf high resolution temperature and salinity profiles in 1997-2007. Examples, how derived meso-scale indexes are used to understand the variability and forecast changes in the pelagic ecosystem, are shown.

LARGE-SCALE NEARSHORE MORPHODYNAMICS: MODEL GUIDANCE TO FIELD MEASUREMENTS

Recent modeling studies have identified processes leading to the development of large-scale morphodynamics at alongshore scales of 100s to 1000s of meters. The morphodynamic behavior can be self-organized (e.g., coastal undulations which grow in response to highly oblique incident waves), or externally forced (e.g., shoreline change resulting from an inner shell bathymetric irregularity). However, these model predictions typically lack field verification. Here, the hydrodynamic model Delta3D is used to isolate the forcing (e.g., pressure gradients, radiation stress gradients) for both self-organized and forced morphodynamics, and to quantify the measurements (e.g., sea-surface elevation, wave height and angle) required for field verification. As an example, in the strongly-forced case of an inner-shelf pit and an initially uniform nearshore, model results suggest that nearshore flow gradients and morphological evolution are driven primarily by pressure gradients resulting from sea-surface elevation differences on the order of 3 cm over a distance of 1 km alongshore. In less strongly forced cases, including those with self-organized behavior, gradients are smaller, and thus the required measurement resolution is higher.

OSCILLATORY FLOWS OVER PERMEABLE WAVE BOTTOM Ripples

In shallow-water environments, oscillatory flows induced by surface waves may generate ripples over flat permeable seabeds. To keep track of the enhanced interfacial flux of solutes, one has to capture simultaneously the flow on either sides of the permeable interface. Exactly this is the key factor if the amount of interfacial exchange of solutes and particulate matter. With the help of a Lattice-Boltzmann Method (LBM), this simultaneous exchange can be calculated very efficiently. The effect of water height, wave number, Pelet and Schmidt number on the interfacial exchange is discussed in detail.

SPATIAL AND TEMPORAL VARIATION OF PHYTOPLANKTON BIOMASS IN THE GULF OF MEXICO: OBSERVATIONS AND NUMERICAL INVESTIGATIONS

A three-dimensional physical-biological model has been used to investigate spatial and temporal variability of phytoplankton growth dynamics in the Gulf of Mexico (GoM). The physical model is based on the Gulf of Maine Ocean Observing System (GoMOOS) nowcast/forecast system, which has been issuing 48-hour forecasts of physical conditions since January 2002. The biogeochemical processes are simulated with an ecosystem model consisting of multiple nutrients and plankton functional groups. The model results are compared with SeaWIFS derived chlorophyll-a and in situ measurements from GoMOOS moorings for the 2002-2007 period. The model reproduces many observed features favorably, such as the timing and intensity of phytoplankton bloom and their spatial distribution in the GoM. The annual mean depth-integrated primary production has the highest value of 380 mg C/m²/day near the coast and the Georges Bank. Ten model sensitivity experiments have been performed to assess the potential impact of several key factors (wind, light, stratification, depth nutrient concentrations, and river discharge) that regulate nutrient transport and phytoplankton productivity.

NOAA CORAL REEF WATCH: OPERATIONAL APPLICATION OF SATELLITE REMOTE SENSING DATA IN NEAR-REAL-TIME GLOBAL MONITORING OF CORAL HEALTH

Coral bleaching is one of the major contributors to the worldwide deterioration of coral reef ecosystems over the past few decades. In response to scientific and management needs, NOAA Coral Reef Watch (CRW) developed a suite of operational near-real-time global coral bleaching monitoring products based on satellite sea surface temperature. Our Bleaching HotSpot, Degree Heating Weeks, Bleaching Virtual Stations, and Satellite Bleaching Alerts, are used by resource managers and scientists around the world. Key to
CRW’s success has been an ongoing dialogue with its user community to assess needs and improve both the products and the tools. By breaking 2005 Caribbean bleaching event has again proven the value of CRW’s satellite coral bleaching monitoring in supporting prompt management decision making and survey organizing by reef managers and scientists. To provide improved ecosystem monitoring, NOAA has released experimental doldrums products from satellite winds and work is underway to develop satellite insolation, ocean circulation, and heat storage, from JASON and GRACE, have been developed so that the annual and interannual variations are related to differences in transport of subarctic waters to the offshore branch of the northern California Current. We explore the utility of these oceanic subarctic copepods as indicators of PDO and climate-driven variability in the source waters which enter the coastal upwelling zone off Oregon. Two water type-specific copepod groups occur in coastal waters off Oregon, cold-water and warm-water species. Cold-water species (Pseudocalanus minutus, Acartia longiremis, and Calanus marshalli) dominate in winter, during El Nino events and during summers with weak upwelling. Changes in their biomass and density among years are determined by the source waters which enter the coastal upwelling zone off Oregon. Abundance and variations are related to differences in transport of subarctic waters to the offshore branch of the northern California Current. Analysis of the Simple Ocean Data Assimilation product and other observation data revealed that the central North Pacific is one of the main formation regions for low Potential Vorticity (PV) water. It is found that the low PV water is transported from the central North Pacific toward the east of the Taiwan Island along a subsurface pathway following the subtropical gyre circulation, and it takes approximately 12 years. Propagation of pycnocline thickness anomalies is detected along the pathway, in association with the decadal variability of the subduction rate. The transportation of the low PV water could be as one of the possible feedback mechanisms for the Pacific Decadal Oscillation, because the variation of low PV water in Northwest Pacific has close relation to the dynamic state of Kuroshio Extension and ocean-atmosphere heat exchange.

The distribution of water masses and circulation reflect on the sea surface height for some oceanic regimes. This allows the inference of the ocean internal structure from sea surface height observations. In this study, we combine the estimates of an eddy resolving ocean model with vertical hybrid coordinates, HYCOM, in the Atlantic Basin with altimeter observations from JASON, GFO, and ENVISAT to correct the internal structure of the ocean model. The sampling altimeter patterns allows a limited access to some scales. The approach taken to carry out a multi scale 2DVAR analysis of the deviations of the model sea surface height from the observed absolute sea surface height. The data includes altimeter sea surface height anomalies, and mean dynamic topography estimated from historical data. A vertical 1DVAR analysis is employed to update the model vertical structure. A sensitivity study to data assimilation parameters including 2DVAR scales, selection of mean dynamic topography and vertical 1DVAR algorithms (Cooper Haines, vertical model covariances, etc.) is conducted. Emphasis is given to the ability of the data assimilation scheme to capture large and mesoscale features.

LOW POTENTIAL VORTICITY WATER TRANSPORT FROM CENTRAL NORTH PACIFIC TOWARD TAIWAN ISLAND AND ITS RELATION TO THE OCEAN-ATMOSPHERE EXCHANGE

Analysis of the Simple Ocean Data Assimilation product and other observation data revealed that the central North Pacific is one of the main formation regions for low Potential Vorticity (PV) water. It is found that the low PV water is transported from the central North Pacific toward the east of the Taiwan Island along a subsurface pathway following the subtropical gyre circulation, and it takes approximately 12 years. Propagation of pycnocline thickness anomalies is detected along the pathway, in association with the decadal variability of the subduction rate. The transportation of the low PV water could be as one of the possible feedback mechanisms for the Pacific Decadal Oscillation, because the variation of low PV water in Northwest Pacific has close relation to the dynamic state of Kuroshio Extension and ocean-atmosphere heat exchange.
COLUMBIA RIVER PLUME INFLUENCE ON SUMMER SHELF CIRCULATION AS REVEALED BY A COASTAL OCEAN CIRCULATION MODEL HINDCAST

A hindcast of the Columbia River (CR) estuarine and coastal ocean circulation in summer 2004 is performed using the ROMS model with open boundary conditions from the NCOM model and realistic atmospheric, tidal and river forcing. The model results are used to describe the subtidal evolution of plume patterns in response to local wind and river flow and to examine the plume influence on the shelf circulation and transport. It is found that a bi-haline plume occurs frequently on the Washington shelf (> 75% of time during 6/15-8/30), during weakening of moderate upstream plume favorable wind events as well as with weak downwelling events. Its high frequency of occurrence indicates that the CR water will have significant influence on Washington shelf circulation and mixing dynamics in summer. In a case study of a cyclonic eddy developed through interaction of the plume and the upwelling jet, an important pathway is found for nutrient rich deep canyon waters to be upwelled onto the shelf from Astoria Canyon and transported northward along the shelf.

TROPHEIC ECOLOGIES OF LARVAL FISHES IN THE LOW-LATITUDE OPEN OCEAN: PREDATION REFUGE AND A FULL TUMMY TO BOOT

The tropical/subtropical open ocean is larval habitat for many species of fish, yet the interactions between fish larvae and the planktonic prey environment in low-latitudes are still poorly understood. To capture broad temporal and spatial variability in larval fish feeding and the feeding environment, two years of monthly sampling was conducted across the Straits of Florida (SOF). Diets of billfishes, tunas and reef fishes were rich with distinct prey selectivity. Before an ontogenetic shift to piscivory, larval billfishes exhibited selection for two species of crustaceans, while larval scobimids fed almost exclusively upon appendicularians. Four genera of scobimids co-occurred in the western SOF where appendicularian abundance was greatest, but only Thunnus spp. and Katsuwonus pelamis were common in the east where prey densities were low. Additionally, these larvae exhibited different vertical separation, with larvae in the SOF (dipluran, scobim and dookey prey) abundances were highest along the western SOF, as were levels of chlorophyll, copepod nauplii and total zooplankton. High feeding incidence and rapid digestion for all taxa indicate that larval fish starvation mortality is low in these warm, oligotrophic waters.

PAST SEA LEVEL RECONSTRUCTION AND VARIABILITY OF SEA LEVEL TREND PATTERNS

Satellite altimetry has allowed precise mapping of the geographical variability of sea level rates over the last 14 years. Comparisons with steric sea level patterns based on situs hydrographic data and outputs of ocean general circulation models have shown that altimetry-based spatial patterns are mainly caused by non uniform thermal expansion, but in some regions sea level trend patterns result from opposite effects of temperature and salinity change. For the past decades, there are no direct global-scale observations of the spatial trend patterns in sea level but past sea level reconstructions methods that combine long tide gauge records of limited coverage and short 2-D sea level patterns based on satellite altimetry have been developed, with the assumption that the satellite record correctly captures the decadal variability of the spatial trend patterns. Here we present past sea level reconstruction results over the last 40 years based on tide gauge data and EOF analyses of sea level patterns based on runs of the ORCA general circulation model (with and without assimilation). The reconstructed sea level patterns will be compared, the dominant modes of temporal variability will be discussed and sea level hindcasts at tide gauge sites not used in the analysis will be compared to actual observations. Other methods of past sea level reconstruction will be also presented.

ECOLOGICAL CONTROLS ON THE CARBON CYCLE OF THE MEGKONG RIVER
Outgassing of CO2 derived from respiration of organic matter within the Amazon River may return 0.5 Pg of terrestrial carbon to the atmosphere per year. If river systems throughout the tropics behave similarly, they would recycle a substantial amount of terrestrial carbon to the atmosphere. River metabolism, or the relative rate of community respiration to photosynthesis, provides a benchmark for ecosystem function and an estimate of outgassing, but is unknown for most tropical rivers. We measured ratios of the stable isotopes of dissolved oxygen and dissolved inorganic carbon throughout the Megkong River basin to determine the relative rates and sources of respiration and photosynthesis. A time series of biweekly measurements on the mainstem of the Megkong River at Phnom Penh, Cambodia, shows that the river is net heterotrophic throughout the year at this site, but that the ratio of respiration to photosynthesis (R:P) increases substantially during the flood season. R:P ranged from 2 to 10 during the rainy season and averaged 2.5 during the dry season. We use these measurements to model the annual outgassing of CO2 at this site.

THE CI-FLOW PROJECT: COMBINING RESOURCES FOR BETTER UNDERSTANDING OF WATER IMPLICATIONS FROM THE SKY TO THE SUMMIT TO THE SEA
For the past seven years, the National Severe Storms Lab has been part of a collaborative effort with Sea Grant, Universities and National Weather Service Forecast Offices in the Carolinas to develop a product to help improve flood observations and forecasts for coastal areas. This project, called the Coastal Inland Flood Observation and Warning project (CI-FLOW), couples a high resolution quantitative precipitation information system with river and coastal/ocean models, which is being demonstrated in the Tar River Basin of North Carolina, where significant flooding from Tropical Storm Dennis and Hurricane Floyd affected the area in 1999. While NSILs expertise focuses on short-term, storm-scale analysis and prediction, the ensemble approach to CI-FLOW encourages the inclusion of other datasets and models to produce information on larger scales. One of the expected outcomes of this project will be to educate coastal constituents from diverse industries on the impacts of variations in the water cycle, to identify their needs and requirements, and to provide them with the tools to manage resources and develop contingency plans.

SCIENTISTS BRINGING A WAVE OF OCEAN LEARNING TO K-12 CLASSROOMS
This presentation will focus on the interesting, exciting and fun ways that graduate-level scientists from USFs College of Marine Science utilize ocean science education to motivate students about learning and doing science. Participants will learn how summer ocean camps can become a vehicle for preparing scientist-teacher teams to teach about the oceans in the classroom. Training programs engage ocean scientists in inquiry-based teaching that parallels the way scientists conduct scientific research. These trainings include a day at sea doing science aboard a research vessel, in the field exploring multiple marine ecosystems, as well as research labs and classroom settings. We believe that scientists and teachers, who learn together, grow together. The growth is realized at the end of each teaching semester when scientists, teachers and students share about the ocean learning gained throughout the semester. This presentation will highlight the win-win aspect of teacher scientist partnerships, its contribution to ocean science literacy, ocean conservation and stewardship of our natural resources.

ENSO DRIVES INTERANNUAL AND DEcadAL-SCALE VARIABILITY OF THE ANTARCTIC PENINSULAR MARINE Ecosystem
The West Antarctic Peninsula region is a major source of Antarctic krill (Euphausia superba) to the Southern Ocean. From 1980-2004 primary and secondary production, krill recruitment success and sea ice extent here were significantly correlated with the atmospheric Southern Oscillation Index and exhibited three-to-five-year frequencies characteristic of ENSO variability. This linkage was associated with movements of the Southern Antarctic Circumpolar Current Front and Boundary, changing influence of Oceanic and Weddell Sea waters, eastward versus westward flow and mixing processes that are consistent with forcing by the Antarctic Dipole high-latitude climate mode. Significant ecological changes indicative of a change in Antarctic Dipole forcing after 1998 reflect a climate regime shift. Natural environmental variability associated with interannual- and decadal-scale changes in ENSO forcing must be considered when assessing impacts of climate warming in the Antarctic Peninsula-Weddell Sea region.

TIDAL MODELING AND TIDALLY-DRIVEN COASTAL FEATURES
Coastal dynamical phenomena can be significantly affected by tidal processes and secondary tidally-driven features. Tidal currents, often a dominant component in a coastal environment, with velocities 50 to 150 cm/s being a common case, generate complex cross-shelf particle transports, highly horizontally inhomogeneous barotropic flow patterns, tidal mixing and internal waves. Correct representation of these tidal processes in regional ocean models is paramount but difficult. The richness in scale and the diversity of the secondary tidally-driven processes (internal waves, tidal fronts, mixing layers) demands a multi-model approach, with several specialized models combined together. Our modeling of tidal phenomena is based on forcing primitive-equation models with our new generalised-inverse and multi-scale barotropic tidal model. This data assimilative tidal modeling system is designed to simulate the barotropic tides at very high resolution and allows to tune its open boundary conditions and model parameters such as friction parameterizations to available regional tide gauge data using the inverse method. We find that the use of multiple localized domains and the data-driven control of open boundary conditions and model parameters are two key elements to successful regional barotropic tidal modeling. Modeling and dynamical results will be exemplified using our recent PLUSIN7 2007 exercise in WA, and AWACS 2006 experiment off the coast of NJ.

THE COASTAL BOTTOM BOUNDARY LAYER
The bottom boundary layer of a rotating, stratified flow on a continental shelf is examined using theory and numerical simulations (Regional Ocean Modeling System). The flow is driven by a downwelling favorable surface stress which is uniform in the along-shore direction. The stress diminishes in the cross-shore direction and produces Ekman pumping as well as an on-shore Ekman flux. The model starts with a wind stress being applied to a uniformly stratified fluid on an f-plane. The flow is then forced by the boundary layer. The model yields an interior flow, between an upper Ekman layer and bottom boundary layer. The vertical diffusivity of density in the bottom boundary layer is considered to be strong enough to render the bottom boundary layer’s density to be a function of only the offshore position. The along-shore flow has enhanced vertical shear in the boundary layer that reduces the along-shore flow in the boundary layer. However, the velocity at the bottom is generally not zero but produces a stress that locally balances the applied surface stress.

LIPID BIOMARKER DISTRIBUTIONS IN OCEANIC AND ESTUARINE DISSOLVED AND PARTICULATE ORGANIC MATTER: SOURCE AND DIAGENETIC SIGNATURES
Lipid biomarkers were used to characterize the sources and diagenetic state of ultrafiltered dissolved organic matter (UDOM) and particulate organic matter (POM) from the North Central Pacific, Sargasso Sea and Chesapeake Bay. Abundances and distributions of lipid biomarkers suggests greater reactivity in oceanic organic matter in surface compared to deep waters. At all depths, oceanic UDOM contained greater abundances of reactive lipids compared to the POM, providing a benchmark for ecosystem function and an estimate of outgassing.

A NEW SOURCE OF IRON TO COASTAL UPWELLING REGIMES
In upwelling regions along the west coast of the United States, low concentrations of dissolved oxygen result in high concentrations of Fe (15-30 nM), over 50% of which is dissolved organic Fe. New sources of dissolved iron to near-surface waters in these upwelling regions are likely to be a balance between the relative inputs of authochthonous vs. allochthonous material, the quantitatively dominant phase in river, coastal and oceanic settings. The results also suggest that the sources of organic matter in each of these environments are likely to be a balance between the relative inputs of autochthonous vs. allochthonous material, the quantitatively dominant. Results from this study support earlier findings on the sources, geochemical character and sources of recycling of dissolved vs. particulate phases of organic matter in river, coastal and oceanic settings. The results also suggest that the sources of organic matter in each of these environments are likely to be a balance between the relative inputs of autochthonous vs. allochthonous material, the quantitatively dominant phase (dissolved vs. particulate) of organic matter, and the extent to which each pool has been recycled.
to these waters from reducing shelf sediments; thereby resulting in a marked increase in Fe(II) concentrations which contribute to elevated dissolved Fe concentrations. During upwelling, this process results in a major new source of Fe which can upwell to surface waters, increasing phytoplankton productivity, which can in turn lead to enhanced export flux, driving the system further into hypoxia, or even suboxic conditions. The mechanism we present here is not limited to this region, and could have a major impact on other productive coastal upwelling regions. Our results suggest that this new source of iron is important in these productive upwelling systems and should be considered in models of oceanic iron cycle.

OPTICAL CHARACTERIZATION OF PHYSICAL AND BIOGEOCHEMICAL VARIABILITY IN A LAKE MICHIGAN COASTAL ECOSYSTEM

Given the extensive coastline and diversity of coastal ecosystems, the Great Lakes region is particularly sensitive to change, both natural and anthropogenic. Our ability to detect and assess change in large-scale processes in response to changing environmental forcing can be greatly enhanced by optical methods. Here, we review findings involving the application of remote and in situ optical approaches for the study of ecosystem dynamics and associated physical and biogeochemical processes in southern Lake Michigan coastal waters. Observations were made during 1998 through 2000 as part of the Episodic Events - Great Lakes Experiment or EELGE. Strong interannual variability was observed punctuated by an intense 1999 El Nino event. Optical measurements and analyses were used to trace inputs and transport of river-borne materials in coastal waters, to characterize sediment distributions and properties during resuspension events, to track algal distributions, and to assess lake-scale temporal and spatial patterns in primary production. Our results highlight the possibility that climate-related changes could profoundly alter the lake ecosystem with associated impacts on autotrophic productivity, phytoplankton community structure, and terrestrial inputs of materials.

IMPROVING OCEAN LITERACY THROUGH CASE METHOD TEACHING

Case method teaching, pioneered at Harvard Business School has been shown to be successful in teaching graduate and undergraduate courses in such disciplines as medicine, business, and law. Success in biology courses, genetics, and even elementary subjects has been reported. Faculty report increased development of critical thinking and reasoning skills in a meaningful context through connection of in-class learning with real-world situations. This action research study examines the use of “cases” in regular high school marine science classes. The main focus of the study was to determine the effect of case method teaching on student acquisition of scientific knowledge and attitudes towards science. Student surveys, class discussions, student writing, and assessments were analyzed to determine the degree of effectiveness that the case method can provide in a high school science classroom. Results indicate that use of the case method is sufficient in conveying factual scientific information and highly conducive to teaching scientific ways of thinking. Additionally, students were found to enjoy the case method of learning experience and highly conducive to teaching scientific ways of thinking. Parallels between riverine and nearshore environments will be drawn.

APPLYING NEARSHORE FLOW MODELS TO RIVERINE ENVIRONMENTS

Tools to predict nearshore flows have matured over the past recent past and efforts are underway to extend the applicability of these tools to the inner shelf. Such models may then also be used in estuaries, and potentially even for predictions in river channels, resulting in models that can cover the entire region from freshwater rivers to the open ocean. This study explores the potential of applying ocean circulation models to the study of riverine environments. In particular, we draw parallels between surf zone longshore currents and river flows and propose to utilize variational data assimilation strategies recently used in determining values for nearshore model free parameters (e.g. friction coefficients) in riverine situations with an interest in determining upstream characteristics such as surface gradients and channel topography. We will begin by considering an idealized 1D situation. However, in reality the river problem is complicated by the presence of bends, meanders, and bars/pools that exist in typical rivers; hence 2D or 3D treatments will also be explored. Parallels between riverine and nearshore environments will be drawn.

MULTI-YEAR CHANGES IN PHYTOPLANKTON BIOMASS AND COMPOSITION AT THE BERMUDA ATLANTIC TIME-SERIES STUDY (BATS) SITE

Euphotic zone integrated chlorophyll at the BATS site has increased over the past 15 years with a normalized [DIC], phytoplankton biomass and primary production have been steadily, and significantly, increasing, with associated changes in phytoplankton community structure. During this same period there has been a steady decline in bacterial productivity but also shows reasonable correlation with NDBC’s “dominant” period calculation. Results also show that CODAR-derived wave data is a reliable source of wave data. More than a month of CODAR wave data from each site were compared to data acquired from nearby National Data Buoy Center (NDBC) buoys; wave data from two sites north of Point Reyes were compared to NDBC 46013, and three sites south of Point Reyes were compared to NDBC 46026. A range cell-to-range cell comparison was conducted at these sites for further evaluation of consistent sea-state as distance increases from the radar. Results show that waves are homogeneous throughout range in this region. Buoy comparisons revealed strong correlation, particularly for wave height, at all locations. The CODAR wave period - which describes a more centred period - also shows reasonable correlation with NDBC’s “dominant” period calculation. Results presented here suggest that CODAR-derived wave data is a reliable source of wave data.

THE BERMUDA ATLANTIC TIME-SERIES STUDY: A RESEARCH PLATFORM TO STUDY CHANGE IN THE OLGOTROPHIC SUBTROPICAL NORTH ATLANTIC

Since October 1988 the Bermuda Atlantic Time-series Study (BATS) program has been studying the biogeochemistry of the Sargasso Sea with at least monthly resolution. While the primary focus has been on carbon fluxes in and out of the euphotic zone, many biogeochemical measurements are made to a depth of 4200m. An integrated suite of rate process and biogeochemical measurements is providing valuable ecosystem information over multiple timescales. The BATS core measurements are enhanced by ancillary research projects including studies of the temporal variability of Prochlorococcus ecotypes and other microbial groups, optical oceanography (Bermuda BioOptics Program), and biogeochemistry of organic sulfur and phosphorus, to name a few. While not as dramatic as the hypothesized DOM Shift in the tropical Pacific, there have been important changes in carbon cycling in the Sargasso Sea ecosystem. Over the past 17 years, salinity normalized [DOC], phytoplankton biomass and primary production have been steadily, and significantly, increasing, with associated changes in phytoplankton community structure. During this same period there has been a steady decline in bacterial productivity with some evidence for increased carbon export.

APPLYING NEARSHORE FLOW MODELS TO RIVERINE ENVIRONMENTS

MULTI-YEAR STUDY OF WAVE MEASUREMENTS AND WAVE HOMOGENEITY FROM FIVE CENTRAL CALIFORNIA CODAR SYSTEMS

CODAR-derived wave data include readings of significant wave height, wave period, wave direction and wind direction. The data from five 12-13MHz Sea sondes on the central California coast were examined to evaluate the effectiveness of operational wave parameters of the CODAR wave software. More than a month of CODAR wave data from each site were compared to data acquired from nearby National Data Buoy Center (NDBC) buoys; wave data from two sites north of Point Reyes were compared to NDBC 46013, and three sites south of Point Reyes were compared to NDBC 46026. A range cell-to-range cell comparison was conducted at these sites for further evaluation of consistent sea-state as distance increases from the radar. Results show that waves are homogeneous throughout range in this region. Buoy comparisons revealed strong correlation, particularly for wave height, at all locations. The CODAR wave period - which describes a more centred period - also shows reasonable correlation with NDBC’s “dominant” period calculation. Results presented here suggest that CODAR-derived wave data is a reliable source of wave data.

CHESROMS: OPERATIONAL MODELING OF CHESAPEAKE BAY PHYSICS AND ECOLOGY

An operational model of the Chesapeake Bay that is based on the 3-D primitive equation numerical ocean circulation model ROMS (Regional Ocean Modeling System) has been
extended to also include fully coupled components that simulate the Bay’s water quality and biological and chemical cycles. The model provides the necessary components for retrospective and near real time data acquisition and pre- and post- processing, which make it suitable for hindcasting, nowcasting and short time forecasting of the bay-wide physics and ecology. Operational model structures, strategies and implementations will be presented. Preliminary results for temperature, salinity, water level, currents and sea nettle abundance levels based on nowcasting and forecasting from January 1, 2007 to December 31, 2007 will be shown together with comparisons against observations. Future development plans, data assimilation, challenges for coupling with regional meteorological models and results dissemination to the general public will be also discussed.

Elliott, J. K.

Biomass size spectra are sensitive to disturbances that alter the energy balances and transfers within a system, and could be potentially useful ecosystem management tools. As an urbanized estuary, Narragansett Bay has a long history of fishing, nutrient and pollutant loads, invasive species and climatic variability. In addition, tertiary sewage treatment is being implemented around the bay, with possible impacts for primary productivity as well as fish. The Rhode Island Department of Environmental Management’s monthly trawl survey data from 1990-2006 were used to construct fish biomass size spectra for different seasons, years and locations, and the species composition, biomass and slope and intercepts of these spectra were investigated. Generally, slopes of all spectra were steeper than -1, indicating a large biomass. Since 2000 however, slopes in the upper and lower bay have been steadily approaching -1. Upper bay intercepts begin to diverge from the lower bay also around 2000, with intercepts decreasing in the upper bay and increasing in the lower bay. This could indicate overall greater numbers of fish as well as more large fish in the lower bay.

Lonsdale, A.

Factors affecting the distribution and abundance of Beggiatoa spp. Bacterial mats in Hood Canal, WA

Bacterial mats were studied in Lynch Cove, an area that has been described as a ‘dead zone’ due to persistence of low oxygen levels. The objectives of this study were to 1) take sediment samples to identify the bacteria making up the mats, 2) use underwater videography to map the distribution and abundance of the mats in space and time, and 3) examine related sediment and water conditions. The mats were composed of Beggiatoa spp., a type of sulfide-oxidizing bacterium. Video surveys indicated that the mats occurred at water depths of 10-25 m and covered an area of 8.4 km² in the fall of 2006. The spatial coverage of the mats was highly reduced during the subsequent winter but increased in size the following spring and summer. The sediments in the area of the mats had a flocculent layer of organic material, high sulfide levels, and low diversity and abundance of macrofauna. High primary productivity and sedimentation rates likely contribute to the high levels of organic material in the bottom substrate, where decomposition results in high sediment sulfide levels.

Loos, E.

Influence of a large riverine system on the optical properties of surface waters of western Canada: Implications for spectral light availability

The influence of the Fraser River plume on the waters of the Strait of Georgia was assessed based on the biophysical and optical properties of the euphotic zone in late spring and early summer of 2006. From optical measurements of beam attenuation and absorption, and chromophoric dissolved organic matter (CDOM) absorption, particulate absorption and scattering were derived. CDOM fluorescence and water samples were collected for total suspended material and chlorophyll a (chl). Overall, these waters were optically variable, but a well-defined surface layer, which allowed for the optical classification of waters under strong (OM1), medium (OM2), and low (OM3) influence of the riverine waters. Generally, particulate scattering dominated the attenuation in waters under the strongest influence of the river; these values decreased two orders of magnitude in deeper water. The particulate scattering was mostly influenced by inorganic particles, especially in OM1. High loads of inorganic particulate scatterers possibly increased the diffuse light into OM2, thus increasing chl concentrations. Conversely, in deeper waters the relative increase of absorption by CDOM possibly indicate competition with phytoplankton for short wavelength radiation.

Phytoplankton photosynthetic competence in Caribbean Sea mesoscale eddies as measured by fast repetition rate fluorometry

Caribbean Sea mesoscale eddies result from vorticity advection through passages into the Caribbean area as inferred from satellite SSH. The Caribbean Vorticity Experiment (Cavortex II and VI) undertaken from June 22-27, 2004 and August 28, 2006 to September 8, 2006 were intended to characterize the physical, biogeochemical, and optical structure of the eddies and to assess their influence on biological productivity of the Eastern Caribbean Region. During Cavortex II, satellite altimetry showed a large cyclone interacting with a small anticyclone south of Puerto Rico and for Cavortex VI altimetry showed a large cyclone south of the Dominican Republic. Fast Repetition Rate Fluorometer measurements showed that photosynthetic competence varied widely in areas of upward pycnocline displacement of isohalines and thermal structures. This displacement suggests that nutrient upwelling is responsible for the higher photosynthetic competence observed between the surface and 90 m. Functional absorption cross-section varied inversely to photosynthetic competence even under the influence of upward flux suggesting nutrient stress on the phytoplankton. Phytoplankton photosynthetic parameters developed from radiocarbon incubations of near surface and the deep chlorophyll-a maximum are consistent with these observations.

How you get there depends on where you start: variation in fiddler crab larval dispersal mechanisms

Successful transport of larvae from adult habitats in estuaries to coastal waters for development can be facilitated by a behavioral mechanism referred to as selective tidal-stream displacement. This suggests that the expression of a circadian rhythm in Uca is associated with the location of the adult habitat relative to development areas. Swimming activity of zoea-1 larvae of fifteen Uca species from seven locations along the Atlantic and Gulf coasts of the United States and the Pacific and Caribbean coasts of Panama were monitored under constant conditions for 72 h. Periodogram analysis of the time series indicated that estuarine species possessed ebh-phased circadian rhythms in swimming. However, coastal species exhibited no clear rhythmic patterns. These results suggest that STST behaviors may have arisen in association with adaptations for estuarine living.

Anaerobic thiosulfate and sulfur oxidation/dissipation mediated by autotrophic bacteria in the Caribbean’s basin sedimentary redoxcline

The Oxygen depletion below ~250 m within the cariaco basin sets a chemocline between 200 and 400m which represents a perfect site to study autotrophic prokaryotic communi-
ties due to depletions of labile organic matter and the vertical distribution of inorganic electron donors and acceptors. Previous studies have shown enriched microbial communities within the redoxcline that coincide with peaks in dark carbon fixation. This production is believed to be coupled to chemoautotrophic activity fueled by availability of elemental sulfur, thiosulfate and sulfate. Based on most probable numbers (MPN), the abundances of sulfur and thiosulfate disproportionating bacteria are high within the redoxcline of the DON/PS (30–133 cells/ml). Our research focuses on the isolation and metatranscript analysis of the thiosulfate and elemental sulfur utilizing bacteria. In the laboratory, isolations of these phyotypes are underway using dilution to extinction, roll tubes and deep agar stab methods in basal media containing thiosulfate or elemental sulfur as sole energy sources. We will also report on isolations utilizing anoxic chemostats with highly selective inorganic media. Isolations will be verified by standard 16s terminal restriction fragment length polymorphism (T-RFLP).

DISSOLVED ORGANIC MATTER IN THE CARIACO BASIN

Measurements of dissolved organic carbon (DOC), dissolved organic nitrogen (DON) and dissolved organic phosphorus (DOP) were made at the CARIACO time-series station (10°30' N, 64°40' W) as part of the CARIACO time-series program. There was a marked seasonal variability in DOC concentrations, with low values (~70 μM) during the well mixing season (December-May), due to the injection of cold, DOC-depleted Subtropical Underwater (SUW) near the coast. During the rainy season (June-November) waters were stratified and DON accumulated in the upper 150m of the water column, increasing to ~80 μM. DON and DOP did not show a seasonal trend. Horizontal DOC advection is thought to be the principal mode of carbon export out of the basin, with an estimated 20.18 Gt/year transported into the Caribbean Sea. Classic profiles were obtained for DOM, with concentrations decreasing with increasing depth. Deep (>350m) DOC concentrations in the Cariaco Basin were ~10 μM higher than average deep waters, thought to be the result of particle degradation. This is the first information available on DOM in the Cariaco Basin, an important upwelling site in the Caribbean Sea.

STATE ESTIMATION IN SUPPORT OF AN IRON FERTILIZATION EXPERIMENT IN THE ANTARCTIC POLAR FRONTAL ZONE

Combining models and data with assimilation or state estimation techniques is promising when both data and models separately exhibit skill. However, in oceanography more often than not, data and in particular sub-surface data are sparse and the prediction skill of ocean models tends to be poor on long time scales. We present a state estimation experiment, in which we exploit the availability of a high-resolution regional data set: Hydrographic, tracer and velocity data from the European iron fertilization experiment (EFEX) are used to constrain a high-resolution coupled ecosystem-ocean circulation model (EFEX) with the experimental site in Atlantic sector of the Antarctic Polar Frontal Zone. The integration time spans the length of the experiment (approximately 39 days). A high resolution hydrographic and ADCP survey during EFEX yielded an exceptionally dense data set. In a first step, temperature, salinity, and velocity data are used to estimate the dynamically consistent optimal trajectory of a regional circulation model with open boundaries and initial conditions as control variables; biogeochemical tracer measurements constrain an ecosystem model in order to optimally estimate model parameters with a particle filter. In a second step, the ecosystem model is coupled to the circulation model in a forward integration to yield estimates of heat and salt budgets, vertical mixing, primary and export production.

Lott III, D. E., Woods Hole Oceanographic Institution, Woods Hole, USA, dlott@whoi.edu; Stanley, R., Princeton University, Princeton, USA, rstanley@whoi.edu; Jenkins, W. J., Woods Hole Oceanographic Institution, Woods Hole, USA, wjenkins@whoi.edu

AN AUTOMATED, HIGH PRECISION, MASS-SPECTROMETRIC NOBLE GAS AND HE-4 HE-3 ISOTOPE MEASUREMENT SYSTEM FOR EXTRACTED SEAWATER SAMPLES

The concentrations of dissolved noble gases in seawater are potentially powerful probes of air-sea exchange, water mass formation, and diapycnal mixing processes. In order to provide useful information, these concentrations need to be measured to an accuracy of better than 1 percent, and preferably to levels approaching 0.1 percent. We have developed a fully automated system for the unattended measurement of extracted seawater samples for the abundances and isotopic composition of the noble gases (He, Ne, Ar, Kr and Xe). Gas samples are chemically purified using SAES getters, and the individual noble gases are cryogenically separated using a 4-stage cryogenic trapping system. Abundances of the gases are determined by peak-height manometry using a quadrupole mass spectrometer equipped for ion-counting, and compared to pure-gas standards calibrated to air aliquots of known composition. Helium isotope ratios are determined using a magnetic sector mass spectrometer. The precision of the method is 0.10%, 0.14%, 0.10%, 0.14% and 0.17% for He, Ne, Ar, Kr, and Xe respectively.

TEMPORAL DISTRIBUTION OF CARDEOMA GUANHUMI LARVAE IN A SMALL ESTUARY IN PUERTO RICO

Cardiosoma guanhumi is a semi-terrestrial brachyuran crab that inhabits coastal tropical areas of the Atlantic Ocean and Caribbean Sea. This land crab shows a complex life cycle with aquatic and terrestrial stages. The temporal distribution and abundance of the larval stages (zoa and megalops) of this land crab is unknown. The purpose of this study is to describe the temporal distribution and estimate density of zoa and megalops in a small estuary in Puerto Rico. Monthly plankton samples were taken with two stationary stream drift nets placed at the mouth of Boquilla’s Creek, Marañ Puerto Rico. Water was filtered for 45 minutes and volume was measured with a flow meter attached to one of the nets. The density of megalops was consistently higher than the density of zoas throughout the study period (May to September 2007). Identification of the larvae to species is ongoing. The results of this study will increase the knowledge the life cycle of a commercially important species in Puerto Rico and are important for the development of a management plan for the species.

SYNOPSIS OF THE RESULTS OF THE MEHI PROJECT AND ALSO DETAIL NEW MAPPING METHODS OF BENTHIC ZONES

Using the MEHI project, developed by commercial and governmental organizations, and a suite of spatial and temporal data, we were able to map the coral reef ecosystems of the entire West Hawaiian Islands (WHI) using multitemporal satellite imagery. All eight of the islands were mapped using digitalization tools in ArcGIS to create GIS maps of the benthic zones. This work created a map of the major benthic zones. The results of the project further NOAA’s commitment towards compiling a state-of-the-art Reef Task Force’s recommendation to develop shallow-water coral reef ecosystem maps for all U.S. waters by 2009. BAE systems is also developing automated methods of benthic habitat mapping, including tools for simultaneous mapping of benthic, bottom class, and water properties, and algorithms for removing glint and waves. This presentation will focus on the results of the MEHI project and also detail new technologies and algorithms that may be applied in future mapping projects.

POTENTIAL IMPACTS OF CHARCOAL ON PALEORECONSTRUCTIONS OF ORGANIC MATTER INPUTS TO AQUATIC SYSTEMS

Fire is a major driver of ecosystem processes as it affects the carbon cycle over a vast suite of terrestrial environments from forests to peatlands. Pyrogenic carbon (PyC) is a heterogeneous class of solid residues from combustion that include slightly altered chars, elemental carbon (EC), and carbonaceous soot which are commonly found in terrestrial environments from forests to peatlands. Previous studies have shown that PyC concentrations in the water column can be up to 100% of the dissolved organic carbon (DOC) concentration. However, the precise contribution of PyC to the DOC concentration is unknown. This study examines the potential impact of PyC on the DOC concentration in the DACHART project that aims to quantify the contribution of terrestrial DOM to the DOC concentration in the surface waters of the DACHART region.

IN FROM THE COLD UNCEUTILIZED PROTESTS IN ARCTIC, A DEEP DARK SECRET

The biogeography and depth distribution of the majority of microorganisms has only begun to be appreciated with the recent explosion in molecular data. The Arctic is a distinct environment with long periods of darkness and low light and provides a particular habitat for phytoplankton and other protists; favoring the maintenance of mixotrophic and completely heterotrophic taxa in the upper mixed layer. Over much of the Arctic Basin the multi-year ice has acted to create conditions that are similar to those in deep oceans.
with stable cold temperatures and no light. Our molecular surveys have shown that many sequences from uncalcified protists in the offshore Arctic Ocean have their closest affinities with deep water temperate and tropical sequences. This suggests the existence of a distinct cold water, low light or dark adapted community maintained along isopycnal surfaces. This pelagic microbial community currently supports a pelagic arctic marine food chain with its distinct biota. Global climate change threatens this balance with a new open ocean habitat created by the loss of multiyear ice over the deep Arctic Basin.

THE FUTURE OF THE SOUTHERN OCEAN CO2 SINK

The Southern Ocean currently serves as a sink for atmospheric CO2, however the strength of this sink has weakened over the past few decades. It has been suggested that the primary cause of the sink reduction is a trend in the position and intensity of the Southern Hemisphere westerlies and the subsequent increase in the upwelling of carbon-rich water. The wind stress trend will likely continue into the coming century, further weakening the Southern Ocean CO2 sink. However, the coming century may also be characterized by enhanced precipitation over the polar oceans, leading to increased stratification and suppressed upwelling of carbon-rich waters in the Southern Ocean. The trends in stratification and wind stress will have competing influences on future CO2 sink strength, and yet the net effect of these two processes is unknown. Here, we test the sensitivity of the Southern Ocean carbon sink to changes induced by alterations of wind stress, stratification, and the combined effect of the two using an ocean box model.

MODELING THE ENERGETICS OF SPECTACLED EIDERS DURING LONG-TERM CHANGE IN SEA ICE AND BIGHTS

The world population of Spectacled Eiders, a threatened species, winters in pack ice of the Bering Sea. To assess possible factors in the eiders’population decline, we used historical data on benthic prey, sea ice, and weather in a simulation model of eider energetics that integrated field, laboratory, and remote sensing studies. Density and duration of leads in the pack ice during extreme versus average winters had little net effect on eider energy balance, as flight distance to other leads was usually short when leads closed. Nighttime cost was greatly reduced by the eiders’resting on ice versus floating on water, but this factor was likely unimportant during the eider decline (1970s to 1990s). Despite a major shift in dominance of major prey species, food did not appear to be limiting at the beginning or end of the eider’s decline. After a decade of poor bivalve recruitment, the area of viable habitat for eiders decreased dramatically between the early 1990s and early 2000s. Reduced prey availability and projected loss of ice for nighttime roosting may decrease the eiders’prospects of recovery.

HYDRODYNAMICS OF FRINGING REEF SYSTEMS: NINGALOO REEF, WESTERN AUSTRALIA

The response of the circulation of Ningaloo Reef (the largest fringing coral reef in Australia) to wave, wind and tidally forcing is investigated using field data and the output from a coupled numerical circulation - wave model. A 6-week field experiment measuring waves, currents, and water levels was conducted during April - May 2006, which focused on the dynamics of flow within a representative reef - channel circulation cell (one of hundreds that comprise the overall system). Results from the study indicate that wave-forcing is the dominant mechanism driving the circulation of Ningaloo Reef, with lagoonal flushing times of 5-8 hours under typical offshore wave conditions. Cross-shelf wave-driven currents, however, were significantly weaker (~0.1-0.2 m/s) than expected from existing one-dimensional analytical models of reef circulation, in part due to the presence of considerable wave setup inside the shallow lagoon that is neglected in these approaches. Preliminary results from the three-dimensional numerical model, presently under development, will be presented.

RTOFS: REAL TIME HIGH RESOLUTION OPERATIONAL OCEAN FORECAST SYSTEM FOR THE ATLANTIC (265-76N)

RTOFS in the Atlantic Ocean is an NCEP operational ocean forecast system based on HYCOM on a 1200—1684 orthogonal grid with 26 vertical coordinates composed of 21 -isopycnal and 5-level. It is forced with winds, heat flux, evaporation and precipitation every 3 hour [derived from NCEP global atmosphere GFS [Global Forecast System]]; with body and boundary tides. Also forced are river outflows with USGS daily stream flows and RIVDIS climatology. The model assimilates 1. SST from GOES, AVHRR, and in-situ; 2. SSH from JASON, GOFO and ENVISAT; and 3. T/S from ARGO and CTD. The model is run once a day. Each run produces sets of 24-hour nowcast and 120-hour forecasts of hourly barotropic and daily baroclinic properties. The main goal of this development is to establish operational high-resolution ocean forecast system for short-term, (0.1 week), predictions for an Atlantic sector (265-76N) covering both shallow and deep waters. We present the performance of the system in real-time, including validation and evaluation of the system components - data streams, model and data assimilation.

ON THE SALINIFICATION OF THE MEDITERRANEAN OVERFLOW WATERS

A recent study of the mid-depth waters of the eastern North Atlantic has detailed significant changes in the temperature and salinity of the Mediterranean Water (MOW) over the past fifty years, increases assumed to be linked to changes in the source waters flowing across the Strait of Gibraltar. To test whether this linkage is viable, we have used a simple box model of water mass transformation by marginal seas to predict changes in the overflow water salinity based on salinity changes of the inflow from the North Atlantic, surface fluxes and stratification in the Mediterranean. Surprisingly, the model correctly predicted the observed increase in salinity of the Mediterranean Water (MOW) over the past fifty years, increases assumed to be linked to changes in the source waters flowing across the Strait of Gibraltar. We work indicates that the magnitude of the observed salinity change noted for the MOW cannot easily be explained by source water or volumetric flow changes; rather it is suggested that local circulation change are responsible for the warming and salinification of the MOW reservoir in the eastern North Atlantic.

TURBULENCE IN REVERSING AND ROTATING TIDAL FLOWS

The disruption rate and friction velocity (Fv) were studied in the East China Sea near the coast of China using ADV and ADCP measurements. Reversing and rotating tidal flows affected small-scale near-bottom dynamics differently. In reversing flows, the near-bottom shear and the shear at the upper levels were almost in phase. In rotating flows, the shear generated near the seafloor, propagated slowly to the water interior with a phase speed of ~ 5 m/s. The highest near-bottom dissipation on a shallow shelf was associated with the stronger flooding current of the reversing tide and the lowest with the reversing ebb current. The log-layer (ADCP-based) and the skin-layer (AVD-based) estimates of Fv showed close correspondence for the reversing tide, but while the tidal vector rotated over a slope- ing bottom the log-layer Fv was approximately twice larger than the skin-layer Fv. The influence of stratification, form drag, and rotation is discussed as possible sources for this discrepancy. Significant departures from the wall-layer parameterization were found when advected warm bottom water caused convective mixing in addition to boundary-induced turbulence.

SHEAR PROBE MEASUREMENTS FROM SLOWLY MOVING PLATFORMS

Microstructure turbulence measurements using shear probes are typically made from free-fall profilers, which descend at a constant rate, typically between 0.5 m s-1 and 1 m s-1. Several research groups are currently working towards the integration of microstructure shear probes into ocean gliders and profiling floats. These platforms move much slower through the water, between 0.1 m s-1 and 0.5 m s-1, raising the question of angle-of-attack and limitations and whether shear probes are sensitive enough to measure at such slow speeds. This presentation reviews available data that demonstrate that shear probes can successfully operate at profiling speeds of 0.05 m s-1. At these speeds, the lower detection limit of dissipation rates is determined by electronic noise, the upper measurement limit is determined by the angle-of-attack of the oncoming flow. These constraints do not impose a serious limitation on open ocean measurements from gliders and floats.

LINKAGES BETWEEN ALGAL COMMUNITY COMPOSITION AND WATER CHEMISTRY DATA ON SHORT SPATIAL AND TEMPORAL SCALES

San Francisco Bay is a heavily urbanized estuary with anthropogenically enriched concentrations of nutrients and trace metals. To evaluate the impact of those contaminants, we looked for relationships between algal community composition and water quality variables

Luengen, A. C., State University of New York, Stony Brook, Stony Brook, USA, aluengen@notes.cc.sunysb.edu; Raimondi, P. T., University of California at Santa Cruz, Santa Cruz, USA, raimondi@biology.ucsc.edu; Flegel, A. R., University of California at Santa Cruz, Santa Cruz, USA, flegel@etox.ucsc.edu
(e.g., nutrients, trace metals, temperature) during the spring 2003 phytoplankton bloom. We analyzed algal community composition and community level approach to uncovering patterns in biological data and linking those patterns to environmental data. The analysis demonstrated that phytoplankton community composition changed significantly over small spatial and temporal (e.g., weekly) scales. Water chemistry variables that best matched patterns in algal community composition were water temperatures (primarily) and dissolved ammonium concentrations (secondarily). When dissolved ammonium concentrations increased during decay of the diatom bloom, Synechocystis sp. grew rapidly, indicating that community composition shifted quickly following an environmental change. Algal community composition was not linked to dissolved trace metal concentrations, despite the known toxicity of some metals (e.g., Cu) to phytoplankton. The absence of such a relationship suggested that algal communities were not impacted by the high trace metal concentrations in the estuary.

UPPER OCEAN STRATIFICATION AT THE HAWAII OCEAN TIME-SERIES STATION ALOHA

Upper ocean stratification plays an important role in controlling the vertical turbulent fluxes of biogeochemically important compounds. Over the past 19 years, the near-surface weakly stratified mixed layer (ML) thickness at Station ALOHA (22°45'N, 158°W) has varied from a few m to as much as 160 m. The mean annual range is 25-80 m, with the maximum depth in early January, and the minimum depth in early April. The sub-ML stratification, which represents a potential energy barrier to entrainment, varies from a maximum of 1-1.5-km to 4-5 km (1-1.5-km to 4-5 km) in early March, to a maximum of about 1.5-2 km in late September. The timing of the sub-ML maximum stratification is associated with the rapid deepening that typically occurs in the fall. On average, salinity plays a significant role in the reestablishment of stratification in the February-April period, before seasonal heating takes over. The maximum nonseasonal (synoptic and interannual) variability of the mixed layer occurs in February-March. The greatest interannual variation of the maximum stratification occurs in the fall, apparently controlled by salinity variations.

SEA-ICE RESPONSE TO STRATOSPHERE-SURFACE COUPLING IN THE BEAUFORT SEA

Previous studies have demonstrated an increased frequency of reversals in the Beaufort Gyre circulation associated with the post-circumpolar jet stream in the northern hemisphere, while also demonstrating a lagged response between stratospheric and surface cyclonic activity. In this study, we examine the relationship between polar stratospheric zonal flow variability and surface cyclonic activity in the form of surface air temperature (SAT) gradients. Of particular interest is the nature of the correlation between the lower and middle stratospheric NAM index and SAT gradients. Here we explore possible correlations between the NAM index and SAT gradients at different latitudes as a function of time lag. Statistical analyses demonstrate that SAT gradients in the tropics are highly correlated with strait in the middle (10 mb) and, to a lesser extent lower (50 mb) polar stratosphere, while SAT gradients in high-latitude regions are highly correlated with polar middle and lower-stratospheric zonal winds. Also of interest are time lags between stratospheric and surface processes, and the implications of stratosphere-surface coupling for sea-ice variability in the Beaufort Sea region.

RELATIVE DISPERSION IN THE GULF STREAM AND ITS RECIRCULATION

As part of the CLIVAR Mode Water Dynamics Experiment (CLIMODE), 60 satellite-tracked surface drifters were released in pairs and trios during the February to March 2007 cruise of the R/V Knox in the Gulf Stream extension. In this talk, we report differences of the drifters is examined as a function of time and separation distance. Isotopic Richardson’s Law behavior is seen for separation distances from 1.5 km to 300 km, with maximum turn-over rates (Vmax) and half-saturation constant (Km) were calculated for glucosidases, peptidases and phosphatase. A decrease in pH led to a significant increase in Vmax of carbohydrates accompanied by a decrease of peptide degradation. Possible implications of this short time changes in heterotrophic organic matter turnover due to acidification will be discussed.

EXPLORING THE FEASIBILITY OF GLIDER-BASED TRANSPORT, STRATIFICATION, AND ECOLOGY MEASUREMENTS ON THE NEW ENGLAND SHELF BETWEEN MVCO AND LINE W

Autonomous gliders, when used appropriately relative to their inherent capabilities, can provide sustained, low-cost, and robust measurements of key physical and biological parameters. Since October 2006 we have repeatedly occupied a 200 km transect spanning the New England shelf from the Grinnell Vineyard Continental Observatory (MVCO) to the Line W moored array on the continental slope. This work constitutes an important step in the development of an integrated and sustainable regional observing system capable of resolving physical and biological variability on timescales from days to decades. However, there are significant logistical and analytical impediments to using slow, relatively fragile autonomous platforms in a demanding operational setting. In this presentation we explore, from both scientific and engineering perspectives, the feasibility of long-term occupation of this cross-shelf transect. We will present a synthesis of more than 20 independent realizations of this section, contrast the glider observations with coincident shipboard measurements, and evaluate our computation of along-shelf baroclinic transport.

IMPLEMENTATION OF THE NAVY COUPLED OCEAN DATA ASSIMILATION SYSTEM AT THE NAVAL OCEANOGRAPHIC OFFICE

The Navy Coupled Ocean Data Assimilation (NCODA) system is a 3D variational optimization (MVO) system developed at the Naval Research Laboratory (NRL). It can provide a 3D analysis of temperature, salinity, and geostrophic currents based on real-time observations. This system is being implemented at the Naval Oceanographic Office (NAVOCEANO) on the supercomputer configuration of the Major Shared Resource Center (MSRC). NCODA is running in both a stand-alone mode and coupled with the Navy Coastal Ocean Model (NCOM). Several case studies will show NCODA results compared with recent bathythermographic data sets acquired in the western Pacific. These studies will include the customization of NCODA to the region and input data sets by means of its adjustable input parameters.

DEVELOPMENT OF BIOLOGICAL SEDIMENT STABILITY IN MUD/SAND MIXTURES: A LABORATORY STUDY

Natural sediments rarely consist of only mud or sand but a mixture of both. Since predictive modeling of estuarine sediment erosion and transport requires a description of the erosional properties and behavior of the bed, a number of different sediment mixtures have been investigated. The investigations were carried out using ananual laboratory C-1 miniflumes with sand-mud mixtures of 0, 15, 20, 25, 30, 35, 40, 45, 50, 60, 70, 80, 90 and 100 percent mud by weight. The sediment was left to stabilize for 0, 2, 5 and 7 days before experiments were carried out to determine the bed stability. The results showed that adding 20 % mud by weight to sand gave a decrease of stability by 29 % due to...
to fact that the added mud did not fully encompass the sand grains. While adding of 20% sand to mud showed an increase of stability by 114%. The development of bio-oxidation was possible from 40 to 100% mud and can be described as a bell shaped curve with maxi-
mum around 60% mud added.

EFFECT OF THE COUPLING BETWEEN THE UPPER AND LOWER CIRCULATIONS NEAR THE FRONT ON THE DEEP MIXING
Observations in the Sea of Japan in the winter of 2000 show evidence of convection to a depth of roughly 1000 m in the subpolar front. Numerical simulations by 3-D model show that this deep mixing is associated with both barotropic and free convection and is pre-existing larger-scale downwelling regimes. The downwelling regime appears to be a result of inter-
actions between frontal meandering and deep circulation in this basin over bottom top-
ographically defined anomalies. The coupling between the frontal dynamics and the deep circulation was explored through the semigeostrophic Sawyer-Essijian equation, solved numerically for the Sea of Japan case. Source terms due to vertical mixing and Ekman lateral buoyancy advection for ship observations were estimated from the solutions of a 1-D turbulence closure model. An analysis of the solution demonstrates that vertical coupling between the upper and lower circulation produces a localized region of downwelling that leads to buoyancy instability in deep layers and supports mixing. The applicability of this mixing mechanism in other locations in the global oceans is discussed.

THE IMPORTANCE OF MICROBIAL DYNAMICS IN MARINE BIOGEOCHEMICAL MODELING. A TESTATIVE DATA ASSIMILATION STUDY OF OPEN OCEAN ECOSYSTEMS
DOM usage by bacteria is important in the carbon cycle especially inorganic nutrient regeneration. However, it is still controversial whether it is necessary to explicitly include bacteria-DOM processes in open ocean biogeochemical models. We constructed a 1-D biogeochemical model that simulates the carbon (C), nitrogen (N) and phosphorous (P) components in picophytoplankton, diazotrophs, bacteria, protozoa, labile and semi-labile DOM, and inorganic nutrients including ammonium, nitrate and phosphate. The C:N:P ratios in the compartments are flexible. The model includes a detailed bacteria-DOM dynamics such as control equations on DOM labilization and bacterial growth effi-
ciency. Data assimilation is applied to objectively optimize parameters so that the misfits of modeled estimates and observations (costs) are minimized. Experiments: (1) A model without microbial dynamics which assimilated chlorophyll, primary production, nitrate, micro-phytoplankton biomass and export. (2) A model with microbial dynamics which as-
similated the same data as (1). (3) Same model as (2) but assimilated more data including bacterial production and DOM stock. Our results show that although the model without microbial dynamics can be optimized to fit the available data, it does so for the wrong reasons. By including microbial dynamics and assimilating the microbial related data, the cost of the model can be significantly reduced while optimized to a reasonable pattern.

HPIES - MEASURING WATER COLUMN CURRENTS AND PROPERTIES FROM THE SEA FLOOR
We will describe a new sea floor instrument, called HPIES, that combines three well-
tested sensors. When deployed in an array and combined with CTD data, the HPIES can provide daily estimates of sea surface to sea floor profiles of temperature, salinity, specific volume anomaly, and absolute horizontal currents across the array. The HPIES is being tested sensors. When deployed in an array and combined with CTD data, the HPIES can provide daily estimates of sea surface to sea floor profiles of temperature, salinity, specific volume anomaly, and absolute horizontal currents across the array. The HPIES is being
developed to take advantage of the emergence of flexible data gateways to the deep ocean, such as cabled observatories and modern-carrying gliders. These gateways create the opportunity for acquiring data for long durations in near-real-time, permitting exploration and data utilization in ways that traditional expeditionary data collection does not. The HPIES sensors measure the horizontal electric field, the vertical acoustic travel time from the sea floor to the sea surface (that is, an inverted echo sounder), and bottom pressure. Besides showing data from recent deep-water evaluation deployments, we will present examples of the use of these variables, from earlier experiments when the variables were measured separately, for producing such analysis tools as daily horizontal maps of meso-

d-scale variability and stream-coordinate representations of frontal jet currents.

BIOGEOCHEMISTRY OF FE(II) OXIDATION IN A PHOTOSYNTHETIC MICROBIAL MAT: IMPLICATIONS FOR PRECAMBRIAN FE(II) OXIDATION
Early photosynthetic organisms are assumed to have played a major role in the forma-
tion of Precambrian Banded Iron Formations (BIFs) by either oxidizing Fe(II) directly or by producing O2 during photosynthesis, which in turn oxidized Fe(II). Microbial mats at Chromatium Pots Hot Springs Yellowstone National Park composed of oxygenic cya-
nobacteria and the anoxicogenic photosynthet Chelatobacteri were studied as a model to dis-
prove the role of either process. Voltammetric microelectrodes were used to measure dissolved O2, Mn(II) and Fe(II) simultaneously in situ with a 0.05 mm depth resolution. Oxygenic photosynthesis produced enough O2 to remove all Fe(II) from the mat at light intensities of ~15 W/m2. The Fe(II) oxidation rates caused by oxygenic photosynthesis was mea-
sured in this study are sufficient to explain BIF formation. Performing kinetic experiments in the dark and light at the depth of maximum O2 production indicates that the decay of Fe(II) follows a zero order rate law consistent with photosynthesis as the source of O2. These dynamic environments show how kinetic data can be obtained in situ and be used to understand the interactions between biology and chemistry.

A COASTAL OCEAN PREDICTION SYSTEM FOR TAMPA BAY, FLORIDA
The USF College of Marine Science has developed a Coastal Ocean Prediction System for Tampa Bay based on an integrated observing system and circulation model. The model system is a real-time observation and forcing system that is designed to produce three-dimensional fields of circulation, temperature, salinity, and water level. The hydrodynamic model is fully operational in either a nowcast-forecast mode or a hindcast mode (see http://oomp.marine.usf.edu/TFMmodel). A water quality module produces fields of dissolved oxygen, nutrients, and dissolved oxygen from time-varying nutrient and fresh water loading and a wave module provides directional wave spectra and bottom stresses. The integrated observing and modeling system provides a decision support tool that is used to enhance security, safety, and efficiency of maritime transportation, to guide search and rescue efforts, and to evaluate the bay ecosystem response to environmental stresses. Such stresses include severe storms, seasonal and interannual changes in fresh water input, as well as human impacts, such as hazardous material spills, fresh water diversions, nutrient loading, changing land use patterns, and alterations in bay bathymetry.

DIRECT ESTIMATION OF THE REYNOLDS STRESSES FROM PIV DATA
A direct challenge in modern turbulence measurements in the coastal ocean is to separate wave induced motions and turbulence when calculating the Reynolds stresses. Here we introduce a direct approach for removing the wave velocities that is suitable for particle image velocimetry (PIV) data, and compare it to the second order structure function method of Trowbridge (1998). The instantaneous wave velocities are estimated as the spatially averaged horizontal and vertical velocity over the two sample areas of 35x35cm2, that are separated horizontally by 60 cm. Subtracting this value and the overall time averaged velocity from instantaneous data provides the turbulent velocity fluctuations, which are then used to calculate Reynolds stresses. The results indicate that dissipation dissipation stresses are in good agreement with the structure function method, and discrepancies between the two approaches are discussed in the context of their underlying assumptions. Error estimates for the two approaches are presented and compared.

ESTIMATING ANNUAL GLOBAL UPPER OCEAN HEAT CONTENT ANOMALIES DESPITE IRREGULAR IN SITU OCEAN SAMPLING
The effects of irregular in situ ocean sampling on estimates of annual globally integrated upper Ocean Heat Content Anomalies (OHCA) are investigated for sampling patterns from 1955 to 2006. An analytical method is presented for computing the effective area covered by an objective map for any given in situ sampling distribution. To evaluate the mode, appropriately scaled sea surface height (SSH)anomaly maps from Aviso are used as a proxy for OHCA from 1993 to 2006. Using these proxy data demonstrates that the simple area integral of such an objective map for sparse data sets does not agree as well with the actual integral as a representative one. From 1955 to 1966, in situ ocean sampling is inadequate to estimate accurately annual global integrals of upper OHCA. During this period, simple integrals for the sampling pattern of any given year underestimate the 13-year mean proxy OHCA from 1993 to 2006 by around 70%, and comparisons of integrals for representative integrals are often very large. From 1967 to 2003 there appear to be suffi-
cient data to estimate annual global integrals. For this time period the simple integrals for any given year’s sampling pattern still underestimate the 13-year trend by around 30%, but the representative integrals match the trend well with small confidence intervals. For 2004 through 2006 in situ sampling, with near-global in situ Argo data coverage, the 13-year trend is equally well represented by simple or representative integrals.
Goldsmith, S. T. and Lyons, W. B. have important implications for the way in which aquatic pathogens are collected, monitored and volume fraction of aggregated material varied throughout the study. These results led to exploring differences in the characteristics of aggregates found in habitats populated by (e.g., clams and oysters), including bivalve pathogens and human pathogens acquired via distribution, and fate of aggregates, few have addressed their role in the ecology of aquatic ecosystems and although many studies have focused on the composition, formation, and distribution, and fate of aggregates.

POTENTIAL SATELLITE FOR MONITORING BIO-OPTICAL PROPERTIES: QUALITY ASSESSMENT OF OCEAN COLOR MONITOR DATA IN THE COASTAL ZONE

We determined a new capability for monitoring bio-optical properties can be performed using the Ocean Color Monitor (OCM) sensor onboard the Indian remote sensing satellite IRS-P4. OCM has a spatial resolution of 360 meters which enables the fine detail of spatial variability present in the coastal zone to be resolved. A suite of automated validation tools have been developed and used to analyze the quality of OCM normalized water leaving radiance (nLw), and derived inherent optical properties by comparing these OCM data to in situ data sets (absorption, backscattering, and attenuation coefficients), co-located SeaPRISM-derived nLw’s, and the Aerosol Robotic Network (AeroNet) derived aerosol properties derived from the Martha’s Vineyard Coastal Observatory site. An automated de-striping algorithm was also applied to the OCM data to correct for instabilities in the characteristics of the benthos bream sensor. The effects of the de-striping algorithm on the match-up data are also presented. These de-striped images can be integrated with current bio-optical algorithms to produce similar MODIS products at a higher spatial resolution. The results indicate OCM can provide useful products in the coastal zone.

PHOSPHORUS COMPOSITION OF SINKING PARTICLES FROM GUAYMAS BASIN, GULF OF CALIFORNIA

The seasonal and interannual composition and fluxes of sinking particulate phosphorus (P) in the Guaymas Basin, Gulf of California were investigated using a sediment trap deployed at 475 m from August 1990 to December 1996. Samples were analyzed using sequential extraction (SEDEX) to examine the various forms of particulate P (TPP). Particulate P(TPP) concentration averaged 40.9 ± 26.7 mg P m⁻³, with particulate P accounting for only 32.2 ± 13.7% of the total particulate N (TPN). The remaining N was comprised of loosely bound (18 ± 13%), mobile nitrogen (22 ± 12%), and nitrogenous (23 ± 12), and detrital (5.4 ± 2.8%) P forms. Annual fluxes varied widely, with significant increases during the summer, likely due to increased atmospheric input. Interannual variations in inorganic P will be discussed and compared to other sites with varying magnitudes of riverine input, upwelling, and upwelling in order to provide insights into the mechanisms that control particulate P composition and its ultimate removal from the marine water column.

GOT SNOW? TRACKING MARINE PATHOGENS IN AQUATIC ECOSYSTEMS

Marine aggregates (i.e., marine snow, floes, and organic debris) are ubiquitous in aquatic ecosystems and although many studies have focused on the composition, fate of aggregates, few have addressed their role in the ecology of aquatic ecosystems. This research focuses on diseases associated with suspension-feeding bivalves (e.g., clams and oysters), including bivalve pathogens and human pathogens acquired via consumption of contaminated bivalves. Marine aggregates were characterized using un-derwater video surveys coupled with direct collection in modified settling cones in order to explore differences in the characteristics of aggregates found in habitats populated by clams (Mercenaria mercenaria) and oysters (Crassostrea virginica). Microaggregate (< 500 µm) concentrations were always greater than macroaggregate (> 500 µm) concentrations, but peak concentrations of microagggregates and macroaggregates, mean size of particles, and volume fraction of aggregated material varied throughout the study. These results have important implications for the way in which aquatic pathogens are collected, monitored, and quantified for risk-based surveillance in shallow-water ecosystems.

DISSOLVED ORGANIC CARBON IN SMALL RIVERS, PANAMA

The climate of Panama is typical of the low-latitude humid tropics, characterized by near-uniform average temperature, abundant rainfall, and a distinct seasonality of precipitation with a dry December to mid-April Dry season and a wet season with near constant average monthly rainfall during the intervening months. Samples for dissolved organic carbon (DOC) analysis were collected from small rivers across Panama from along a transect from the Lake Bayano area to the Costa Rican border during both the wet and the dry season. Analyses of our data demonstrate that during the wet season the DOC concentration in all but three of the streams are higher than during the dry season. Concentrations vary greatly from river to river and from season to season, with values as low as 0.053 to high values of over 2.0 mM/L. The highest concentrations were observed in rivers draining sedimentary rocks in coastal watersheds. DOC dynamics from these rivers will be discussed in terms of what is known regarding SSMRs draining tropical forests in Puerto Rico and other Central American locations.

KNOWLEDGING A LONG-TERM STABLE ISOTOPE RECORD DERIVED FROM NORTH ATLANTIC RIGHT WHALE BALEEN: IMPLICATIONS FOR ECOSYSTEM-LEVEL CHANGES IN THE GULF OF MAINE?

North Atlantic right whales (Eubalaena glacialis) experience high anthropogenic mortalit y rates and have not recovered from the population bottleneck induced by commercial whaling. The majority of the extant population can be found foraging seasonally in several areas within the Gulf of Maine (GoM). We collected incremental stable isotope ratios (δ¹³C, δ¹⁵N, δ³¹P, δ δ) from 25 right whale baleen plates to examine long term trends in right whale migration behavior, health, and diet. The same isotope ratios were determined for zooplankton collected in GoM right whale feeding habitats, as so to ground-truth the observed whale baleen isotope patterns. Here we present the baleen isotope time series, which spans from 1880-2006, in the context of zooplankton isotope ratios as well as biogeochemical and physical measurements from the GoM. Most interestingly, we explore potential causes of a marked decrease in whale baleen δ¹³C that occurred in all whales sampled after 1999. Our results demonstrate that in addition to recording whale diet data, baleen may record environmental data, useful for documenting ecosystem-level changes.

INFLUENCE OF NET Ecosystem METABOLISM IN TRANSFERRING RIVERINE ORGANIC CARBON TO THE Atmosphere: C14 DIC IN A TROPICAL COASTAL LAGOON (CHILKA LAKE, INDIA)

Biogeochemical cycling of carbon in the Chilka Lake, Asia’s largest brackish lagoon on the east coast of India, was studied twice during May 2005 (premonsoon) and August 2005 (monsoon). The dissolved inorganic carbon (DIC) in the lake is higher by ~22% and dissolved organic carbon (DOC) was lower by ~36% during premonsoon than monsoon due to increased rainfall variations in the tributary rivers. Surface PCO2 values of over 2.0 mMC/L. The highest concentrations were observed in rivers draining seasonal changes in the lake seems to be governed by PCO2 levels in rivers and their discharge rates, which were several folds higher during monsoon than premonsoon. The net DOC efflux from entire lake during monsoon (2.64 Gg C·d⁻¹) was higher by 44 times than during premonsoon. 15% of DOC efflux from lake in monsoon was contributed by its supply from rivers and the rest was contributed by in situ heterotrophic activity. Based on mass balance, net ecosystem production (NEP) of lake (~377 Gg C·d⁻¹) was found to be in consistent with the total riverine carbon trapped in the lake (2.80 Gg C·d⁻¹) suggesting that strong heterotrophy in the pelagic compartment of the lake is mainly responsible for elevated fluxes of CO2 during monsoon. This suggests that Chilka lake is an important region in biogeochemical transformation of organic carbon to inorganic carbon and its export to the atmosphere.

OBSERVATION OF INTERNAL SOLITARY WAVES IN THE NORThern SOUTh CHINA SEA

Several remote sensing techniques are employed in observing the large internal solitary waves (ISWs) in the northern South China Sea in April 2007. The surface expressions of the ISWs are monitored from the same ship-borne radars. Two frequencies of acoustic ISWs are monitored from the satellite and ship-borne radar. Two frequencies of acoustic ISWs are monitored from the satellite and ship-borne radar.
are also observed at the location with sharp topographic changes. The 3-5 kHz chirp sonar is used in these areas. Large sand dunes with cascading runout near the beach are exposed to wave action, and affecting biolabile compounds derived by photolysis of CDOM. We examined the relative importance of these effects in an experiment that separated UV-shielding from supplementation of organic matter. Heterotrophic flagellates (HNAN) exposed to UV filtered through 5.5 cm of oligotrophic lake water (1.1 ppm DOC) suffered 100% mortality. HNAN shielded by an equivalent layer of CDOM (2.4 ppm DOC) maintained a stable population for ~48 h. HNAN incubated in the dark had maximum specific growth rates of 0.5 m/s. HNAN incubated in the dark had maximum specific growth rates of 2.08 and 2.17 d⁻¹ in lake water and CDOM, respectively. DNA dosimeters indicated that DNA damage was reduced by the CDOM shielding. These data confirm the importance of CDOM as a UV shield, but suggest that the biologically available organic matter may not be transferred to higher trophic levels during periods of UV stress.

DIRECT AND INDIRECT EFFECTS OF UV RADIATION AND CDOM ON A HETEROTROPHIC FLAGELLATE

Natural levels of UVB radiation can reduce microbial population growth. Climate change may alter the direct effects of UVB by changing input of chromophoric dissolved organic matter (CDOM), which absorbs UVB. CDOM fluctuations in oligotrophic lakes could alter the production of heterotrophic flagellates by modifying exposure to damaging radiation and affecting biolabile compounds derived from photolysis of CDOM. We examined the relative importance of these effects in an experiment that separated UV-shielding from supplementation of organic matter. Heterotrophic flagellates (HNAN) exposed to UV filtered through 5.5 cm of oligotrophic lake water (1.1 ppm DOC) suffered 100% mortality. HNAN shielded by an equivalent layer of CDOM (2.4 ppm DOC) maintained a stable population for ~48 h. HNAN incubated in the dark had maximum specific growth rates of 2.08 and 2.17 d⁻¹ in lake water and CDOM, respectively. DNA dosimeters indicated that DNA damage was reduced by the CDOM shielding. These data confirm the importance of CDOM as a UV shield, but suggest that the biologically available organic matter may not be transferred to higher trophic levels during periods of UV stress.

The ecological importance of pteropod physiology

Pteropods have recently received attention in respect to ocean acidification because of their production of aragonite shells. Swarming in large numbers in parts of the world, pteropods can be a substantial part of the diet of seabirds, whales and fishes. Shells and direct microstructure measurements using an AUV, in addition to numerical simulations. The 2006 campaign, during a period of extremely high river flows, yielded estimates of TKE dissipation rate on the order of 10⁻³ m²s⁻¹, one to two orders of magnitude higher than observed during the more moderate flows of the 2007 campaign. These data sets provide a unique opportunity for comparisons between various measurement techniques, and indicate how the use of multiple approaches can yield valuable information about the nature of the turbulent field.

THE MEAN WOCE-ERA PACIFIC OCEAN GENERAL CIRCULATION AS SEEN THROUGH ASSIMILATIVE AND INVERSE MODELS

A primary goal of the one-time Woce global hydrographic survey was to procure data capable of providing a basic description of the ocean's general circulation. Analysis of these data has taken a variety forms, but over the time frame of the Woce project two analysis techniques for synthesizing oceanographic data have emerged: steady-state box model inversions and OGCM observation assimilations. Recent analyses of data from spatial and temporal scale flow variations in specific regions have brought into question our ability to use hydrographic data as a basis for understanding, and quantifying, general/mean circulation patterns, and more particularly decadal time-scale changes in such patterns. The goal of this investigation was to compare the time-averaged, 3D Pacific circulation estimates provided by a box inverse analysis of Woce-era observations and a general circulation model, ECCO which assimilates many of the same (and additional) data. Results indicate that 1) surface (outcropping) circulations are often different, 2) upper layer subsurface and intermediate circulations are more often similar in both character and magnitude, 3) and deep circulations are often quite different. The details of these similarities and differences are presented.

MacDonald, A. M., Woods Hole Oceanographic Institution, Woods Hole, USA, amacdonald@whoi.edu

MacDonald, A. M., Woods Hole Oceanographic Institution, Woods Hole, USA, amacdo
from major river systems from the last glacial maximum (LGM) on into the future with emphasis on the influences of human activities and climatic change on the land-coastal margin system. As we came out of the LGM and atmospheric CO2 concentrations increased, net ecosystem metabolism (NEM) and net ecosystem carbon fixation (NEM) changed in response to climatic change and introductions of new nutrients to the ocean via rivers. The net air-sea exchange of CO2 in the coastal zone prior to extensive human influences on the land-coastal ocean system was from sea to air; soon that direction will reverse, if it has not already done so, driven by some extent by excess nutrients being added to coastal environmental from the land owing to human activities. NEM and NEC as we move into future centuries will be modified. Uptake of anthropogenic CO2 by the ocean will continue to acidify ocean waters and lead to potential changes in biogenic calcification rates and other effects on marine communities and carbonate sediment composition.

BLOOD OR DORM: SURVIVING THE TRANSITION FROM MIXING TO STRATIFICATION

In seasonally stratified seas, the onset of stratification in spring traps nutrients and phytoplankton within the euphotic zone where photosynthetic light limitation is reversed, resulting in a phytoplankton bloom. To identify key acclimation strategies that occur in response to such a rapidly changing light environment, we simulated a stratification event to induce bloom formation in natural phytoplankton populations collected from a deep- mixed, low-nutrient water column in the Red Sea. By replicating light conditions within the surface, middle, and deep euphotic zone following stratification, our results show that acclimation responses to high and low irradiances differ substantially during a bloom. Fluorescence, cellular chlorophyll content, and photosynthesis-short term relationships suggested that photosynthetic acclimation is characterized by an initial lag, in which photo-protective mechanisms may continue to function in a circadian pattern indicative of acclimation to a previous light regime, followed by rapid acclimation to new growth irradiances. In contrast, cell growth did not require a lag period, and picoeukaryote and Synecococcus populations bloomed within several hours of exposure to new light regimes. Bloom processes are therefore rapid and dynamic, encompassing a combination of seasonal and photosynthetic acclimation processes that occur over a period of hours to days.

INTERNAL WAVES ACROSS THE PACIFIC: THE ROLE OF SUBHARMONIC INSTABILITIES

As part of the Internal Waves Across the Pacific experiment, we conducted intensive shipboard and moored observations spanning 25-37°N (1600 km) along an internal tide emanating from the Hawaiian Ridge. Our goal was to understand the processes affecting the vertical propagation of the ocean's internal tides, and in particular their susceptibility to parametric subharmonic instability (PSI) at the critical latitude of 28.8°N. At the critical latitude, velocity and shear were observed to occur in intense vertically-standing, inertia-rotating bands of several hundred meters vertical wavelength, consistent with generation through PSI. These occurred in bursts following spring tide, and contrasted sharply with the downward-propagating, wind-generated features seen at other latitudes. Associated turbulent diffusivity is elevated by a factor of 4 or more over this latitude range, and by more than a factor of ten in what appears to be a strong tidal beam to the east. Details of the observed waves will be shown and implications for turbulent mixing in the global ocean discussed.

ECOLOGICAL AND FUNCTIONAL RECOVERY OF SEDIMENTS ASSOCIATED WITH FINISH CAGE AQUACULTURE - DO SOME SYSTEMS COPE BETTER?

In Tasmania access to coastal water for finfish aquaculture is limited, consequently following of whole lease areas is rare and cage rotation within farms is a more common approach for managing sediment recovery. We compare and contrast the ecological and functional recovery response associated with short and long-term recovery at salmon farms in Tasmania. Although the benthic communities at the short-term (3 month) recovery locations showed a strong recovery response, the community structure did not return to that observed under reference conditions. Differences in recovery response were shown to directly reflect the background environmental conditions and indicated that sediments in some areas have a greater resilience to organic inputs. The longer-term recovery studies indicated that once the ecological function of the sediment was restored subsequent community changes were relatively minor, suggesting that restoration of system function may be a more useful indicator of generalized recovery from organic enrichment than commu-
nary equivalence. Implications for farm/environmental management will be discussed with reference to current key environmental issues and the need to understand the ecological effectiveness of current fa
ing protocols will be highlighted.

THE INFLUENCE OF PERIMETER HABITAT ON AN ESTUARY: MODIFIED TRANSPORT IN A TIDAL CHANNEL DUE TO EXCHANGE WITH RECOVERING SALT MARSH IN SOUTH SAN FRANCISCO BAY

Exchanges between an estuary and its perimeter habitats are explored in this study by examining the impacts of salt marsh restoration on an adjacent channel. The channel restoration consists of breaching levees separating the tidal channel from subsided salt ponds for the first time in decades, effectively doubling the local tidal prism. The breaches allow mechanisms such as tidal trapping and tidal pumping to alter hydrodynamics in the channel, modifying transport of ecologically pertinent scales like salt and sediment. Field observations of velocities, salinity, temperature, depth, and suspended sediment concentrations were collected over four months at several locations in and near one levee breach in South San Francisco Bay. Analysis of these data establishes the existence of a buoyancy-driven, lateral exchange in the tidal channel induced by relatively saline waters that emerge from the breached salt pond during ebb tides. This exchange is further explored using a two-dimensional scalar transport model in an idealized domain. The results provide insight into the dynamics of estuarine transport as they are modified by exchange with perimeter habitats.

ECOSYSTEM-BASED MANAGEMENT OF THE EVERGLADES-FLORIDA BAY ECOSYSTEMS USING INTERLINKED SIMULATION MODELS

Restoration of the Everglades and coastal Florida ecosystem complex follows an ecosystem-based management (EBM) strategy that relies on integrated, whole-system planning. The highest priority south Florida ecosystem includes Lake Okeechobee, Everglades River and Slough, Cypress Wetland, Marl Prairie, Mangrove Estuaries, Biscayne Bay and Florida Bay subsystems. This series of connected ecosystems is linked hydrologically by a slow-moving, shallow fresh water flow discharging into multiple estuaries. Relationships within the subsystems are dependent on hydrologic timing, quantity and quality, inundation schedule and connectivity. Design of the south Florida restoration plan relies on simulation modeling at all levels for evaluating strategies and predicting response to ecosystem changes. Though the ecosystem restoration plan rests largely on repairing hydrological function, models of hydrology, biogeochemistry, physiology, landscape processes, water quality, human impacts, and upper trophic levels are needed to develop a coherent restoration plan. The linkage of geochemical and biological processes models to hydrologic and hydrodynamic transport platforms creates a geospatial, landscape framework integrating bottom-up components with upper level consumers. This talk discusses the capabilities and limitations of such an ambitious simulation environment.

CREATION OF AN INTEGRATED TOPOBATHY DEM FOR COASTAL AND OFFSHORE NORTH CAROLINA

The Renaissance Computing Institute (RENCI), at the request of the state of North Carolina Floodplain Mapping Program, and with funding from the Federal Emergency Management Agency (FEMA), is modernizing the floodplain maps of the state of North Carolina. This work is being conducted by computing a series of worst-case scenario flood models for coastal North Carolina using Octocore, RENCI’s IBM Blue Gene/L supercomputer. Over 500,000 Octocore computing hours will be needed to complete the work. As a part of this larger work, RENCI had to develop a new and more detailed integrated topo-bathymetric elevation dataset of coastal North Carolina. This paper presents the process used to create and quality control the single, integrated raster Geographic Information System (GIS) dataset that will be useful for a variety of purposes, including inundation modeling, mapping and other purposes. A single 1/3 arc-second (~10 meter) elevation grid was generated from multiple best available digital datasets in the region of different scales. It consists of 54,000 rows by 64,800 columns and 3,499,200,000 individual cells. The final raster file is as over 25Gb in size.

REGIONAL OCEAN CLIMATE MODELING FOCUSING ON THE NORTH SEA- BALTIC SEA TRANSITION ZONE

The North Sea and the Baltic Sea form a semi-enclosed sea area, and are linked by a quite narrow and shallow transition zone. To make multi-decadal simulations of this area, it is essential to model the North Sea-Baltic Sea water exchange correctly. Hence the complex topography in the transition zone must be resolved. We use a 6-1 nautical mile two-way nested model, BSHcmod, to make climate simulations. The model has been used operationally to forecast sea level, currents, temperature, and salinity since early 1990s, and has a well-documented ability to simulate specific events in the area. Here, we present hindcast simulations and validation results, comparing our model with unique historical temperature and salinity records from lightships in the transition zone. The validation focuses on the model’s ability to simulate special events, especially inflow events to the Baltic Sea, and the model’s performance on seasonal, interannual, and longer time scales. This is the first climate simulation with this BSHcmod. In future studies we will compare the model output with simulations for the years 2070-2100.

DEI VARIATION OF LIGHT ABSORPTION OF MARINE PHYTOPLANKTON ISOCYRIS GALBANA IN RESPONSE TO NITRATE CONCENTRATIONS

Light absorption of marine phytoplankton Isochrysis galbana in response to nitrate concentrations were examined under 12h:12h light:dark cycles. Isochrysis galbana was grown in a continuous culture with various concentrations of nitrate (800µM, 200µM, 100µM, and 50µM). Nitrate were replete in culturing vessel except 50µM experiment. At 50µM nitrate experiment, nitrate in the outflow was depleted (~1µM). In all conditions, chlorophyll a specific light absorption coefficient α(λ) had primary maximum at around 440nm throughout diel cycles. The α(440) at 440nm except for 50µM nitrate concentration exhibited diel variation with the maximum during light periods and the minimum during dark periods. Diel average of α(440) at 50µM was significantly higher than those at other nitrate concentrations. The average of α(440) for the nitrate replete experiments was highest at the highest nitrate concentration (p<0.01). This may suggest that light absorption efficiency per unit of chlorophyll a may increase with increasing nitrate concentration in the replete nitrate condition.

CAPES AND FORM DRAG: THE ROLE OF STRATIFICATION

Capes and headlands are topographic features important for coastal circulation since they are associated with high values of mixing and dissipation. Phenomena like current separation, lee waves and generation of eddies has important biological consequences and influence the drag force being imparted on the larger scale flow. In this work, the effect of stratification on eddy generation past capes is investigated. We present a sensitivity study considering a steady barotropic current impinging on an idealized triangular headland in a rotating and linearly stratified environment. Numerical experiments are conducted using ROMS in a wide range of parameter space, consisting of the slope of the obstacle, the Burger and the Rossby numbers. The form drag exerted by the cape on the coastal current and the mixing downstream are calculated. It is found that the eddy shedding regimes depend on the Burger number. The form drag coefficient is expressed as a function of both the Burger number and the cape slope.

SUBMESOSCALE FLUXES AND BIOLOGICAL PRODUCTION IN THE UPPER OCEAN

We explore the impact of submesoscale processes on the distribution and flux of biogeochemical tracers in the upper ocean using a numerical model. We characterize the vertical flux of nutrients for phytoplankton production in the euphotic layer in terms of stratification, wind stress, frontal strain, vorticity, and the ambient vertical gradient of the tracer. Horizontal transport across fronts is examined at frontal singularities. Vertical nutrient flux into the euphotic layer results in a phytoplankton production with a characteristic time scale for growth. The flux of nutrient and the distribution of phytoplankton are highly sensitive to the biological uptake time scale and are not necessarily coincident in time and space. Longer lived phytoplankton are found to accumulate not where fluxes are highest, but where mixing is weakest, e.g. at the centers of eddies formed by frontal meanders. We attempt to correlate the patterns in surface phytoplankton that are discernible from sea surface chlorophyll, with physical characteristics of the flow.

PHYSIOLOGICAL AND COMMUNITY RESPONSE OF AUTOTROPHS TO SIMULATED UPWELLING OF NUTRIENT RICH DEEP WATER AT STATION ALOHA IN THE NORTH PACIFIC SUBTROPICAL GYRE

Between October 2005 and May 2007, seven mesocosms experiments (20L) were conducted in the North Pacific subtropical gyre, to examine the physiological and community
response of autotrophs to the addition of nutriment-rich deep seawater (750m, 5% vol.-vol.), the goal being to assess bloom dynamics and community structure in the oligotrophic region. Inorganic nutrients, size fractionated autotrophic biomass and rates of primary production, as well as community composition were monitored for up to 170 hours. Here, we show that although primary production increased during all experiments, community composition and size structure did not change significantly in 5 of the 7 experiments. The magnitude of autotrophic responses was water column-dependent on water column history, nutrient status and season. Parallel “nirrate only” experiments showed that up to 60% of the physiological response observed by adding deep seawater was due to the addition of inorganic nitrogen. These experiments demonstrate the unpredictable response of the autotrophic community to nutrient fertilization and emphasize our inability to predict bloom dynamics in the open ocean.

OCEANIC GERMANIUM/SILICON FRACTIONATION: EVIDENCE FROM OCEANIC PROFILES AND DIATOM CULTURES

The cycling of inorganic germanium (Ge) in the ocean closely resembles that of silicon (Si). Here we present ten Ge and Si concentration profiles collected from the Atlantic and the Southwest Pacific Oceans. A plot of Ge concentration versus Si concentration produced a near-vertical line with a slope of 0.86±1.2 and an intercept of 1.16±0.6. When the Ge to Si ratio (Ge/Si) was plotted versus depth, higher values were observed in surface waters and the ratio declined with depth. Short-term Ge and Ge uptake experiments involving the marine diatom Minutocellulus polymorphus produced half saturation constants of 0.87±0.1 and 2.70±0.1, respectively. Azarn (1974) obtained similar results for the marine diatom Nitzschia alba. This suggests that the uptake of Ge is slower than that of Si and that the lower uptake efficiencies of Ge are related to the same fundamental mechanism leading to Ge/Si fractionation in diatoms, and ultimately the positive intercept in the Ge vs Si seawater relationship. If Ge/Si fractionation is driven by subtle differences during uptake then paleo-nutrient reconstructions utilising the Ge/Si signature of diatoms need re-examination.

PHYTOPLANKTON COMMUNITY STRUCTURE IN THE SOUTHERN MID-ATLANTIC BIGHT: BASELINE MEASUREMENTS FOR THE WA-COOL PROJECT

Phytoplankton community structure in the southern Mid-Atlantic Bight was examined during a time-series of cross-shelf surveys from Wallops Island, Virginia, as a part of the Wallops Coastal Oceanic Observing Laboratory (Wa-COOL) program over the previous 8 years. Cruises were conducted approximately monthly on the RV Phillip N. Parker and covered a transect of five stations from 5.2 m to 21.7 m offshore. Dominant diatoms at the offshore station included Fossiulina, Saccharina, and Chaetoceros. Pseudonitzschia peaked during March 2007, with a density of 18.2x10^6 cells L^-1 at 5m depth. In the southwest section of the transect, but peaked in November 2006 to 1.5x10^7 cells L^-1 at 5m depth. Chaetoceros was most abundant in late summer, peaking at 9.6x10^6 cells L^-1 in late July 2007. Phaeocystis appeared in large numbers on the order of 6.9x10^7 cells L^-1 in surface samples in November 2006, and was typically observed in colonial form. This first year baseline study indicated the presence of harmful algal species during the spring, and also the presence of a nuisance algal species, Phaeocystis.

ULTRAVIOLET RADIATION (UVB) EFFECT ON NATURAL PHYTOPLANKTON ASSEMBLAGES IN SAGAMI BAY, JAPAN

To assess the effect of solar ultraviolet radiation (UVB, 280-320 nm) on primary productivity and natural phytoplankton assemblages, samples were collected at coastal water off Manzuru, Sagami Bay, central Japan from August 2006 to March 2007. UVB and photo-synthetically active radiation (PAR) were determined in air. Samples were placed in acrylic aquariums and exposed to PAR+UVA+UVB and incubated with inoculation of Na_2SiO_3 at respective levels of 6.97x10^-2 and 9.60x10^-3 mol L^-1. Paramecia were present throughout the cruises, but peaked in November 2006 to 5x10^6 cells L^-1 at 5m depth. Thalassiosira was present throughout the cruises, but peaked in November 2006 to 5x10^6 cells L^-1 at 5m depth. Phaeocystis appeared in large numbers on the order of 6.9x10^7 cells L^-1 in surface samples in November 2006, and was typically observed in colonial form. This first year baseline study indicated the presence of harmful algal species during the spring, and also the presence of a nuisance algal species, Phaeocystis.

EFFECT OF SMALL-SCALE TURBULENCE ON GRAZING AND GROWTH OF SEA URCHIN LARVAE

Small-scale turbulence may reduce food limitation in marine invertebrate larvae, with important implications for growth, dispersal, and recruitment. This study investigates whether small-scale turbulence reduces food limitation and enhances growth in larvae of the sea urchin Lytechinus variegatus. Short-term food conditions were exposed to steady laminar shear generated in simple Couette flow. Clearance and ingestion rates were determined based on changes in cell concentration of the unicellular alga Rhodomonas lens. Postlarval (PO), midline body (M), and stomach (S) lengths were measured as indices of growth. Clearance and ingestion rates were significantly different and increased nearly two times greater larval exposure to shear compared to still controls. But the effects of shear treatment on growth were more complex and may reflect age-specific differences in flow sensitivity. Biochemical analyses indicated that sheared larva had advanced to later stages of development compared to still controls. These results support predictions that turbulence, which increases encounters with prey, leads to increased grazing and growth. But biochemical markers may be more useful indicators of growth compared to morphological indices of development.

PARALLEL NITROGEN CYCLES IN SOUTHWEST FLORIDAS TIDAL RIVERS: SELECTIVE REMINERALIZATION OF ALGAL MATERIAL SUPPORTS RECYCLING OF Bioassayable and recalcitrant nitrogen pathways and the flow of nitrogen from autotrophic production to fish biomass was investigated in naturally and anthropogenically influenced tidal rivers and tributaries in Southwest Florida. d15N composition of water column and sedimentary components were used to identify 1) the primary producers (plankton, benthic microalgae, vascular plants) that contribute to bulk sedimentary organic matter, 2) the types of organic nitrogen that support foodwebs via remineralization, and 3) the primary producers that support fish biomass. Strong isotopic linkages were found between 1) microalgae and sediment porewater ammonium, 2) living vascular plants and bulk sedimentary organic matter, and 3) microalgae and fish. These results suggest that of two distinct but parallel nitrogen cycles co-occur in these systems. The labile nitrogen cycle contributes to the fish trophic base either directly or indirectly via remineralization, while the recalcitrant cycle involves burial of low-nutrition vascular plant detritus. To safeguard processes that support valued fish production, resource managers must identify 1) the types of primary producers that support higher trophic levels and 2) the contribution of nutrient recycling and burial to the total nutrient load.

INUNDATION ALONG SOUTH EAST COAST OF INDIA FOR 26TH DECEMBER 2004 TSUNAMI : FIELD MEASUREMENTS VS NUMERICAL MODEL

The tsunami generated by the 26th December, 2004 at Sumatra Mw = 9.3 earthquake inundated many countries along Indian Ocean and worst tsunami-related death toll in this decade. Field measured data have indicated the run-up levels varying from 1.5m to 5m in Andaman Islands and 3m to 7m in Nicobar Islands. In the case of south coast of India (Tamilnadu), it was between 2.8m and 6.0 m. Locations with gentle land slope showed penetration of seawater to long distances compared to steeper slopes. Inundation along south east coast of India (450 km) and Andaman Nicobar groups are among the highest ever documented for non-landslide generated tsunamis by us, where the high magnitude of runup and run up heights were measured in a short period using Real Time Global Positioning System without loosing the signatures. We model this event to confirm the estimated inundation, and we find that current state-of-the-art shallow-water wave models can predict tsunami inundation correctly including extreme runup. Results suggest that the predicted extreme inundation is more sensitive to land elevation and nearshore bathymetry. We used the Airborne Lidar Terrain Mapper (ALTM) data with an accuracy of 0.35m for land elevation and model results compared for three sites indicated good agreement. Also, analysis of bathymetry collected pre and post Tsunami indicated that the tsunami wave caused changes in the seabed morphology, sediments removed from offshore long shoals are deposited in nearshore.

NEW INSIGHTS INTO QUATERNARY SEA LEVELS AND ISOSTASY BASED ON OPTICAL DATING OF SILICICLASTIC PALEO-SHORELINE FEATURES ON THE U.S. ATLANTIC COASTAL PLAIN

Improvements in geochronological techniques now allow for more precise dating of siliciclastic coastal lithosomes that have the potential to provide many more sea-level index
points (SLIPs) for the Quaternary Period. These techniques include optically stimulated luminescence (OSL) and electron spin resonance dating (ESR). This investigation uses these new dating tools in conjunction with ground penetrating radar (GPR) and sedimentological data to establish the age and relative sea level (RSL) as recorded by stranded coastal lithosomes (Holocene and Pleistocene beach ridges) in North Carolina and Florida. Sites have been cored using vibracore and geoprobe techniques, sampled for granulometric and radiometric analysis, and surveyed using GPR. These coastal deposits consist of silicilastic or mixed carbonate silicilastic sands. However, due to intense subaerial weathering, the carbonate sediments are typically too badly altered, or too scarce to acquire meaningful U-series dates. Granulometric and GPR data are being used to indicate the elevation of the beach ridges - surf zone transition, which provides a datum for determining RSL. These data are being used to refine the Quaternary relative sea-level record of the SEUS Atlantic Plain and, by comparison to other Quaternary sea-level data and isotopic models, will help to refine models of mantle and lithosphere rheology and isostasy.

SOUTHERN PUGET SOUND DISSOLVED OXYGEN STUDY - AN OVERVIEW

The Washington State Department of Ecology has embarked on a comprehensive study of South Puget Sound to understand the relative influence of various natural and anthropogenic sources of nitrogen near bottom dissolved oxygen levels. This fjord-type estuary has low DO levels that occur in late summer and that violate state water quality standards. The first phase of the study indicated that both point sources from wastewater treatment plants and nonpoint sources from both uplands and downlands contribute significant nitrogen loads. The current project further refines those loads of nitrogen and other parameters. Data collection includes marine water column data collected monthly from 80 marine stations, watershed and wastewater treatment plant inputs, boundary conditions, current fields, and benthic fluxes. A three-dimensional circulation and water quality model will enhance understanding of how nitrogen moves around South Puget Sound and the relationships with dissolved oxygen levels. The calibrated model will be applied to a variety of management actions to determine how much point and nonpoint source nitrogen loads must be reduced to meet water quality standards.

DEVELOPING A EUROPEAN OCEAN COLOUR SERVICE SUPPORTING WATER QUALITY ASSESSMENT AND OPERATIONAL OCEANOGRAPHY

The Water Framework Directive (WFD), started to be implemented in Europe in 2000. As the European directive that provides guidelines on the management of water resources, it clearly defines environmental objectives in terms of water quality for lake, river, underground and characteristic coastal waters (so-called water masses). Several initiatives have been performed, under ESA support and in the context of GMES, to apply Ocean colour techniques from space to operational management of coastal water quality with relevant results obtained at local, regional and European scales by using such techniques. These experiments have opened the door to reliable services for water quality monitoring and their extension at global level through Ocean colour data merging. This will be the basic component of the global Ocean colour Thematic Assembly Centre that is presently put in place by EU to support operational oceanography and shall have a significant role in the building of the Global Earth Observing System of Systems.

TOWARDS MODELING THE CARBON CYCLE OF THE ARCTIC OCEAN

We use a numerical model to examine the fate of riverine fluxes of dissolved organic carbon (DOC) in the Arctic Ocean. The model is based on the Arctic sector of an eddy-permitting ocean model (MITgcm), where spherical geometry is projected onto a cube to avoid polar a singularity in the Arctic region. The physical model is forced by time-varying NCEP re-analysis products and an explicit representation of fresh water run-off in the Arctic region. Passive tracers and idealized
estimated with satellite-derived products from OCTS, SeaWiFS, AVHRR, and the VGPM primary productivity algorithm. These results were compared with the distribution and abundance of three pelagic species within the California Current System, Humboldt jumbo squid (Dosidicus gigas), sardine (Sardina pilchardus), and yellowfin tuna (Thunnus albacares). Fronts and primary productivity are key ocean process linked with a variety of biological processes that may directly or indirectly enhance population success. Our analysis, conducted in the last few years, suggests different responses of these three species to interannual ocean-climate variability. Humboldt jumbo squid and sardine have progressively expanded poleward, which is most likely explained by latitudinal change of favorable conditions, which are discussed in this presentation.

PARTICULATE AND SEDIMENT ORGANIC MATTER IN TWO CANADIAN ESTUARIES INVESTIGATED BY SOLID-STATE NMR: VARIATIONS OF CHEMICAL STRUCTURES WITH LOCATION AND DEPTH

We used advanced solid-state NMR, especially new spectral-editing techniques, to investigate chemical structures of five humic acids (HAs) from particular organic matter at different depths and sediment organic matter in the Saguenay Fjord and St. Lawrence Estuary, Canada. Despite different locations and depths, the five HAs were found to have a common structure: peptides, aliphatic chains, aromatics, and sugar rings. Advanced NMR presented structural information such as a small proportion of N-heterocycles, and very mobile aliphatic chains in close proximity to the other structural components. A major bacterial contribution to these samples could explain why the samples, which had different dominant organic matter sources (terrestrial vs. marine), were similar. Nevertheless, some significant structural differences were observed for HAs from the same depth and those from sediments at two locations: HAs in the Saguenay Fjord had more aromatic/olefinic carbons and lower aliphatics than corresponding HAs in the St. Lawrence Estuary, suggesting more lignin input for organic matter in the Saguenay Fjord. With increasing depth, aliphatics decreased while aromatics and aromatic C-O groups increased, suggesting that diagenetic alterations occur with depth.

MULTIPLE EQUILIBRIUM STATES AND ABORTED TRANSITIONS IN TIDAL ECO-MORPHOLOGY

Changes in relative sea level, sediment loading, and ecological characteristics expose tidal landforms and ecosystems to responses which may or may not be reversible. Here we present a point model of the joint evolution of tidal landforms and biota, including the dynamics of intertidal vegetation, benthic microbial assemblies, erosional and depositional processes, local and general hydrodynamics, and relative sea-level changes. Alternative stable states and abrupt transitions among them emerge, governed by vegetation type, disturbances of the benthic biofilm, sediment availability and marine transgressions or regressions. Multiple equilibria are the result of the interplay of erosion, deposition and biostabilization, highlighting the importance of the coupling between biological and sediment transport processes in determining the evolution of a tidal system as a whole.

LONGITUDINAL CHANGES IN THE QUALITY OF DISSOLVED ORGANIC CARBON IN THREE TROPICAL WATERSHEDS

Dissolved organic carbon (DOC) is considered the most important source of energy of river ecosystems, including tropical rivers. The source of allochthonous organic matter inputs to rivers can be either natural or anthropogenic. It is hypothesized that the source can also affect the quality or biodegradability of the DO. This research pretends to perform nutrient amendment experiments in the eastern (140°W) and western (165°E) equatorial Pacific with a particular emphasis on measuring the changes in C, N, and Si incorporation during the enhanced phytoplankton growth. Iron and silicic acid additions at 140°W caused the greatest growth response (10-fold increase in 122-fold increase in 14C uptake rates) with the resulting biomass composed primarily of diatom diatoms. Combined iron, nitrogen and phosphate concentrations at 165°E caused the greatest growth response (3-fold increase chla and 16-fold increase in 14C uptake rates) with the resulting biomass composed primarily of photosynthetic picophytoplankton. We will compare between the regions, the changes in (1) phytoplankton biomass and composition—assayed by size-fractionated chla and particulate organic matter, biogenic silica, flow cytometry and diatom enumerations and (2) productivity—assessed by C, N (nitrate, ammonium and dinitrogen gas) and Si uptake rates and maximum photochemical yields—before and after nutrient amendments.

CHARACTERIZATION OF SEABED GEOMETRY IN A FREE SURFACE WAVE ENVIRONMENT

The goal of this effort is to increase our understanding of seabed geometry induced by free surface gravity waves. Observations of seabed geometry and wave characteristics were obtained at two water depths (1.723 m and 1.625 m) during the collaborative 2005 CROshShore Sediment Transport EXperiment (CROSTEX) at Oregon State University. Seabed elevation and beach slope observations were obtained with a two-axis scanning acoustic backscatter sensor. More detailed ripple geometry observations were measured with a submersible PIV system. The free stream velocity time series was measured with an Acoustic Doppler Velocimeter (ADV) located 60 cm above the bed. In this effort, we examine the impact of offshore wave characteristics (wave height and period) and local beach slope on ripple geometry and migration. Offshore wave heights ranged from 20 to 60 cm and peak periods ranged from 4 to 8 seconds. The observed ripples are of the anisotropically type and are consistent with the field observations of Crawford and Hay. The observations show that increasing wave energy results in a general flattening of the seabed.

ACROSS-SHORE EDDY TRANSPORT OFF CENTRAL CALIFORNIA

The mesoscale and submesoscale eddies on the across-shore transport observed off Central California was studied using 65 isobaric RAFOS float launched in the California Undercurrent between 150 and 600 m in 1992-2004. The floats typically move poleward for some period of time, perhaps reversing direction for short periods, but eventually escape the undercurrent and move to the west where they enter a region dominated by mesoscale and submesoscale motion. The kinematics of this eddy-dominated region are studied here. About 50 loops, i.e. floats which demonstrated two or more consecutive rotations of the same sign, have been identified from the data, most of them (>75%) trapped in anti-cyclonic eddies travelling roughly westward. Assuming that the looping floats were translated by nonlinear eddies, their geographic distribution, mean period of rotation, characteristic swirl velocity, size, and eddy kinetic energy were estimated. Trajectories are also compared with the motion of persistent depressions of the sea surface as measured by satellite altimeter.

AN EDUCATIONAL WEB-BASED OCEAN CURRENT REFERENCE SITE

An educational web-based ocean current reference site is being constructed. Each major ocean current has a listing of important links, text and data plots. The text provides a detailed summary of observed velocities, transport, salinity, temperature, water mass characteristics, and seasonal variability for each current. Data plots include average and seasonal surface summary of observed velocities, transport, salinity, temperature, water mass characteristics, and seasonal variability for each current. These results were compared with the distribution and abundance of three pelagic species within the California Current System, Humboldt jumbo squid (Dosidicus gigas), sardine (Sardina pilchardus), and yellowfin tuna (Thunnus albacares).
Johnson, R. Marshall, H. G. corroborate other USGS cores from the freshwater Everglades. The pre-drainage salinity reduced more than Shark River Slough. The hydroperiod estimates from model output reduced significantly over pre-drainage estimates, with the Taylor Slough hydroperiod season. Stage values in both Shark and Taylor Sloughs are about 0.15 meters lower on flow into the Everglades is about 2-2.5 times lower than it was during the pre-drainage to estimate pre-drainage stage and flow conditions in Shark River Slough and Taylor used to develop an estimate of the salinity regime in Whipray Basin prior to about 1900. Paleoecological data from were collected and interpreted by the USGS and US Fish and Smith, D. T. Marshall, F. E. an explicit eddy energy budget following the above procedure. Extensions of this approach circulation model in which the Gent and McWilliams eddy closure is modified to include parameterized eddies. Preliminary results will also be presented from an ocean general calculation and freely decaying turbulence in ocean basins, with both explicitly resolved and parameterized some necessary ingredients to parameterize the gross effects of eddies in both forced-dissipative and freely-decaying turbulence. An important issue concerns parameterization of the dispersion and dissipation of the eddy energy, for which some simple schemes are suggested. These ideas are illustrated through applications to wind-driven circulation and freely decaying turbulence in ocean basins, with both explicitly resolved and parameterized eddies. Preliminary results will also be presented from an ocean general circulation model in which the Gent and Williams eddy closure is modified to include an explicit eddy energy budget following the above procedure. Extensions of this approach to include angular momentum constraints will also be discussed.

THE USE OF STATISTICAL MODELS WITH PALEOSALINITY DATA TO SIMULATE THE PRE-DRAINAGE HYDROLOGY IN THE GREATER EVERGLADES ECOSYSTEM
Paleocological data from were collected and interpreted by the USGS and US Fish and Wildlife Service from Whipray Basin in Florida Bay. After interpretation, these data were used to develop an estimate of the salinity regime in Whipray Basin prior to about 1900. Statistical models coupled salinity in Whipray Basin and the hydrology in the Everglades to estimate pre-drainage stage and flow conditions in Shark River Slough and Taylor Slough. The overall mean values produced by the models indicate that existing freshwater flow into the Everglades is about 2-2.5 times lower than it was during the pre-drainage period. The deficit in Taylor Slough is much greater than Shark River Slough in the dry season. Stage values in both Shark and Taylor Sloughs are about 0.15 meters lower on average now than during the pre-drainage period. The average hydroperiod has also been reduced significantly over pre-drainage estimates, with the Taylor Slough hydroperiod reduced more than Shark River Slough. The hydroperiod estimates from model output corroborate other USGS cores from the freshwater Everglades. The pre-drainage salinity regime throughout Florida Bay was also estimated.

RE-OCCURRING HARMFUL ALGAL BLOOMS IN THE TIDAL RIVERS OF VIRGINIA, U.S.A.

A total of 37 potentially harmful algal have been identified for the Chesapeake Bay estuary transect. (Marshall 2007). Of note, is the increased occurrence of Cochlodinium polykrikoides in the James and Elizabeth rivers following a 1992 Chesapeake Bay bloom that entered these sub-estuaries. This intrusion established fertile seed beds containing C. polykrikoides cysts; the source of subsequent blooms that annually have perpetuated this pattern, resulting in an increased occurrence of its blooms in these waters. Highest local pre-1992 abundance recorded was 5-6 cells ml⁻¹, today bloom levels reach 1-15 x10⁶ cells ml⁻¹. Also a 2007 York River C. polykrikoides bloom (1,170 cells ml⁻¹), included as a co-dominant Alexandrium monilatum at 1,200 cells ml⁻¹. PCR analysis of Karlodinium venenatum has indicated this taxon is widely distributed in Virginia tidal waters, including numerous rivers and streams. This species produces an extensive and long lasting bloom and estuaries bordering the Potomac River in 2007 from mid-June into August. Concentrations reached 337 x10⁶ cells ml⁻¹. These blooms were also frequently accompanied by high concentrations of Akashiwo sanguinea, Heterocapsa rotundata, and/or Prorocentrum minimum.

RECENT DEVELOPMENTS IN THE STUDY OF EDDY STIRRING AND MIXING IN THE SOUTHERN OCEAN
We review recent progress in the understanding and mapping of mesoscale eddy stirring in the southern ocean placing emphasis on the interplay of observations and theory. In particular we discuss: (i) the spatial distribution of mixing zones and barriers and their relation to the geography of the oceans potential vorticity field and steering levels in the southern ocean. (ii) the vertical variation of the eddy stresses and its interplay with the applied surface wind stress in setting the meridional overturning circulation of the ocean. (iii) Implications of the above for the forthcoming DIMES southern ocean mixing experiment.

IN SITU MEASUREMENTS OF DIEL VARIATIONS IN BARREL SPONGE RESPIRATION FROM NOAAS AQUARIUS UNDERWATER OBSERVATORY ON CONCH REEF, FLORIDA KEYS (USA)
The barrel sponge Xestospongia muta accounts for approximately 60% of sponge biomass in a 660m2 area on Conch Reef off Key Largo, Florida Keys. Respiration by X. muta generally results in a 5-15% oxygen drawdown in the huge volumes of ambient water pumped through the sponge and released as excurrent flow and thus can significantly lower concentrations in the overlying water column. Excurrent DIN fluxes resulting from organic matter consumption during respiration far exceed those from coral substrate and sediments. During 2005 and 2007 missions using the Aquarius underwater observatory, chemical transformations and fluxes resulting from X. muta respiration were quantified for periods of hours to several days by coupling dissolved gas measurements with acoustic Doppler velocimetry measurements. Three different instrument arrays, including Clark sensors and an in situ mass spectrometer, were utilized to continuously measure dissolved gases including O2 (mass 32), N2 (28), Ar (40) and CO2 (44, 45). The stoichiometries of CO2 consumption, CO2 production and DIN release are utilized to quantify the role of barrel sponges in total respiration and C and N cycling on the reef.

NUMERICAL MODELLING OF THE INTERACTION OF INTERMEDIATE WAVES WITH BATHYMETRY USING ADAPTIVE MESH TECHNIQUES
Internal gravity waves can provide a sufficient source of energy to activate strong diapycnal mixing in the near-surface of open ocean. Our model is motivated by the desire to study wave breaking and subsequent mixing; and the effect of the depths of the thermocline and shelf-break on the transport of colder nutrient rich water up onto continental shelves, with important implications for bioproductivity. We present two- and three-dimensional results of numerical investigations of internal wave breaking using the Imperial College Ocean Model (ICOM), a non-hydrostatic, finite-element model that includes anisotropic mesh adaptivity. The ability of the model to focus resolution where it is most needed in response to the evolving flow makes ICOM an ideal tool to study the small-scale processes that result from the interaction of internal gravity waves with bathymetry. We examine: (1) the interaction of internal waves with idealised and realistic bathymetry, in particular wave-breaking and subsequent mixing; and (2) the effect of the depths of the thermocline and shelf-break on the transport of colder nutrient rich water up onto the continental shelf.
Fish assemblages in urban areas are commonly characterized by a dominance of non-native species over time. This life history strategy might benefit native species by providing different environments thus reducing the negative impacts of urbanization. In this study we characterized fish assemblages in the Río Piedras Basin, one of the most urbanized watersheds in Puerto Rico. Ten sites were sampled using backpack electrofishing. All individuals were counted and identified on site. We found a mixture of native and non-native species at all sites. A total of 9 species were found. Half of them were native. Results indicate that streams within this highly urbanized watershed support a diverse assemblage of fishes and that native species are still abundant, potentially due to their catadromous life history.

IMPACT OF SAHARAN DUST ON THE CIRCULATION OF THE NORTH ATLANTIC

Satellite images regularly show dust clouds entering the eastern tropical North Atlantic from the Sahara. Generally, Sahara dust can impact the ocean through two processes: (1) by reducing the solar insolation with associated cooling of the surface water and (2) by enhancing primary productivity and thereby altering the absorption of solar radiation in the upper ocean. Knowing the importance of either of these processes is important for understanding the feedback mechanism between dust and the physical and biogeochemical ocean. In this talk we present an analysis of the dynamical response of the ocean due to dust forcing. The problem is studied by forcing the MITgcm with perturbations in solar radiation observed from observed dust concentrations. The response can be rationalized in terms of fast propagating to the trade winds, and also Kelvin waves that are triggered by dust-induced cooling. Associated sea surface high anomalies propagate first northward and then around the entire basin within 1 month of simulation. Atlantic heat transport anomalies at different latitudes and the perturbations in the Atlantic MOC stream function react to the dust forcing through this propagating density anomaly

INTEROPERABILITY BETWEEN SEA-SONDE AND WELLEN HF RADARS IN THE FLORIDA CURRENT

A dual-station high frequency (HF) Wellen Radar (WERA) transmitting at 16 MHz have been observing near-real time surface currents over a range of 100 km in the Florida Straits since July 2004. A pair of 25 MHz Sea-Sonde HF radar were deployed by the NOAAs Center for Operational Oceanographic Products and Services south of WERA sites during a period of 10 days in April 2005. The Sea-Sonde grid produced overlapped the southern portion of the WERA domain. During the same period of time, a moored acoustic Doppler current profiler (ADCP) obtained subsurface current measurements within these HF radar grids starting at 14-m. To examine this question of interoperability between beam-forming and direction-finding technologies, comparisons of radial and vector currents for an 8-day concurrent time series were made suggesting good agreement in direction in both domains where maximum surface currents of about 1.4 m s⁻¹. In the core of the radar domains, hourly vector currents were obtained by combining radials from these radars and compared and will be discussed relative to the ADCP measurements.

INVESTIGATING HISTORICAL LAND USE WITHIN THE MANATEE RIVER WATERSHED

The Tampa Bay estuary has become severely altered by anthropogenic activities. There are few studies that link changes in the Manatee River Watershed to changes in land use. The objective of this project is to examine historical land use in Southeast Tampa Bay.
Sediments, water samples, and water quality measurements were collected near Native American middens located in Emerson Point Park to provide insight regarding historical land use of the Manatee River Watershed. Sediments were analyzed using gamma spectrometry techniques as well as lithologic characteristics including grain size, total organic content and carbonate content. Standard Inductively Coupled Plasma and Optical Emissions Spectrometry methods have been used to determine concentrations of trace, minor and major elements in the sediments related to land disturbances. The geochemical record will reflect the impact of land use prior to the industrial age through modern day. This project is part of a larger on-going investigation. If successful, this investigation will ultimately yield a tool for determining the effect of anthropogenic activity on the watersheds of Southeastern Tampa Bay over the last one hundred years.

FISH HEALTH IN A TROPICAL URBAN WATERSHED
Urban land use impacts streams by altering their hydrology and geomorphology resulting in reductions in biodiversity. Riparian deforestation, sewage discharges, and increased nutrient loading are some of the factors driving ecological degradation. The fish community reflects these impacts. In this study, we evaluated fish health in an urban watershed in Puerto Rico, which is characterized by having a migratory native fish fauna that closely connects with the ocean. The objective was to evaluate fish community health and condition in the Rio Piedras basin. We sampled fish in ten streams reaches and recorded external abnormalities (deformities, lesions and ulcers, tumors) and parasite infections. Native fishes did not present morphological damages. In contrast, exotic fishes showed external abnormalities, like tumors in anal fins. The migratory behavior of native fishes and the constant recruitment of juveniles from estuaries provide native fishes with a strategy to potentially reduce the negative impacts of urbanization on their populations. Alternatively, native fishes could be tolerant to the impacts of urbanization. Overall, our study indicates that native fishes are healthy suggesting a large potential for management and restoration of urban river ecosystems in Puerto Rico.

LOCAL AND REMOTELY-GENERATED INTERNAL WAVES ON THE OREGON CONTINENTAL SLOPE
Turbulence observed on the Oregon continental slope, which is strong enough to be of potential importance to global mixing budgets, is hypothesized to result from the breaking of locally- and/or remotely-generated internal waves. To determine which, a moored and shipboard field program was conducted in full 2005. Semidiurnal energy fluxes are obtained from harmonic fits to horizontal velocity and vertical displacement profiles from McLane Moorled Profilers on 5 moorings, deployed for 40 days in a zonal line across the continental slope at 43.215° N. The direction and magnitude of zonal energy fluxes are temporally- and spatially-variable. At times, onshore semidiurnal fluxes converge as internal waves generated at remote sites shoal onto the continental slope. At other times, fluxes diverge between the shallowest moorings indicating a local source. Refraction and/or scattering of the internal wave field to higher wavenumbers on ‘rough’ or near-critical slopes is thought to be the cause of enhanced dissipation. Observations are presented and implications for the observed mixing are discussed. Observations are presented and implications for the observed mixing are discussed. More, recently, there are few studies directly related to this topic. The study site was used to investigate a historical record of contaminants at the study site. This information will also be used to provide information regarding historical regional climate and terrestrial land use changes.

INTERCOMPARISON OF VARIOUS GLOBAL EVAPORATION PRODUCTS
Fresh water flux consists of two components, i.e. precipitation and evaporation. Since ocean reserves huge amount of water, the evaporation over the ocean is expected to play an important role in global water cycle. However, studies related to evaporation are not so many compared with those related to precipitation. Recently there are several products of global latent heat flux over the ocean. The products include reanalysis data (e.g., NRA, ERA and IRA), in situ data (e.g., NODC and ICOADS), satellite-derived data (IOHAPS, GSTST and J-OFURO) and hybrid data (OAIfux). We can obtain evaporation using latent heat flux data. While there are some studies of intercomparison of global latent heat flux data over the ocean, for example, Kubota et al. (2003). However, their analysis covered only several years. Moreover, there are few recent studies directly related to evaporation over the ocean. In this study, we compare various global evaporation products. The analysis period is from 1988-2000. The temporal and spatial resolutions are monthly and 1 degree, respectively.

ACOUSTIC SIGNATURES IN A FORECASTING OCEAN MODEL
Global and regional ocean models run operationally at the Naval Oceanographic Office (NAVO), such as a suite of Navy Coastal Ocean Models (NCOM), provide a wealth of nowcast and forecast information of ocean features on varying resolutions. Recently, efforts have been made to translate the ocean physics contained in these models into products that provide horizontal and temporal variability of the acoustic signature of an area. Variables such as Mixed Layer Depth (MLD), Sonic Layer Depth (SLD), Below Layer Gradient (BLG), and In-Depth Gradient (ILG) have been used to provide a basic understanding of ocean feature location, structure, and acoustical significance. In particular, the western Philippine Sea and East China Sea regions will be discussed using model results validated against recent observations. These regions allow for assessments of variations in acoustic signatures caused by boundary currents, eddies, and internal tides, plus the effect of temporal variations due to atmospheric forcing.

ACCELERATED ARCTIC WARMING - A WORKABLE INTERPRETATION AND FUTURE PROJECTION
Despite of the recent Arctic sea ice melt, its causes and effects are not fully understood and require improved knowledge of interactions and feedbacks in the Arctic system. To address some of these outstanding issues, results from a high resolution coupled ice-ocean model of the pan-Arctic region are analyzed to investigate causes and variability trends of Arctic sea ice cover and the regional climate system. Our model results, validated against submarine
and satellite observations, suggest that the rate of melt represented by sea ice thickness and volume might be faster than that of ice extent/concentration. We find that the recent decrease of sea ice cover is partially due to an anomalous sea ice export through Fram Strait in the mid-1990s. This has been followed by the increased advection of warm Atlantic and summer Pacific waters into the upper Arctic Ocean, which acts to increase thermodynamic interactions at the ice-ocean interface as well as feedbacks to the atmosphere. We conclude that sustained high resolution modeling studies of regional Arctic climate are necessary and critical to advance understanding and prediction of Arctic environmental change.

THE ASSESSMENT OF DISSOLVED ORGANIC MATTER BIOLABILITY IN LOTIC SYSTEMS

The “River Continuum Concept” suggests that the nature of DOC can vary in lotic systems as a function of flow and load in a watershed. Headwater sites can be dominated by humic DOC mainly of terrestrial origin. Downstream sites usually have DOC derived from more autochthonous sources. The biolability of DOC can be expected to vary along a river system in accordance with its source. In this study we use a batch culture technique to assess the biolability and metabolic growth efficiency for DOC along a continuum of the Lehigh and Delaware Rivers, Pennsylvania, USA. DOC consumption rates varied significantly between the headwater sites in the upper Lehigh watershed (0.17 % / week) and a site along the lower Delaware River (2.84 % / week). Bacterial growth efficiency also varied. DOC consumption rates and RGE both decreased with increasing stream order. This is likely due to differences in DOC quality, which have been observed using spectral absorbance and fluorescence techniques. Comparisons will be made between DOC consumption rates obtained using batch cultures and those made using plug-flow bioreactors, which were performed simultaneously.

A HIGH-RESOLUTION NUMERICAL MODEL STUDY AT THE CANARY ISLANDS

The Canary Islands off the northwest African coast perturb the southwestern flowing Canary Current. The complex island circulation is revealed in studies based on satellite imagery and in situ data. Island-generated eddies interact with filaments of cold upwelling water that extend from the coast. Understanding of these mesoscale features is limited by the sparsity of data available. Few modelling studies exist for the region, none specifically to address the island circulation. At ULPGC/UCLA a high-resolution regional ocean model (ROMS) configuration has been developed to study the dynamics in this region. A large domain (10-km resolution) covers the NE Atlantic, feeding two successively finer domains (ROMS) configuration has been developed to study the dynamics in this region. A large domain (10-km resolution) covers the NE Atlantic, feeding two successively finer domains

GREATER ORGANIC PHOSPHORUS UTILISATION IN THE NORTHERN SUBTROPICAL GYRE

The northern and southern subtropical gyres of the Atlantic Ocean have distinct biochemical regimes, with depleted phosphate in the North Atlantic subtropical gyre (NASG). Our observational surveys reveal that within the gyres dissolved organic phosphorus (DOP) provides the dominant surface pool of available P, accounting for 94±4% of total dissolved phosphorus in the NASG and 49±12% in the Southern subtropical gyre (SASG). In order to assess the utilisation of DOP we investigate the kinetics of the enzyme alkaline phosphatase (APA), which releases inorganic phosphorus from DOP for uptake. There is a reduction in the bioavailability of DOP from late spring to autumn, in both gyres. Enhanced production in spring releases fresh labile DOP which is subsequently removed via plankton uptake. APA activities show that utilisation of DOP in the NASG is significantly higher than in the SASG, and increases 3-fold in late spring from 1.15 to 3.43 nmol P L⁻¹ h⁻¹. Concurrently we observe a seasonal NASG decrease in DOP of 60%. We invoke nitrogen fixation in the NASG to deplete phosphorus and drive the utilisation of DOP, maintaining production.

NET COMMUNITY PRODUCTION AND THE BIOLOGICAL PUMP IN THE WESTERN ARCTIC OCEAN

The Chukchi shelf is the site of some of the highest rates of primary production in the global ocean. In late summer and spring of 2002, rates of net community production over the shelf were as high as 2,000 mg C m⁻² d⁻¹, and averaged 800 mg C m⁻² d⁻¹ across the entire shelf. Using conservative tracers to construct a carbon mass balance, we found that 10% of the DIC consumed during net community production was converted to DOC and 15% was converted to suspended POC. The remaining 75% was exported from the mixed layer as sinking organic particles. At the termination of the bloom, nutrient concentrations had been reduced to near zero and most of the organic matter had been exported from the mixed layer, leaving surface waters undersaturated with respect to atmospheric CO₂. Presently, these shelf surface waters are transported offshore beneath the permanent ice cover before any significant re-equilibration with atmospheric CO₂ can occur. As such, the biological pump on the Chukchi shelf plays an important role in conditioning the highly oligotrophic waters of the Canada Basin. If the forecasted reduction in Arctic sea ice occurs then this basin will initially act as strong sink for atmospheric CO₂ by allowing the re-equilibration. However, the depletion of nutrients from shelf processes will continue to limit any significant biological activity prohibiting the deep central Arctic Ocean from being a long term sink of that CO₂.

NOAA NESDIS MULTI-SEA SURFACE TEMPERATURE ANALYSIS

NOAA NESDIS has been in the process of developing a new high-resolution (0.1° x 0.1°) global SST analysis to replace the previous 100-km, 50-km and 14-km (regional) products. The new scheme, which uses a recursive estimator to emulate the Kalman filter, also provides continuously updated uncertainty estimates for each analysis grid point. Since the analysis is entirely satellite-based, there is no explicit attempt to correct regional

260
biases to an in situ standard. However, biases between individual datasets are corrected in a statistical manner, with certain assumptions of persistence and correlation length scale. The operational polar-orbiting satellite’s Advanced Very High Resolution Radiometer (AVHRR) and the Geostationary Operational Environmental Satellite (GOES) imager are the current satellite SST datasets used in the analysis, although there are plans to incorporate data from other geostationary sensors (MT-SAT and Meteosat-9) and microwave instruments. We show the results in situ data and other analysis products. This product is running pre-operational at NESDIS and is planned to be transitioned to operations in January 2008.

ANTHROPOGENIC CARBON UPTAKE IN A NEWLY CONFIGURED INTERMEDIATE COMPLEXITY CARBON-CYCLE CLIMATE MODEL

Reliable quantification of the anthropogenic carbon budget is an important goal in the carbon cycle modeling community. The usual trade-off between computational efficiency and spatial resolution provides a niche for intermediate complexity models that high resolution models cannot fill. Here we use a modified version of GENIE (Edwards and Marsh, 2005; Ridgwell et al., 2007), a global carbon-climate model of intermediate complexity, to investigate the mechanisms of the oceanic uptake of anthropogenic carbon. Our modifications include changes in the vertical resolution and depth-dependent vertical diffusivities in the physical model as well as a more prognostic representation of ocean biology. One of our foci is the effect on carbon uptake of riverine flux of anthropogenic nitrogen, carbon, and alkalinity.

OCEAN CLIMATE VARIABILITY AND WATER MASS VARIABILITY IN THE REANALYSES OF THE MERRA MULTIVARIATE OCEAN VARIATIONAL ESTIMATION (MOVE) SYSTEM

Salinity field estimation is a key issue for reproducing realistic ocean state by data assimilation. For practical implementation of a multivariate analysis scheme we adopted a coupled temperature-salinity empirical orthogonal function model decomposition for the background error covariance matrix in a Meteorological Research Institute ocean data assimilation system. Salinity field is reproduced well by using information of temperature and remote-sensed sea level observation through the multivariate analysis scheme. We conducted reanalysis experiments for global ocean and the North Pacific. Periods of the reanalyses are 1948-2006 for global ocean and 1955-2005 for the North Pacific. Using these reanalyses, we investigated climate variability in the South Pacific ocean and trends in the water mass variability (e.g., North Pacific Tropical Water) have been investigated. Interannual variability of oceanic heat content in the North Pacific subtropical gyre is connected with variability of wind stress curl. Distribution of the salinity maximum, which characterizes North Pacific Tropical Water (NPTW), is controlled by variability of the shape of the subtropical gyre, and variability of the salinity maximum is concerned with freshwater influx in the NPTW formation region.

TOPOGRAPHIC EFFECTS ON DENSE GRAVITY CURRENTS

Around Antarctica, cold and saline waters created at coastal polynyas descend on coastal slope and exported to deep ocean as Antarctic Bottom Water, the densest water in the world ocean. The direction of downslope gravity current tends to be parallel to isobaths due to Coriolis force, so the dense water is hard to descend after the front of the dense water is geostrophically balanced. Observations suggest that topographic barriers break such balance and control where and how much of the dense water descend to the bottom. Using a high resolution nonhydrostatic model, we study the topographic effects on dense gravity currents. Under an idealized setup, sensitivity of the down-sloping water to topography and depth-dependent vertical diffusivity in the physical model as well as a more prognostic representation of ocean biology. One of our foci is the effect on carbon uptake of riverine flux of anthropogenic nitrogen, carbon, and alkalinity.

CALIFORNIA CURRENT

The California Current is a unique oceanic system that exhibits a complex balance of physical and biological components and plays a key role in the global climate system. The current is characterized by cold, nutrient-rich water that flows southward along the west coast of North America, with significant upwelling of deep, cold water. The current is an important source of productivity and plays a key role in the global carbon cycle and climate system. The current is also important for the fisheries of the region, with significant catches of anchovies, sardines, and other species.

OCEANOGRAPHIC AND CLIMATE CHANGE RESEARCH: A COMPREHENSIVE APPROACH TO ENSURE SUSTAINABILITY

The ocean plays a key role in regulating the Earth’s climate and supports a diverse array of marine life. The ocean’s temperature, salinity, and currents are influenced by continental runoff, ocean currents, and solar radiation. These conditions are crucial for the survival of many marine species, including fish, whales, and other oceanic species. The ocean also plays a role in the global carbon cycle, with the ocean absorbing a significant portion of the carbon dioxide released by human activities.

three-dimensional, gridded fields of temperature, salinity, and absolute geostrophic velocities in the global upper and intermediate-depth ocean. The advanced technique developed in this study effectively triples the number of independent observations available from the Argo floats array and allows efficient quality control of the original data. Obtained three-dimensional structure of the mean geostrophic ocean circulation is shown to improve previous products, such as the one based on the World Ocean Atlas. Temporal variability of the circulation, temperature, and salinity is discussed along with the effects of the large-scale advection of heat, salt, and momentum. In the upper ocean the dataset is supplemented by the gridded maps of the mixed layer and barrier layer depths. The release of the near-real-time product for the public use will be announced at the meeting.

IMPROVED FINE SCALE MODEL PERFORMANCE USING AUV FEEDBACKS IN A TIDALLY DOMINATED SYSTEM.

A challenge for model prediction and validation is providing the models with data of appropriate spatial and temporal resolution. Use of autonomous underwater vehicles allows data collection on these scales. The goal was to apply a model and an AUV system for improving model performance and AUV mission planning. A dye release was conducted in a tidally dominated bay. The initial experiment was to simulate the dye plume based on the best available data. This was used for a baseline evaluation and for AUV mission planning for plume following. The model correctly predicted the general shape and direction of the dye and allowed for successful mission planning. Bathymetry data collected by the AUV was incorporated into the model and re-run and dye measurements were used to re-evaluate the model. Field data comparisons indicate that the model effectively predicted the plume edge and the propagation characteristics. The location of the evolving plume was confirmed by remote sensing. Stratification was the dominant controlling factor for improving model performance. Modeling results coupled with the field information present a quantitative improvement to the understanding of the circulation and demonstrate the integration of observational datasets into model evaluation for applications related to short, short duration surface contaminant releases. This study highlights the strength of this approach with AUVs and may serve as a guide towards improving the model performance.

EVALUATION OF COASTAL SIMULATIONS IN THE WESTERN PACIFIC

We deploy and evaluate a flexible globally-relocatable ocean-atmosphere simulation capability (COAMPS & NCOM), linked to initial and lateral boundary conditions from data-assimilating global HYCOM and global NCOM. We focus on several coastal regions in the Western Pacific in order to compare and contrast relatively data-poor (Philippines) and data-rich (Japan) areas. Atmospheric simulations for Japan and the Philippines achieve resolution greater than 15 km while the accompanying ocean simulations are run at greater than 5 km resolution. Error statistics for the two global models are presented for the two regions using available observations, along with an analysis of the regional coastal models.

PHOTODISSOLUTION OF PARTICULATE ORGANIC MATTER CAN SHUNT ITS DECAY TO MICROBIAL COMMUNITIES

Particulate organic matter (POM) is efficiently utilized by metazoans, while dissolved organic matter (DOM) is more efficiently utilized by unicellular organisms. We examined the potential for light-induced dissolution of POM to make photodissolved DOM (FotDOM) available to microbes. POM from fresh and aged phytoplankton membrane debris and sediments each photodissolved strongly after dozens of hours under simulated sunlight. Photodissolution selectively removed polysaccharides from sediments, implying greater photochemical lability of fresher components of the heterogeneous, sedimentary POM. FotDOM had high C:N ratios, but simultaneous photoammonification converted particulate N to a form that favors its use by microbes, perhaps in combination with utilization of the high C:N FotDOM. Microbial inocula metabolized significant fractions of FotDOM on timescales down to minutes. The net effect is enhanced production of smaller oligomers by Photodissolution of POM, which may serve as an additional food source for many microorganisms.

ASSESSING RADIODEECHOICHEMICAL TECHNIQUES AS A TOOL FOR MANAGEMENT OF TWO MARINE PROTECTED AREAS IN PUERTO RICO: A CASE STUDY

Baseline studies provide data that can help identify and develop management strategies for impacted marine ecosystems. This study intends to provide radiogeochemical baseline data of mangrove sediments for monitoring purposes at two marine protected areas. Prior to becoming a reserve, the Jobos Bay National Estuarine Research Reserve (JBNEER) received contaminated sediments (e.g. heavy metals, pesticides, and other hazardous substances) from nearby agricultural and industrial activities. Preceding its designation by the US Fish and Wildlife Service (FWS), the Vieques National Wildlife Refuge (VNWR) was the site of various military activities that introduced toxic waste, explosive compounds, and depleted uranium to the local environment. Radionuclide concentrations, distributions and behaviors have been determined for sediment samples collected throughout the two study sites. Clay mineralogy, organic matter content, elemental composition, and particle grain-size distributions of the samples have also been determined. An educational and outreach component has been specifically designed for this project to promote basic environmental awareness and literacy within the surrounding communities of both study sites. Specific educational and outreach activities include the development of teacher workshop materials, teacher workshops and development of curriculum-based environmental education activities.

DIURNAL CURRENTS, SEA BREEZE AND TIDES ON THE INNER SHELF OFF CARTAGENA DE INDIAS, CARIBBEAN COAST OF COLOMBIA

Inner shelf current variability from the inner shelf and nearshore off the Colombian coast, near Cartagena de Indias, is examined from data collected during the period 2000-2002. This presentation focuses on diurnal oscillations present in the records which are surface intensified, with amplitudes of up to 8 cm/s in the nearshore. In all the sites the main axes are parallel to the predominant direction of the isobaths. The currents appear to be correlated with the oscillating wind forcing associated with sea breeze which has an amplitude of up to 1.21 m/s and a rotational clockwise pattern. Harmonic analysis, spectral, complex correlation, complex demodulation and analytical modeling are used to verify this correlation with the wind. The results indicate a significant contribution from the sea breeze winds and a lesser contribution from the tides in the generation of the observed diurnal currents.

IDENTIFYING THE LOCATION AND TIMING OF GLOBAL MODE WATER FORMATION PROCESSES

Mode water formation processes are often quantified in the theoretical framework developed by Walin, 1982, who precisely expressed diapycnal volume fluxes through the sides of a chosen control volume - based on, for example, temperature - in terms of non-advective (mixing) supply of heat to that control volume. However, it is an integral statement and therefore necessarily integrates over space and so blurs regional details that may be indicative of mechanism. We have developed a diagnostic approach, consistent with the integral Walin budget, to precisely localize the underlying formation/destruction process through air-sea buoyancy interaction and mixing processes. We apply the approach to study tropical mode waters in the global ocean using a model-data synthesis and air-sea flux data sets. We draw out both similarities and differences between the model water cycle in the Kuroshio extension, the Gulf Stream and the Southern Ocean. We also use our approach to discuss the relative importance of formation in vs away from regions of intense jets.

OBSERVATIONAL AND NUMERICAL MODEL ANALYSIS OF NEAR-FIELD COLUMBIA RIVER PLUME ENTRAINMENT AND WIND EFFECTS

We present an analysis of both observational surface drifter measurements and 3D numerical model simulations of the Columbia River plume. River water exits the estuary mouth during ebb tides forming a pulsed plume. As plume water transits offshore it expands laterally and entrains underlying ambient fluid. A control-volume analysis of surface drifter data is used to estimate the plume depth and entrainment rate as the flow evolves seaward. Entrainment is largest near the river mouth O(10^4 m/s) and decreases seaward, but remains significant between the mouth and the ocean-plume boundary. Beyond ~20 km our entrainment analysis breaks down as the surface drifters begin a return loop shoreward at slack tide. Numerical 3D model fields are used to examine the ebb-cycle plume momentum balance and relate it to the observed entrainment analysis. Our findings are similar in quality to previous 1-layer model attempts in vs away from regions of intense jets.

A MULTI PROXY APPROACH TO ASSESS TROPICAL CLIMATE VARIABILITY DURING MARINE ISOTOPE STAGE 3: RESULTS FROM THE CARIBIAO BASIN

With the growing interest in using Caribio Basin sediments to reconstruct climatic and hydrologic conditions, it is necessary that we understand the 818O/salinity relationship in this region and assess the implications for paleosalinity reconstructions. Our results show that this relationship varies significantly over the course of the year primarily due to an increase in freshwater input from the local rivers into the Caribio Basin. Additionally the freshwater data reveal two distinct trends that represent the upwelling and run-up welling seasons. We further use a multi-proxy approach, combining detailed oxygen iso- trope and Mg/Ca records for G. ruber from MD03-2621, to evaluate the magnitude of sea surface temperature, 818Ow, and sea surface salinity variations associated with 10 stadial/interstadial oscillations during marine isotope stage 3. The variability in the 818Oc of G. ruber correlates very well with the color reflectance data, which is considered a proxy for marine productivity. The Mg/Ca results for G. ruber across several of these stadial/inter- stadial oscillations tend to co vary with the 818O data. Interestingly the Mg/Ca and 818O records for G. ruber diverge shortly after IS9 and 6 suggesting warmer, saltier conditions during these stadial periods. We compare this record with Greenland and Antarctic ice cores to evaluate the role that the tropics play in millennial scale climate change.

OCCURRENCE OF PHAGE INTEGRASE-LIKE GENE EXPRESSION IN TAMPA BAY

Phage integrase genes often play a role in the establishment of lysogeny in temperate phage. To investigate temperate gene expression, an induced viral metagenome from Tampa Bay was sequenced by the 454/R sequencing method. The sequencing yielded 294,068 reads with 6.6% identifiable. There were 103 Integrase hits, yet only 4 significantly significant ones. Real-time PCR primers and probes were designed for each of these four integrases. Initial testing of the assay with microbial viral DNA from Tampa Bay revealed 1.9 x 10^4 copies and 1,300 gene copies of Vibrio-like integrase and Oceanicola-like integrase (gene) respectively. The other two integrases we not detected. The integrase assay was then tested on the microbial RNA fraction extracted from 200 ml of Tampa Bay water over an annual cycle. Vibrio-like integrase gene expression was detected in three samples, with estimated copy numbers of 2.4-1280 gene copies per liter. Clostridiun-like integrase gene expression was detected in 6 samples, with estimated copy numbers of 37 to 260 copies per liter. In all cases, detection of integrase gene expression corresponded to statistically significant phage induction events.

WHAT DO YOU WANT TO BE?

Many students do not consider science as a career because they have no contact with anyone who works as or with a scientist. In K-12 science classes, students study scientific concepts, but not how they were researched and who participated in the work of supporting ideas for theory. In an eGyF program, high school students to consider careers in science, this exploration-based learning exercise is designed to help them realize that many opportunities in science are open to them. In this project students are encouraged to discover the similarities between themselves and workers described on the Joint Oceanographic Institutions webpage: http://www.joicos.org/careers_flash.html. It requires students to explore the career of a scientific ocean driller working, including education, training, certifications, daily routine, and the drilling projects in which they participate, sharing information with classmates via classroom presentation. The outcome of this class project is that students see that their backgrounds are not very different from these professionals, and realize that they can join the working world of science and contribute to its ongoing discoveries.

DEPICTIONS OF LABRADOR SEA WATER FROM THE IPCC MODELS AND A FINE RESOLUTION POP SIMULATION DURING HIGH AND LOW NAO INDEX PERIODS

The oceanic uptake of properties such as heat and freshwater result from mode water formation. We examine the representation of mode waters in the one-degree class oceans of the IPCC global coupled simulations. Initially we examine two present day green house gas forcings control runs of high school students into the Great Oceanographic Expedition (GOE) that differ only in their dynamical atmospheric cores in the Community Atmospheric Model 3 (CAM3) that differ only in terms of their dynamical atmospheric cores in the Community Atmospheric Model 3 (CAM3). We examine formation rates and trace mode waters into the ocean interior using their potential vorticity (PV) signature. Particularly we consider Labrador Sea Water (LSW) and examine its PV interior signature in composites of high and low North Atlantic Oscillation (NAO) index periods. We also calculate formation rates and the interior PV distributions using output from a fine resolution (0.1-degree, 40-level) North Atlantic basin simulation of the Parallel Ocean Program (POP) forced with synoptic forcing only in terms of their dynamical atmospheric cores in the Community Atmospheric Model 3 (CAM3). We examine formation rates and trace mode waters into the ocean interior using their potential vorticity (PV) signature. Particularly we consider Labrador Sea Water (LSW) and examine its PV interior signature in composites of high and low North Atlantic Oscillation (NAO) index periods. PARTNERS: A PERSPECTIVE FROM THE STUDENT STANDPOINT

A pan-arctic field sampling effort was conducted from 2003 through 2006 to improve understanding of river export to the Arctic Ocean. Sampling focused on the Yukon and Mackenzie Rivers in Northern America and the Ob, Yenisei, Lena, and Kolyma in Siberia. The success of the project, apny named Pan-Arctic River Transport of Nutrients, organic matter and Suspended Sediments (PARTNERS), required an extraordinary degree of international cooperation. In addition to the parameters identified in the project title, many others were measured including major ions, trace elements, and isotopic tracers. While a variety of previous studies have focused on the chemistry of large arctic rivers, differences in methods and objectives have hampered river inter-comparisons and understanding at the pan-arctic scale. Furthermore, a majority of the previous studies were conducted only after peak flow during summer months. This presentation will emphasize comparisons among the major rivers and highlight insights that have emerged as a result of the PARTNERS project. More comprehensive knowledge of seasonal and inter-annual dynamics in arctic rivers is essential for detecting changes in constituent runoff to the Arctic Ocean.

inverse analysis of the 36N section with boundary current, bottom water and net volume and silicate constrained a northeastward flux of 1.25PW ± 0.62PW across 36N and a freshwater divergence of 0.8 Sv ± 0.1 Sv between 36N and Bering Strait (implying a fresh water flux into the ocean). At 36N the overturning strength is 195 ± 15S at 117°N ± 40°. We combine the 36N section with a section across the Gulf of Cadiz made in 2005 and a section across 24N made in 2004. There is a heat divergence of <0.1PW between the sections and a freshwater convergence of 0.35S (implying a freshwater flux out of the ocean).

USING INFORMATION THEORY TO DETERMINE OPTIMAL MODEL COMPLEXITY IN AQUATIC BIOGEOCHEMICAL MODELING

The complexity of aquatic biogeochemical models (e.g. plankton functional types) is increasing in an attempt to capture the real complexity of nature. The data sets available for model calibration and validation, however, are often relatively small. This situation creates the danger of models containing unjustifiably large degrees of freedom and can result in 'overfitting' the data. In such cases, the usefulness of the model (especially for prediction) may be compromised. We present a strategy to use the principles of information theory to rank the performance of a set of models incorporating varying degrees of complexity against a single calibration data set, in order to determine the 'optimal' level of complexity. The models are evaluated using a metric based on Akaike's Information Criterion (AIC), which takes into account not only the model's ability to replicate the data, but also the number of estimated parameters in the model relative to the number of data points. Preliminary application of this method shows that even modest levels of complexity in aquatic biogeochemical models are often unjustified, and reinforces the importance of parsimony in modeling.

BUILDING PARTNERSHIPS BETWEEN SCIENTISTS AND EDUCATORS: A PERSPECTIVE FROM THE CENTERS FOR OCEAN SCIENCE EDUCATION EXCELLENCE - MID ATLANTIC (COSEE MA)

In five years, the National Science Foundation’s Centers for Ocean Science Education Excellence (COSEE) network has grown from infancy through a phase of intense development. The COSEE network has explored new territory, learned to cooperate, and shared learning experiences. One of the main goals of the COSEE program is to engage scientists and educators in meaningful partnerships that translate into improved Ocean Science Literacy outreach and broad reach of ocean issues including students, teachers, and the general public. In this presentation, we will explore the successes and challenges of engaging scientists and educators in partnerships and discuss what we have learned about differences and similarities between scientists and educators in their approach to the pedagogy of science education. We will share our lesson learned with engaging scientists, educators, and the public in ocean science education and discuss how we have applied our lessons learned in the new COSEE Networked Ocean World (COSEE NOW).

NOAA’S EFFORTS IN SUPPORTING FORMAL AND INFORMAL EDUCATION USE OF STREAMING DATA: CHALLENGES IN ADDRESSING THE NEEDS OF THESE AUDIENCES WITH EVER-CHANGING DATA

NOAA has developed several programs and pilot projects aimed at facilitating the use of earth system science data, streaming ocean observing data, and data visualizations by formal and informal educators. One program, Science On A Sphere, a large visualization system that uses networked LCD projectors to display animated global datasets onto the outside of a 1.7-meter diameter opaque sphere, enables science centers and museums to display real-time and current earth system science data. NOAA’s Ocean Data Education Portal is a pilot K-12 teacher-focused integrated data portal for several of NOAA’s streaming ocean data. Additionally, NOAA has begun to explore the creation of educational gaming and web interfaces for ocean data sets. Results of needs assessments and formative evaluations for these projects will be presented. Initial results indicate that not only are simple-to-use data interfaces necessary, but also a large amount of contextual informational and updated scientific interpretation needs to be available. There is a clear need for both ongoing technical developments to support educators’ access to data, but also continuous scientific support to explain the significance of the data.

TEMPORAL AND SPATIAL PATTERNS OF CARBONATE AND SILICICLASTIC SEDIMENTATION ACROSS A TROPICAL CONTINENTAL MARGIN

The Gulf of Papua (GoP) is a tropical continental margin where significant amounts of both river derived silicates and neritic/pelagic carbonates accumulate. The goal of the MARGINS Source-to-Sink (S2S) study in the Papua New Guinea (PNG) focus area is to develop an understanding of sediment production, transport, and accumulation across the GoP. The flux of carbonate and siliciclastic sediments reaching the most distal part of the PNG focus area, including the slope, troughs, and Eastern Plateau, will be presented from a number of cores. Sediment fluxes are based on oxygen isotope stratigraphies and elemental data collected using an X-Ray Fluorescence core scanner. Spatial and temporal changes in carbonate and siliciclastic sedimentation will be described based on changes in percent carbonate source elements (Ca, Sr) and terrestrially derived elements (Fe, Al, K). Results from the deep Gulf of Papua do not show a simple glacial/interglacial pattern of siliciclastic or carbonate sedimentation. Spatial and temporal patterns of siliciclastic and carbonate sedimentation change throughout the Quaternary as a result of changes in sea level, production, transport pathways, climatic and environmental conditions.

AUTOMATED DECISION MAKING FOR A NEW CLASS OF AUV SCIENCE

Autonomous Underwater Vehicles (AUVs) are an increasingly important tool for oceanographic research. However, control of these platforms has relied on fixed sequences for execution of pre-planned actions limiting their effectiveness for measuring dynamic and episodic ocean phenomena. At MBARI, we are developing an advanced Artificial Intelligence based control system to enable our AUV’s to dynamically adapt to the environment by deliberating in-situ about mission plans while tracking onboard resource consumption, dealing with mission failures by allowing dynamic re-planning and being cognizant of vehicle health and safety in the course of executing science plans. Existing pre-scripted behavior-based approaches offer limited flexibility in dealing with opportunistic science needs, are unable to deal with uncertainty in the oceanic environment and put undue burden on the mission operators to manage complex interactions between behaviors. Our system the Tele- Reactive Executive (TREX http://www.mbari.org/autonomy/TREX/index.htm) has been tested on an MBARI Dorado 21’ vehicle with a range of scientific instruments for water-column surveys in Monterey Bay. Our year-end goals revolve on mapping unstructured phenomenon such as Ocean Fronts and Thin Layers.

HINDCASTING THE HISTORIC 2005 NEW ENGLAND RED TIDE: FORCING MECHANISMS AND FUTURE IMPLICATIONS

In 2005, a massive bloom (red tide) of the toxic dinoflagellate Alexandrium fundyense closed shellfish harvesting along the coastlines of Maine, New Hampshire and Massachusetts, as well as a 40,000 km² area of offshore, federal waters. Blooms of this organism are common in the Gulf of Maine (GOM) region, but outbreaks of this magnitude are rare - the most recent similar event being in 1972. Three factors have been identified to explain the massive 2005 bloom: high cyst abundance, heavy rainfall and runoff, and major storm events (northeasters that pushed surface waters and cells to the shore and down the coast. We combine field observations with numerical model simulations to demonstrate that a major cyst deposition or accumulation event was the dominant factor leading to the historic 2005 New England red tide, and provide additional evidence that the persistence of that cyst deposit is likely to result in sustained and significant blooms in the coming years. Monitoring of the regional abundance of cysts may thus hold the key to interannual forecasts of A. fundyense bloom severity.

ALOHA-MARS MOORING SENSOR NETWORK FOR OCEAN OBSERVATORIES

The ALOHA-MARS Mooring Sensor Network combines adaptive sampling methods with a moored deep ocean sensor network. A test version of the mooring system was installed 26 June 2007 and connected to the Seaburst Observatory in Puget Sound in a water depth of 30 m. The ocean deployment of the mooring system on the MARS Observatory in Monterey Bay in a water depth of 900 m is currently scheduled for spring 2008. This project will demonstrate the scientific potential of combining adaptive sampling methods
with a moored deep-ocean sensor network at the MARS Observatory. We will directly address the challenge of sampling along the ocean with both high temporal resolution and high vertical resolution. With the moored sensor network consisting of a profiler moving between near-surface and abyssal fixed sensors under program control, we will be able to focus the sampling and measurement capabilities on the scientific features of most interest. The long term goal is to deploy similar moorings at the Aloha Cabled Observatory and the Hawaii Ocean Time-Series (HOT) station, near Oahu, and on the cabled nodes of the Ocean Observatories Initiative (OOI) of the Ocean Research Interactive Observatory Networks (ORION). This project is funded by the National Science Foundation (NSF) and managed by NSF and the Joint Oceanographic Institutions (JOI).

STABLE ISOTOPE PROBING USING 13C AND 15N IN THE ORINOCO RIVER PLUME

Understanding carbon and nitrogen cycling in topical river plumes will help delineate the effect of terrestrial ecosystems on the coastal environment. In this study, the Orinoco River Plume was sampled at 12 stations and 4 depths along the plume axis and screened by stable isotope probing using 13C-amino acids and 15N-nitrate. Two-liter samples were amended with 200-2000 nM substrate and incubated for 3 hours. Isotopically labeled DNA was recovered with carrier DNA methods using halophile DNA. For the carbon analysis, approximately 2/3 of the peaks detectable in the 13C fraction (average=30 ± 5.2 peaks for all stations) were observed to incorporate 13C (average=21 ± 4.8 peaks). Furthermore, the samples treated with amino acids showed clustering more strongly with depth than by station. The transect is dominated by a different pattern with significantly smaller peak numbers in the 15N fraction and clustering along station rather than depth. Additional effort in cloning/sequencing of specific peaks from these analyses is underway. Similar SIP studies, in both marine and terrestrial environments, should help to relate microbial community structure to function.

Mckenzie, B. D., UNC Chapel Hill, Chapel Hill, USA, bmckenzie@unc.edu

UP THE TIDAL RIVER: IN SEARCH OF ANOTHER MISSING LINK

Particle-bound materials that originate within the watershed and are transported via rivers to the ocean undergo many transformations en route. Knowledge of what transformations take place (and where) is crucial to our understanding of river-ocean systems and their response to global change. A major limitation is that traditional “river endmember” measurements have been made above the tidal freshwater zone — in many cases is 100s of kilometers upriver of the river mouth. Our understanding of residence times and transformations within the tidal (fresh) lower river represents a critical missing link. Direct examination of the lower Mississippi River reveals that the tidal (fresh) zone is much more important than the adjacent margin in terms of loss of particulate organic carbon, iron, manganese and associate constituents such as uranium. Indirect examinations (comparing “river endmember” and margin values) suggest that net gains in bulk particulate organic carbon, iron, manganese and uranium within the tidal river zone are also possible in other RioMar systems. The use of isotopic tracers (stable and radioactive) will be discussed as a possible approach for future studies.

IDENTIFICATION OF PREVIOUSLY UNCHARACTERISED NATURAL SEDIMENT ORGANIC MATTER USING ULTRA-HIGH RESOLUTION MASS SPECTROMETRY AND NUCLEAR RESONANCE SPECTROSCOPY

Using a new analytical strategy for characterizing the unidentified portion of sedimentary organic matter (combined use of some new NMR techniques and Fourier transform ion cyclotron resonance mass spectrometry-FTICR-MS), we examine diagnosis of organic matter in two cores of organic-rich deposits from Mud Lake, Florida, and Mangrove Lake, Bermuda. The sediment is extracted with pyridine, is verified as being representative of the whole sediment by matching its NMR peaks with high resolution magic angle spinning (HR-MAS) NMR spectrum of the solid, and then analyzed using ultra-high resolution FTICR-MS. Preliminary mass spectra data for Mud Lake suggest an increase in aromatic type structures, accompanied by a decrease in lignin as depth increases, consistent with solid state NMR data. Combining NMR and MS techniques, whole sediment samples of a terrestrial or marine source can be analyzed at the molecular level which characterizes the previously uncharacterizable organic matter.

OPERATIONAL METOP SEA SURFACE TEMPERATURE PROCESSING AT THE NAVAL OCEANOGRAPHIC OFFICE

The Naval Oceanographic Office (NAVOCEANO), Stennis Space Center, Mississippi, is operationally producing Multi-Channel Sea Surface Temperature (MC SST) retrievals from Meteorological Operational Satellite (METOP) Advanced Very High Resolution Radiometer (AVHRR) data. This new EUMETSAT polar orbiter is the first to provide global 1km AVHRR data. NAVOCEANO modified its existing operational SST processing software to generate retrievals within 1000 km of coastlines globally and in areas significant to the Navy. NAVOCEANO also processes METOP global area coverage 4km AVHRR data provided by the NOAA/NESDIS Office of Satellite Data Processing and Distribution (OSDPD). The MC SST data are distributed in near real time to thermal analyses and circulation models at NAVOCEANO, to other oceanographic and weather centers in the United States, and to the GODAE High Resolution Sea Surface Temperature (GHR SST) pilot project. This paper will provide details on the SST processing steps, validation results from buoy matchups, and examples of the SST product.

CARBON CYCLE VARIABILITY AT BERMUDA AND IN THE NORTH ATLANTIC: SUBTROPICAL GYRE

Progress in understanding the carbon cycle and its variability require us to take full advantage of both imperfect numerical models and limited data. Timeseries observations are crucial because they reveal carbon cycle variability in time, but do not directly allow study of spatial variations. Coupled physical-biogeochemical models estimate both spatial and temporal variability, but are imperfect representations of the real world. In this paper, we report on a new physical-biogeochemical model that is able to capture much of the observed carbon cycle variability from 1983 to 2005 at Bermuda (Bates, 2007). Preliminary results suggest that sea surface temperature at Bermuda has been stable since 1984 due to horizonal advection balancing decadal timescale warming and cooling trends in the local atmospheric forcing. The result is that temperature-driven pCO2 trends have been negligible. There is an increasing trend in surface ocean pCO2 driven by increasing atmospheric pCO2, and DIC anomalies due to changing vertical mixing also strongly influence surface ocean pCO2. Following detailed model-data comparisons, we use the model to construct a physically and biogeochemically predictive power of time series observations at Bermuda for the rest of the subtropical gyre.

CHARACTERISTICS OF A MICROBIOLOGICALLY DERIVED IHS REFERENCE FULVIC ACID FROM A SALINE COASTAL POND IN ANTARCTICA

The study of the biogeochemistry of dissolved organic matter (DOM) has been advanced by the availability of a reference material from a terrestrial source, i.e., the IHSS Suwannee River fulvic acid, but has been limited by the lack of a reference from a purely microbially based aquatic ecosystem. The chemistry of fulvic acid from Pony Lake, a eutrophic, subtropical gyre.

Large-scale physical and geochemical surveys of the southern Canada Basin conducted in the 2000’s show that changes observed during the 1990s have progressed further into the basin. Temperature of the Bering Sea summer water has increased, the volume of Bering Sea Winter Water has decreased and temperatures of the Fram Strait Branch have
increased. Distributions of increased ventilation together with the above data are used to infer circulation and show that the boundary current is not the sole mechanism for the delivery of change in the southern Canada Basin.

COMPARING FINGERPRINTING AND PHYSICS: MULTIPLE APPROACHES TO LARVAL CONNECTIVITY OF MYTILID MUSSELS

Connectivity patterns of mytilid mussel species, Mytilus californianus, Mytilus galloprovincialis and Musculista senhousia were studied in San Diego County using trace elemental fingerprinting of retained larval shell to assess recruitment and connectivity and by simulating transport with open coast (ROMS) and bay (ADICIRC) numerical simulations. Location-specific chemical signatures needed to interpret recruit origins were determined from outplanted mussel larvae at bay and open-coast sites spanning 100 km of shoreline. Using this regional ‘reference map’ of chemical signals, we assigned settler origins by compared the expected larval chemistry for each region to the larval shell chemistry of newly settled recruits collected 2 wk after outplanting. Within species we observed temporal and spatial variation in patterns of connectivity and self seeding. We also observed species differ-
ences related to adult distributions and larval supply. Metrics are developed for quantify-
ing connectivity across space and time, and for drawing comparisons between results of fingerprinting and larval supply simulations for the same time period. These fingerprinting/modeling approaches offers insight into key determinants of species-specific connectivity patterns, and interannual variability, with potential benefits for conservation and management.

THE IMPACT OF LARGE SCALE COASTAL DYNAMICS ON THE OPTIMIZATION OF BEACH REPLENISHMENT DECISIONS

Human alterations to the coast in the form of beach replenishment depend upon the state of the beach, which itself is related to past alterations; the human occupied coastline thus forms a dynamical system with strong coupling between human and natural processes. Within this coupled human-natural system replenishment decisions are driven by coastal management and localized in space. Previous work has shown that an instability in plan-view coastline shape, and subsequent self organization, has likely given rise to the large-scale cuspate shape of the North Carolina coastline. These emergent behaviors operate over time and space scales considerably greater than considered for localized replenishment decisions. How does the context set by large-scale dynamics affect net benefits from replenishment? To explore this question, we present a numerical model featuring coupled human and coastline interactions. The physical model incorporates coastline changes associated with alongshore sediment transport. The economic model represents replenishment decisions. The combination of potential benefits from enhanced beach width minus costs of replenishing. We present results that illustrate the degree to which localized dynamic optimization fails to maximize net benefits of replenishment. We also explore how net benefits change due to changing storm behaviors. Finally, we present a heuristic optimiza-
tion procedure that adapts to the context of large-scale coastal change.

RECONSTRUCTING THE OCEAN 13C SUSS EFFECT

We applied a multi-parameter mixing approach to quantify anthropogenic changes in the delta-13C of dissolved inorganic carbon (D13IC) (Sonnerup et al. 2007) to WOCE D13IC sections in the Pacific (P11, P13, P18 and P06), Indian (I2, I3 and I85/95) and Atlantic (A20 and A22) Oceans. Central to analysis is the proper selection of endmember water masses for the analyzed sections. For each ocean basin, we chose four endmembers using potential temperature/salinity diagrams. Additional constraints were imposed based on the physical and chemical properties of the individual basins. In the South Pacific Ocean, the calculated surface and depth-integrated delta-13C changes are largest in the subpolar and decrease towards the south. In the South Indian Ocean, a similar pattern in depth-in-
tegrated changes was observed. Also, the greatest surface changes were observed north of 20S, and decreased to the limit of detection south of 50S. The North Atlantic reconstruc-
tions indicate that the maximum delta13C changes are fully equilibrated with respect to 20S, and decreased to the limit of detection south of 50S. The North Atlantic reconstruc-
tions were also be presented.

EVOLUTION OF THE 2006-07 EL NIÑO: THE ROLE OF INTRASEASONAL TO INTERANNUAL TIME SCALE DYNAMICS

This presentation describes the development of the 2006-07 El Niño, which started late, ended early and was below average strength. Emphasis is on the interplay between large scale (intraseasonal and interannual) time scales, to illustrate the evolution of the event. Efforts to forecast the El Niño are reviewed, with discussion of factors affecting its predictability. Perspectives on possible influences of global warming on the ENSO cycle, which exhibited unusual behavior in the first decade of the 21st century, will also be presented.

MIXING ASYMMETRY IN TURBULENT FLOWS WITH LARGE HORIZONTAL SCALAR GRADIENTS

On several occasions, measurements made from sea ice of flow with horizontal gradients in salinity and temperature have shown significant modification in the character of turbulence compared with regimes without horizontal gradients. If density at the measurement site increases (decreases) with time, turbulence is suppressed (enhanced) by shear induced vertical gradients in the underice boundary layer, in a manner analogous to what Rippeth et al. (J. Phys. Oceanog., 31, 2001) have termed strain induced periodic stratification. An example from tidal flow near the mouth of Van Mijen Fjord, Svalbard, during June, 2004, illustrates the phenomenon. We observed periodic variation in salinity in a tidally modulated flow generally directed into the fjord. During times when salinity decreased there was large downward salt flux and increased turbulent drag, 1 m below the surface, despite upward heat flux and evidence of rapid basal melting (which would typically result in upward salt flux). A simple heuristic model suggests that this originated from a positive vertical salinity gradient as fresh water advected faster at depth. Examples from other locations are also shown.

INTEGRATING MULTIPLE COASTAL OBSERVING EFFORTS TO DESCRIBE THE CIRCULATION FEATURES OF A SOUTHERN CALIFORNIA TOXIC BLOOM EVENT

A suite of separate interdisciplinary coastal observing systems were drawn from to de-
scribe the dynamics surrounding a highly productive, toxic bloom event in the Santa Barbara Channel (SBC). Measurements from an outer-shelf SBC mooring maintained as part of the Southern California Coastal Ocean Observing System (SCCOOS) program show that the September 2005 event was characterized by the highest Chlorophyll levels of the surrounding years. Using data from a variety of other ongoing observing efforts, including an array of inner-shelf moorings, monthly profiling, HF-radar surface current fields, satellite images, and Channel-wide hydrographic surveys, we determined that the bloom was advected into the basin and then transported shoreward by a convergent jet associated with the eddy field that commonly characterizes SBC circulation. HF-radar surface currents combined with moored subsurface data provide a unique understanding of event dynamics, and suggest that a relaxation shift in SBC synoptic circulation states was responsible for the demise of the bloom. These findings emphasize the importance of understanding both local, mesoscale dynamics and offshore, coast-wide scales in under-
standing the evolution of coastal bloom events.

THE OPTICAL PROPERTIES OF FLORIDA BAY: IMPACTS FOR SEAGRASS PRODUCTIVITY

Sediment dispersal and capture across the land-sea interface plays a critical role in defin-
ing the sensitivity of continental margin stratigraphy to fluctuations in the terrestrial sediment signal. A process-based understanding of this dynamic interface that bridges the gap between event and stratigraphic time scales is an important first-order requirement towards a seamless, source-to-sink model. To this end, geophysical data (interferometric swath bathymetry and EdgeTech sub-bottom) were collected across Poverty Bay, the land-sea interface of the Waipaoa Sedimentary System, in August 2005 and April 2006 along with thirty surface sediment grabbs, thirty gravity cores, and nine vibracores. Seismic profiles groundtruthed by vibracores and coastal plain well logs suggest very efficient segregation processes over the past 7 K, capturing sand within the rapidly prograding beach and bypassing fine-grained sediment to the shelf. "Be and excess" activities from surface grab samples as well as the lithology of the 30-cm gravity cores also indicate substantial reworking and rapid dispersal of fine-grained sediment to the shelf over short time scales.

2008 Ocean Sciences Meeting

266
This study investigated the relationship between seagrass productivity and water column optical properties in Florida Bay. The region adjacent to the Everglades National Park encompasses areas of high seagrass density close to the Keys, with small seagrass further north towards Cape Sable. The vertical attenuation coefficient KPAR was low in the south and increased towards Cape Sable. Approximately 86% of variance in KPAR was explained by absorption. Along the Keys, phytoplankton contributed 9% to total absorption compared to 8% by colored dissolved organic material. The average cosine of the submarine light field was 0.7 to 0.9 in the south. Towards Cape Sable values decreased to 0.6 due to higher suspended material, indicating a more diffuse light field. Seagrasses were excluded from high turbidity areas where incident irradiance reaching the plants was less than 10% of surface irradiance. Although eutrophication processes have contributed to historic die-offs of seagrasses in Florida Bay, high suspended sediment loads currently prevent sufficient light from reaching the seabed. Therefore, nutrient load reductions may be necessary, but insufficient to promote seagrass growth in North Florida Bay.

**CLIMATE EXACERBATES EUTROPHICATION IN THE NORTH SEA**

During the 1980s, a rapid increase in the Phytoplankton Colour Index (PCI), a semiquantitative visual estimate of algal biomass, was observed in the North Sea as part of a regional-wide regime shift. Two new datasets created from the relationship between the PCI and SeaWiFS Chlorophyll a (Chl a) quantity differences in the previous and current regimes for both the anthropogenically affected coastal North Sea and the comparatively unaffected open North Sea. The new regime maintains a 13% higher Chl a concentration in the North Open Sea, 21% higher concentration in coastal North Sea waters. However, the current regime has lower total nitrogen and total phosphorus concentrations than the previous regime. Besides becoming warmer, North Sea waters are also becoming clearer (i.e., less turbid), thereby allowing the normally light-limited coastal phytoplankton to more effectively utilize lower concentrations of nutrients. Linear regression analyses indicate that winter Secchi depth and sea surface temperature (SST) are the most important predictors of coastal Chl a while Atlantic inflows is the best predictor of open Chl a; nutrient concentrations are not a significant predictor in either model. Thus, despite decreasing nutrient concentrations, Chl a continues to increase, suggesting that climatic variability and water transparency may be more important than nutrient concentrations to phytoplankton production at the scale of this study.

**DYNAMICS OF OCEANIC SURFACE FRONTS: DEFORMATION AND INSTABILITY**

In some regions (e.g., the California Current), the submesoscale regime is full of near-surface temperature fronts created by mesoscale-eddies straining ambient temperature variation. This frontogenesis is the primary mechanism for transfer of energy from the mesoscale to submesoscale en route to dissipation at microscales. The transfer is initiated as a forward cascade of available potential energy accompanied by conversion to kinetic energy, and it is carried forward on smaller scales by a forward cascade of kinetic energy; none of these behaviors are consistent with geostrophic turbulence. The frontogenesis effects a restratification of the upper ocean, in competition with the mixing by boundary-layer turbulence. The fronts themselves become unstable, even in the midst of active frontogenesis, giving rise to frontal breakdown and emergence of submesoscale vortices.

McWilliams, J. C., UCLA, Los Angeles, USA, jcm@atmos.ucla.edu

**SUBMESOSCALE PROCESSES EVIDENT IN NEAR-SURFACE HORIZONTAL SPECTRA**

Horizontal wavenumber spectra of temperature, velocity, and tracers near the ocean surface in the scale range from 100 m – 100 km are an indication of the sub-inertial, rotating stratified, forward cascades of variance from mesoscale eddies into and through the submesoscale range en route to even finer scales. The variance distributions within this scale range are also indicative of the lateral dispersion rates (i.e., mixing). Although diagnosing processes from spectrum shapes is a notoriously non-unique method of inference, a discussion will be presented for relevant dynamical models for the spectrum shape, including geostrophic turbulence, surface quasi-geostrophy, frontogenesis by mesoscale straining, Stratified turbulence, and inertia-gravity waves.

**DECADAL CHANGE IN OCEANIC WIND SPEED AND WATER VAPOR**

The Special Sensor Microwave Imager series of satellite-borne microwave radiometers is capable of making measurements of windspeed, water vapor, cloud water and rain over the world's oceans. At least one of these satellites has been operating for the past 20 years, long enough to begin to examine the measurement evidence for global climate change. We will discuss SSM/I measurements of decadal-scale changes in wind speed and total water vapor, and compare these results to the predictions of climate models. We have succeeded in detecting a fingerprint of human-induced climate change in the water vapor measurements. Detecting and attributing anthropogenic change in wind speed measurements has been more difficult, primarily due to the large interannual fluctuations in atmospheric circulation.

**CHANGES IN NATURAL SOURCE INPUTS TO SEDIMENTARY ORGANIC CARBON ALONG THE MULLICA RIVER AND ESTUARY, NJ: A MULTI-BIOMARKER AND STABLE ISOTOPE CHARACTERIZATION**

The Mullica River, NJ (watershed ~ 1700 km²) drains two distinct land cover vegetations, predominantly pine-oak forests in the Pinelands, changing progressively to salt marshes towards the estuarine source. Sources and potential transformation processes of dissolved organic carbon (DOC) and particulate organic carbon (POC) were assessed using a detailed molecular identification of several biomarker classes, ranging from arap to polar compounds. That was accomplished by the extraction of sediment samples with DCM:MeOH (2:1) and the consequent analysis of their 5ylated total extractions by GC-MS. Overall, sediment biomarker compositions reflected changes in the catchment vegetation along the river; however, dipterocarps (e.g., eucalyptic, debbyroahetic acid (a biomarker for conifers)) were detected predominantly up river, the latter triterpenoid taxarol occurred in downstream sediments, mainly from the salt marsh vegetation. Significant levels of low MW fatty acids (C28-C3) and saccharides (e.g., glucose, mycoste) were observed in the estuarine sediments and are likely derived from marine microorganisms. 6°Abundances of individual fatty acids add specificity in understanding C3 versus C4 vegetation inputs to the system and terrestrial versus marine OC processing in the estuary.

**EFFECTS OF CHEMICAL CUES ON VISUAL ORIENTATION OF EARLY LIFE STAGES OF THE AMERICAN HORSESHOE CRAB (LIMULUS POLYPHEMUS)**

Although adult horseshoe crabs (Limulus polyphemus) have long served as models for the study of vision in marine arthropods, little is known about the visual responses of early life history stages. We examined the visually directed movements and orientation of first stage juveniles to horizons containing dark areas of different sizes. The study tested the hypotheses that (1) early life history stages use visual cues to avoid predators or locate potential refuge areas and (2) responses to visual targets depend on the presence or absence of chemical cues from potential nursery habitats. Visual orientation of crabs to horizontal rectangles subtending angles from 30-300 degrees was tested in a circular arena containing water that either lacked estuarine chemical cues (offshore water) or contained odors from aquatic vegetation or predators. In offshore water, juveniles oriented away from dark horizons. Yet, in water containing chemical cues, including odor from manate grass Syringodium filiforme and blue crab Callinectes sapidus, they swam toward the solid targets. Results support the hypothesis that the visual orientation of juvenile horseshoe crabs changes dramatically upon exposure to estuarine chemicals.

**USING PARTNERSHIPS TO IMPROVE EDUCATIONAL USE OF SCIENTIFIC DATA**

The use of authentic scientific data in effective learning materials for students, educators, and adults in classrooms and in informal learning venues has been a significant aspect of NASA's education efforts for about the last 15 years. Although much of the technology has changed, there has been a vast increase in the technical challenges that existed 10-15 years ago still remain. However, the magnitude of those technical challenges has decreased significantly. As a consequence, today's biggest challenges are not technical but rather limitations of expertise, organizational infrastructure, and sustainability and continuity of data streams. These human and information challenges have existed all along but were masked by the technical challenges. One way to address these human and information challenges is through partnerships with individuals or organizations that already serve the target educational audience. Specific examples of such partnerships will be examined to highlight key features of successful partnerships and the challenges they face.

**SIMULATION OF PRIMARY AND SECONDARY PRODUCTIONS OF GULF OF ST. LAWRENCE (CANADA): IMPORTANCE OF TEMPERATURE REGULATION**

Primary production in the NPZD models is usually formulated as either light- or nutrient limited, and zooplankton growth, as prey limited. However, the importance of temperature regulation of phytoplankton and zooplankton growth re-emerged during early and
flow. Also, for the first time, we report here the jets signature detected in satellite SST and resemble a stationary Rossby wake induced by a force in the California Current (possibly, coherent in vertical from the sea surface throughout at least 700 m depth, and correlates scales, and to extract it a special filter is developed. The thermal signal is found to be ocean topography data. We use historical XBT profiles providing satisfactory coverage of Ubiquitous nearly-zonal jets have recently been found in the 1992-2002 mean dynamic structures.

VARIATIONS OF THE FLORIDA CURRENT TRANSPORT FROM 1964 TO 2007 AND THE RELATIONSHIP TO FORCING

Flowing through the Straits of Florida at 27°N, the Florida Current carries most of both the western boundary circulation of the North Atlantic Subtropical Gyre and the upper limb of the Atlantic Meridional Overturning Circulation. Variations in the Florida Current volume transport can result from changes in either horizontal or vertical gyres. Given the breadth of observation data that have been collected within the Florida Current over the past 44 years (more than 300 ship sections, and more than 25 years of continuous submarine cable observations), one might hope that it would be possible to determine the various forcing mechanisms behind the observed variations. A careful analysis of these different data sets demonstrates that at some times and at some times-scale there are possible links between Florida Current transport fluctuations and indices monitoring changes to the forcing fields (e.g. the North Atlantic Oscillation), however no simple relationship seems to hold over the full time period of the record. Statistical analyses using the continuous time series records illustrate the difficulties in extracting meaningful annual and interannual signals from this time series given the high degree of short-period variability observed in the Florida Current. Nevertheless, the Florida Current represents one of the best locations to search for meaningful ‘climate scale’ ocean fluctuations due to the exceptional length of the observational record.

IN SITU DEPTH PROFILES AND BENTHIC FLUX MEASUREMENTS TO DETERMINE SEASONAL VARIATIONS OF BIOGEOCHEMICAL PROCESSES IN ESTUARINE AND CONTINENTAL SHELF SEDIMENTS

Estuarine and continental shelf sediments are areas where rates of natural organic matter respiration are extreme, yet very few studies have thoroughly investigated variations in biogeochemical processes and elemental fluxes in such environments. The Satilla River in the South Atlantic Bight, (Georgia, USA) is an example of a relatively pristine estuary that experiences pronounced seasonal variations. An autonomous benthic lander equipped with a benthic chamber for monitoring oxygen fluxes across the sediment water interface, and a micromanipulator for volumetric profiling of the main redox species in sediment porewaters (O₂, Mn⁴⁺, Fe⁴⁺, S²⁻ and other iron and sulfur complexes) discovered strongly for more than two years at multiple stations along the river and the nearby bay. Benthic chamber data indicate increased respiration during the late summer and early fall months. The in situ sediment profiles garnered clearly illustrate seasonal variability between times of high and low oxygen saturation along the river. A correlation to river discharge and salinity is also apparent. This study demonstrates that heterotrophy in continental shelf sediments is controlled by a combination of temperature, supply of inorganic and organic substrates, and hydrological processes.

VALIDATION AND PHYSICS OF QUASI-STATIONARY OCEANIC JET-LIKE STRUCTURES

Ubiquitous near-zonal jets have recently been found in the 1992-2002 mean dynamic ocean topography data. We use historical XBT profiles providing satisfactory coverage of the eastern North Pacific to successfully validate these structures. The mesoscale jet-like signal is overwhelmed by both horizontal heterogeneity and temporal variability at larger scales, and to extract it a special filter is developed. The thermal signal is found to be coherent in vertical from the sea surface throughout at least 700 m depth, and correlates with SSH at about 0.7. Consistent with the high-resolution OFES model, dynamics of jets resemble a stationary Rossby wave induced by a force in the California Current (possibly, by secondary circulation in the California Current meanders). The wakes are Rossby waves with their crests tilted in the meandering direction and propagating against geostrophic flow. Also, for the first time, we report here the jets signature detected in satellite SST and ocean color data and discuss physical mechanisms sustaining these structures.

UNDERSTANDING FLORIDA BAY HYPSOSALINITY AND WATER EXCHANGE

Florida Bay is made up of a collection of shallow basins separated by mud banks and mangrove islands situated between the Florida mainland and the Florida Keys. The bay is located downstream of the Everglades discharge that has been altered over the past century by human activities. Florida land use practices, leading to reduced water delivery to Florida Bay and subsequently elevated salinities. The reduced water flow has had the strongest impacts in the north-central region of the bay where extreme hypersalinity can develop along with degradation of water quality and sea grass die-off. Hypersalinity development was found to be caused by the combination of reduced fresh water inputs during the dry season and with weak basin water renewal rates. Using direct measurements of the volume transports through connecting channels, indirect estimates of the total transport to the subregions from mean sea level variability and a computer-generated animation model of observed sub-tidal sea level anomaly fields combined with wind vectors in the region, we show that interior basin water exchanges are weak and are controlled by local wind forcing.

QUANTIFYING BIOLOGICAL MECHANISMS OF PLANKTON LAYER FORMATION IN EAST SOUND, ORCAS ISLAND, WASHINGTON

Small boat surveys were combined with laboratory experiments to quantify the importance of biological mechanisms in plume patch formation. Four stations along the longitudinal axis of East Sound, a shallow foray in the northeast Pacific were sampled on 15-day cruises in summer 2007. At each station, water column physical properties and phytoplankton fluorescence were recorded with a SeaBird CTD 19+. Using a horizontally-mounted Niskin bottle, water samples were collected to quantify species assemblage, phytoplankton standing stock and dissolved inorganic nutrients. Plankton growth- and mortality rates were determined experimentally. Over 5-weeks, multiple phytoplankton layer formation and dissipation events were observed, including surface and sub-surface layers. Species assemblages shifted between large diatoms and the smaller, toxic alga Heterosigma akashiwo. Heterosigma formed layers at the surface, whereas diatoms formed deeper layers. Intense, size-specific grazing on only larger phytoplankton may be an important structuring mechanism in shaping species composition and subsequently layer type. There was no deterministic relationship between physical properties of the water column and layer presence. These results demonstrate that several biological mechanisms can lead to or prevent layer formation and influence layer characteristics.

ANALYSIS AND DETECTION OF BREVETOXIN ANALOGS IN MARINE SEDIMENTS: A NEW BIOMARKER?

Harmful algal blooms of Karenia brevis (K. brevis) produce a suite of lipid soluble polyether brevetoxins known to cause environmental, health and economic ill effects. Recently there has been an increase in the magnitude and duration of these blooms along the Florida west coast in the Gulf of Mexico. However, it remains unclear if the cause of these blooms is anthropogenically influenced or is the result of natural variability. The objective of this research was to analyze sediment from an area that have had known K. brevis blooms and to investigate if these compounds are being recorded in the underlying sediment, thus, potentially be used in paleo-reconstruction studies of these blooms and relate back to forcing mechanisms. Preliminary data indicates PB7-2 and PB7-3 are incorporated into recent marine sediments collected from the southwest coast of Florida with values ranging from 0.17-1.65 ng g⁻¹.

THE ECCO2 HIGH RESOLUTION GLOBAL-OCEAN AND SEA-ICE DATA SYNTHESIS

The Estimating the Circulation and Climate of the Ocean, Phase II (ECCO2) project aims to produce increasingly accurate global-ocean and sea-ice data syntheses at resolutions that start to resolve ocean eddies and other narrow current systems, which transport
heat, carbon, and other properties within the ocean. ECCO2 data syntheses are obt-
tained from a global state-of-the-art deep ocean and sea ice configuration of the Massa-
thusetts Institute of Technology general circulation model (MITgcm) to the avail-
able satellite and in-situ data. A first ECCO2 data synthesis has been obtained using a
Green's Function approach. This presentation provides a brief overview of this ocean and
sea ice data synthesis, of the estimation methodology, of the solution characteristics, and
of some first science applications.

INTERMITTENT MIXING IN EQUATORIAL DEEP JETS

The closure of the mass budget in the global ocean circulation is a fundamental and
still open problem. In particular, the dynamics of the resupply to the abyssal oceans with poten-
tial energy lost through polar deep water formation is poorly understood. Equatorial de-
ephenal jets are a significant reservoir of kinetic energy, and their transport reaches about 2/3
of the thermohaline circulation. For these reasons, the equatorial regions could be prefer-
ential places for abyssal mixing. Observations in the equatorial Atlantic show two distinct
vertical scales. On the deep jets, of scale 500-800m, is superimposed a smaller scale signal
of thin layers (50m) of well-mixed tracer fields. The thin layers coincide spatially with lati-
tudinal plateaus of zero potential vorticity within the deep jets and as such are interpreted
as due to inertial (and/or parametric inertial) instability mixing. In very high resolution
numerical simulations, equatorial deep jets of 500-800m vertical scale are produced by an
oscillating forcing in the western boundary of an ocean-scale basin. In such a flow, the
time-evolution of a passive tracer field shows a characteristic depth of mixing of about 50m.
A statistical analysis shows that the well-mixed layers are located in latitudinal plateaus of
zero potential vorticity. As an alternative to the breaking of internal waves, which appears
to be less significant at the equator, inertial instability can be a source of

LOCAL TO GLOBAL - SCALE BIODIVERSITY PATTERNS ON CONTINENTAL
MARGINS: FIRST OUTPUTS FROM COML/COMARGE SYNTHESSES

Of all ocean habitats, the seafloor biota of the continental slopes experiences the narrow-
est vertical gradients of temperature, salinity, pressure, and food availability. These global-
uearly scales interact with local and regional phenomena to control the composition and
processes of an ecosystem distinct from continental shelves and abyssal plains. The syn-
theses, undertaken by COMARGE, aim at providing an estimate of the relative impor-
tance of local versus global-scale variations in habitat. At the larger scale, the concepts
of zonation and diversity maximum at mid-slope depth are revisited. Repetitions of pat-
tterns are sought in the Gulf of Mexico, on Brazilian and European margins. Comparisons
are made with Arabian Sea margins, influenced by an oxygen minimum zone. These
depth-related patterns are discussed in relation with their potential environmental drivers.
At a local scale, the concepts of COMARGE classification of habitats are introduced. The
merits of higher resolution imaging and bathymetric charting of the seafloor in mapping
habitats and quantifying habitat heterogeneity are underlined. The outcomes of these
ongoing syntheses are discussed in relation with the Known, Unknown and Unknowable
on continental margin ecology.

EVOLUTION OF THE DEEP AND BOTTOM WATERS OF THE SOUTHERN OCEAN, DURING 1995-2005

Repeat hydrographic section data from the eastern Scotia Sea are used to investigate vari-
ability in deep and bottom waters of Southern Ocean origin. U.K. sections in 1995 and
1999 are combined with the 2005 occupation conducted via the U.S. CLIVAR/CO2 repeat
hydrography program (section A165). Significant changes in the Warm Deep Water (a region
of the previously observed warming) and Weddell Sea Deep Water (WSDW) are observed.
Changes in the abyssal circulation of WSDW are also observed. The WSDW changes are best explained by interannual varia-
tions in the density of the deepest waters exiting the Weddell Sea, superimposed on a
longer-term (decadal) warming trend. The interannual variations are related to changes in
the strength of the Weddell Gyre, reflecting large-scale atmospheric variability that poss-
ibly includes the El Niño / Southern Oscillation phenomenon. The Scotia Sea is the most
direct pathway for WSDW to penetrate northward and fill much of the world ocean abyss
as the densest component of Antarctic Bottom Water; thus the regional changes observed
potentially have globally climatic implications.

DIURNAL INTERNAL TIDES OBSERVED DURING THE HAWAII OCEAN MIXING
EXPERIMENT

The Kaena Ridge, one of the main semidiurnal internal tide generation sites along the
Hawaiian Archipelago, is also a site of diurnal internal tide generation. The barotropic to
baroclinic conversion of diurnal tidal energy is simulated using a primitive equation model
and compared with mooring and shipboard observations collected during the Hawaii
Ocean Mixing Experiment. The generation of low trajectory diurnal internal tide beams
from the ridge crest is captured in the model and validated with the in-situ measurements.
The diurnal internal tide appears to feel the Earth’s rotation more than the semidiurnal
tide, which radiates directly away from the ridge, leading to a quasi-trapped diurnal
internal tide component that propagates around the island of Oahu. The trapped wave
encounters other areas of strong barotropic forcing, however, because of phase delays,
the barotropic forcing does work against the baroclinic wave, leading to a decrease in energy
levels that are independent of turbulent dissipation. Implications for the spatial variation
in tidal currents around the island are considered.

PROBING THE NEPTUNE EFFECT: EDDY-TOPOGRAPHIC INTERACTION IN AN
ULTRA-HIGH-RESOLUTION PRIMITIVE EQUATION MODEL

Eddies interacting with sloping bottom topography tend to drive along-slope currents in
the direction of topographic Rossby wave propagation, with shallower water to the right of
the current vector in the Northern Hemisphere. This effect is well-established theoretical-
ly and in idealized (e.g. quasi-geostrophic) flow simulations. Here we apply a more realistic
primitive equation model, MOM4, to simulate wind-driven circulation in an idealized,
mid-latitude basin with varied bathymetry. Forcing is via a steady, meridionally varying
zonal wind stress, and horizontal resolutions ranging from O(1°) to 1/48° are considered.
Questions addressed include (i) how is the strength and direction of abyssal mean flows
affected by model resolution/eddy intensity; (ii) at what resolution (if any) do eddy inten-
sity and the mean flow field become insensitive to further refinements. A prescription for
adjusting viscous dissipation coefficients when model resolution changes is also suggested.

EVOLVING TECHNOLOGICAL IMPROVEMENTS OF THE USF/CMS HF RADIAR
NETWORK

In an effort to improve our understandings on the workings of the coastal ocean for a
variety of environmental applications and to improve upon forecasts of storm surge for resi-
dents along the West Coast of Florida, the University of South Florida’s College of Marine
Science (USF/CMS) established a real-time Coastal Ocean Monitoring Prediction System
(COMPS) for the West Florida Shelf region. COMPS program observing assets consist
of arrays of offshore buoys and coastal tidal stations for surface meteorology and in-water
measurment (AIRC, standing for salinity, and currents; along with several High Frequency
(HF) Radar sites for offshore surface-current velocity field measurement. Commerically
available CODAR Seasonde long range HF Radar systems have been in operation for over
3 years in this challenging region of limited beach availability/access, low wave energy,
severe weather, and frequent lightning activity. The intent of this presentation is to pre-
sent the ongoing technological improvements that have occurred within our evolving HF

269
Radar network, present and discuss achieved historical performance, and discuss possible system enhancements/modifications and their effect on overall system performance.

INTERANNUAL VARIABILITY AND LONG TERM TRENDS IN EASTERN PACIFIC UPWELLING ECOSYSTEMS

Time series of in situ biogeochemical and physical data from Peru, California and the eastern equatorial Pacific have been compiled. These time series have been analyzed using the same techniques to extract the interannual variations and trends of the time series, to highlight different regime shifts and to examine changes in the seasonal cycle. The impact of the 1982-83 and 1997-98 ENSO events are also very clear. The techniques used are standard time series analysis as well as newer spectral methods. We look at surface and subsurface temperature, salinity, oxygen, chlorophyll, nitrate, nitrite, phosphate and silicate as well as some derived parameters such as N/P ratios and N*. The presentation highlights the similarities and differences among the regions.

TRACER-DERIVED TRANSIT TIME DISTRIBUTIONS IN THE NORTH ATLANTIC ALONG 36ºN AND INFERRING ANTROPOGENIC CARBON CONCENTRATIONS

We present Transit Time Distributions (TTDs) derived from the transient tracers data set of chlorofluorocarbons (CFC-11, CFC-12) and sulfur hexafluoride (SF₆) measured along 36ºN in the North Atlantic during the May-June 2005 Charles Darwin cruise. The CFCs and SF₆ tracers complement each other, since their atmospheric source functions are different. In particular, SF₆/CFC ratios is a good dating tool of post-1970s water because, unlike the CFC-11/CFC-12 ratios, which have not changed consistently for the last 3 decades, the SF₆/CFC continues to increase. Using the concept of Transit Time Distributions (TTDs) makes no assumptions about the magnitude of mixing in comparison to the common tracer ages or tracer ratio ages. The TTDs from the surface to the interior are characterized by a mean transit time (τ) associated with a width (Δ) that implicitly includes the effects of mixing on transport. The derived TTDs are used to estimate the distribution of Anthropogenic Carbon along 36ºN and we corroborate our results to the inventory of Brown et al., who applied the Δ* and TrOCA method to the same data set.

A POSSIBLE ROLE FOR AGGREGATING FORAMINIFERANS IN THE GROWTH OF DEEP-WATER CORAL BIOHERMS

Exploration of deep-water bioherms dominated by the scleractinian corals Lophelia pertusa and its role in the feedback of the ocean carbon cycle is a priority for climate research. The CLIVAR/GOOS Indian Ocean Panel—a consortium of scientists from major oceanographic agencies around the world—prepared a prepared a plan for Indian Ocean observations. The key initial step in coordinating the implementation (NCODA) system is scheduled for transition to the Naval Oceanographic Office (NOVAOCENO) by the end of 2007. With ~7 km mid-latitude resolution, the system will 1) depict the location of mesoscale features such as oceanic eddies and fronts, 2) provide the 3 dimensional ocean temperature, salinity and current structure, and 3) provide ice concentration and thickness along with a capability to predict areas of lead opening and closings. The system (minus PIPS) has been running in real-time since December 2006. A series of phased validations/evaluations for the system began in 2007 and will continue this and next year. These will be performed relative to the existing operational global ocean nowcast/forecast system running at NOVAOCENO. First year evaluations include examination of mixed layer depth, sonic layer depth, vertical profiles of eddy kinetic energy, bottom pressure, and sea surface height at tide gauge stations. Second year evaluations will look at HYCOM as a provider of boundary conditions to nested models, comparisons with drifting buoys, current cross-sections, eddy tracking and ice performance. Validations have been performed on both nowcast and forecast fields. A subset of these results will be presented.

Residence time in Tampa Bay and its variation with natural and anthropogenic influences

The non-tidal (residual) circulation in Tampa Bay strongly influences the transport of suspended biological and chemical quantities within the bay. Residence time, essentially the time for a substance or volume to be removed from the bay, is expected to vary with environmental conditions and bathymetry. A realistic ECOM-based ocean model is used to examine changes in residence time within Tampa Bay. The model is first forced with
WHAT CONTROLS THE RATE OF ORGANIC MATTER PROCESSING IN MARINE SEDIMENTS: GEOCHEMISTRY, PHYSICS OR ECOLOGY?

About a quarter of the organic matter that is exported from the surface of the ocean eventually arrives at the ocean floor, and within the sediment, another 90% of this flux is further degraded. There is great interest in the processes controlling the processing of organic matter within marine sediments, because decomposition fuels the benthic ecosystem and burial depletes the ocean’s carbon cycle. However, explaining why some organic matter in marine sediments is mineralized, and what controls the mineralization rate, has proven to be a real challenge. Past explanations favour either a “chemical” view (organic matter consists of a mix of different compounds, and the chemical structure of each compound determines the kinetic rate by which it succumbs to microbial enzyme attack) or a “physicochemical” view (the sediment redox gradient entrains the dominance control, through oxygen exposure or physical exclusion of the digestive enzymes). However, organic matter decomposition results from the metabolic activity of the benthic food web, and so, one can ask whether and how food web ecology matters. To examine this, we constructed a database of decay coefficients of organic matter across a wide range of oceanic sediments, and parameterized it at a function of the flux of organic matter to the sediment. This provides a novel and intriguing “ecological” perspective on organic matter decomposition: the more food the sediment ecosystem receives, the faster the food web processes the incoming food.

POTENTIAL EFFECTS OF EXOPOLYMERIC SUBSTANCES ON ENGINEERED SILVER NANO Particles (ESNs) BIOAVAILABILITY AND TOXICITY TO A COASTAL MARINE PHYTOPLANKTON

The production of extra-cellular polysaccharides, the main components of exopolymeric substances (EPS), by the coastal marine diatom Thalassiosira weissflogii was examined after exposure to different concentrations of engineered silver nanoparticles (ESNs), under different nutrient conditions (nutrient enriched, and nitrogen- or phosphorus- starved conditions). ESNs were toxic at sub-µg/L concentrations, as determined by the significance of the results from the metabolic activity of the benthic food web, and so, one can ask whether and how food web ecology matters. To examine this, we constructed a database of decay coefficients of organic matter across a wide range of oceanic sediments, and parameterized it at a function of the flux of organic matter to the sediment. This provides a novel and intriguing “ecological” perspective on organic matter decomposition: the more food the sediment ecosystem receives, the faster the food web processes the incoming food.

WORKFORCE SHORTAGES IN THE OFFSHORE INDUSTRY: CAN OOS COMPETE?

Employers in the offshore oil and gas industry are experiencing a perfect human resource storm. The growing global demand for oil, fueled largely by the rise of wealth and industrialization in China and India, is pushing oil prices to record highs. These prices make it economically feasible not only to extract oil from the deeper waters of areas like the Gulf of Mexico, but also to rework older shallow fields. Scores of new drill rigs, dynamically positioned multi-capability service vessels, and remotely operated vehicle (ROV) systems are being built to meet the demands noted above, and to meet the anticipated continuing and growing demand for oil. All of this, coupled with an aging and retiring experienced workforce has resulted in shortages of engineers, vessel officers and crews, ROV pilots, electronics and hydraulics technicians, welders; and employees in many other occupations. This presentation will describe the state of the offshore industry, explain how the industry is coping, and explore how the industry’s workforce issues will impact other industries, including the ocean observing system industry, that are competing for human resources.

DATA AS SIMILATION ON THE NW EUROPEAN SHELF

The 3-D baroclinic hydrodynamic coastal ocean model POLCOMS of the Proudmound Oceanographic Laboratory in Liverpool has been used to describe and hindcast the on-shelf ocean behavior for the year 2004. For the same time span several satellite missions like TOPEX, POSEIDON and ENVISAT provide sea surface height measurements. These data are used in an Ensemble Interpolation assimilation scheme to update the ocean model. In addition to the error statistics of the satellite, the correlation structure of the model is necessary for successful integration of real measurements. This talk will follow the building blocks of data assimilation: introducing the North West European Shelf as area of interest, presenting the ocean model and the corresponding background information, introducing the realization of the assimilation code and focusing then on the impact of the satellite data. Here it is especially interesting to investigate the model’s comparison with tide gauge reference data with the aim of assessing the value of assimilating alimetry data in shelf seas with strong tidal signals.

OBSERVATIONS OF STRONG, PERSISTENT, 4–10 DAY-PE RIOD INTERNAL WAVES IN HOOD CANAL, WASHINGTON

Recent observations from moorings within Hood Canal, a fjord reach of Puget Sound, Washington, have led to the discovery of persistent, full-depth waves with periods of 4–10 days and velocity magnitudes comparable to the barotropic tide at ~0.07 m/s. With the local inertial period 16 hours, these waves are significantly sub-inertial, or well below the lower frequency limit for freely-propagating oceanic internal waves. Observations suggest that in the along-channel direction these waves behave as linear internal waves without rotation, with the narrow-channel (~2 km) likely suppressing the Coriolis term. Observations at Hood Canal’s southern end show predominantly upward phase propagation indicating downward energy fluxes. Horizontal energy flux calculations give primarily northward (up-channel) fluxes with typical values of 50 kW. The downward energy flux and a strong correlation of the horizontal energy flux with wind stress suggests the waves are wind-generated, explain ing a strong seasonal cycle in wave energy. Theoretical ray paths indicate that these waves may reflect critically at the bottom, potentially elevating near-bottom mixing and influencing nutrient and oxygen fluxes in Hood Canal’s frequently-hypoxic southern end.

A 13C LABELING STUDY TO TRACE CARBON FLOWS WITHIN NATURAL PLANKTON COMMUNITIES AT ELEVATED CO2

We will present the results of a deliberate 13C DIC tracer addition experiment during the Pelagic Ecosystem CO2 enrichment study (PeECE III). Following nutrient additions at day 0 and 13C DIC additions at day 1, bloom development of a natural plankton community was studied in triplicate at 750, 1050 and 1500 ppm CO2 for a period of 25 days. The transfer of 13C from the DIC pool to phytoplankton and heterotrophic bacteria in the suspension was monitored. The increase in 13C uptake by phytoplankton and heterotrophic bacteria indicates the achievement of the 13C DIC tracer addition experiment. These data will be combined with a simple model that allows identification and quantification of apparent differences in carbon processing in natural phytoplankton communities at different CO2 levels.

OCEAN CIRCULATION WITHIN A MID-SIZED BAY OR GULF TO WIND AND REMOTE FORCING

We consider the barotropic, wind-forced ocean circulation within gulfs or bays that are of order the external deformation radius in extent, with specific application to Spencer Gulf, South Australia.
Australia. Surprisingly, this problem seems to have attracted little attention. Rectangular
hull geometries are adopted so that analytical and numerical solutions can be compared.
For the low-frequency wind forcing, these solutions show that the fundamental balance is
between the wind stress and sea level gradient whereby water is raised or lowered at the
head of the gulf or along the sides of the gulf. Even with strong winds (0.1Pa), the currents
within the gulf are weak due to side-wall effects. The interaction with the shelf circulation
and coastal trapped wave generation and scattering are discussed.

EVOLUTION OF LEAD CONCENTRATIONS IN THE WESTERN MEDITERRANEAN ATMOSPHERIC AEROSOL DURING THE LAST TWENTY YEARS

Temporal and spatial variations in Sea Surface Temperature (SST) and Ocean-color
fields in the Southern Atlantic and Gulf of Mexico (SAOGOM) are examined for 2004
February to December 2007. Temperature and Ocean-color data are optimally interpolated
daily cloud-free SST and daily cloud-free Chlorophyll. a . We also use 10m winds to characterize
surface wind variability which affects ocean circulation, surface temperature and color
distributions. Three sub-regions in SAOGOM are analyzed: the South Atlantic Bight
(SAB) near the Charleston Bump, central Gulf of Mexico (GOM), and the Louisiana-
Texas (LATEX) shelf. The SAB outer shelf and slope is predominantly forced by the Gulf
Stream, meso-scale eddy shedding, and topographically forced meanders. The central
GOM is governed by wind shedding and frontal variations of the Loop Current. The
LATEX coast is affected by local winds, Mississippi river discharge, and tropical cyclones
during summer months. Case studies on characteristic hydrographic conditions during
extra-tropical and tropical cyclone passage, large anoxic river runoff, and strong deep-
sea ocean forcing events will be presented to quantify covariations between SST and Ocean-
color, and their respective temporal and spatial decleration scales.

QUANTITATIVE EVALUATION OF A MULTI-TROPHIC LEVEL ECOSYSTEM MODEL FOR POPULATION DYNAMICS OF THE INVASIVE SPECIES BYTHOTREPHES LONGIMANUS IN LAKE MICHIGAN

The LM-Eco model constitutes a first step toward a comprehensive Lake Michigan ecosystem productivity model to investigate dynamics among multiple trophic levels within the lower water food web of the lake. The effect of the invasive species Bythotrephes longimanus on individual zooplankton species was investigated quantitatively based upon extensive field data collected at multiple locations in Lake Michigan during the 1994-1995 Lake Michigan Mass Balance Project (LMBBP). In addition, more recent field data collected for zooplankton and Bythotrephes longimanus in Lake Michigan beyond the 1994-1995 time period was analyzed for population level trends. Further, the LM-Eco model was utilized in conjunction with this field data to forecast population dynamics of Bythotrephes longimanus and zooplankton in Lake Michigan throughout a 15 year period beyond the 1994-1995 LMBBP. This abstract does not necessarily reflect EPA policy.

FUTURE REGIME SHIFT IN FEEDBACKS DURING ARCTIC WINTER

The Arctic is among the regions where climate is changing most rapidly today. Climate change is amplified by a variety of positive feedbacks, many of which are linked with changes in water vapor, cloud cover, and other cloud properties. In this study we use a global climate model to examine several of these feedbacks, with a particular emphasis on determining whether there are significant temporal trends in these feedbacks that would make them stronger or weaker during the 21st century. The model results indicate that one of the most significant feedbacks on Arctic surface air temperature is related to increasing water vapor, cloud cover, and cloud optical depth. The results also indicate that the enhanced Arctic wintertime warming slows toward the end of the 21st century. This appears to occur, in part, because of a regime shift during Arctic winter in which the positive feedback involving downward longwave radiation, water vapor, and cloud cover weakens substantially.

DIRECT AND INDIRECT EFFECTS OF UV RADIATION ON BACTERIAL ABUNDANCE AND COMMUNITY STRUCTURE IN PONY LAKE, ANTARCTICA

Pony Lake, a saline, hypersaline trophic pond located on Cape Royds, Antarctica, supports a rich microbial community. Although nutrients are not limited, Pony Lake is an extreme environment for life, specifically due to a high level of ultraviolet radiation in the summer, 6 months of darkness and extreme cold temperatures. Monitoring Pony Lake through two field seasons revealed temporal and seasonal changes in bacterial abundance and community structure. The results from season one suggest changes in bacterial abundance were linked to two factors: 1) direct damage to bacteria from sunlight and 2) indirect inhibition from decreased DOM bioavailability due to photobleaching. In the second season, under diminished UV intensity, the results show no evidence for decreased DOM bioavailability or bacterial damage. While photobleaching decreased the overall UV/Vi absorbance and fluorescence intensity in Pony Lake water from both seasons, only in season one, did photobleaching reduce the quantity of redox-active functional groups. Taken together these results suggest UV light influences bacterial community composition both directly by damaging non-UV resistant cells, and indirectly, by rendering changes in the bioavailability of DOM.

DIAGNOSTIC STUDY OF A BAROCLINIC QUASIGEOSTROPHIC MODEL OF THE KURSHIO OFF JAPAN

We examine the properties of a baroclinic quasigeostrophic regional model of the Kurashio off the coast of Japan. This model has been used successfully in data assimilation experiments, and demonstrated the capability of predicting the formation of the large meander a year in advance, initialized by assimilating satellite altimetric data for 18 days prior to the start of the experiment. The first guess was a steady state in which the meander was absent. Posterior velocity time series showed that the underlying hypothesis of Fey 1972 could be rejected. Here we examine in detail the qualitative properties of the model, i.e., the structure of its attracting sets, and begin to relate this qualitative structure to the Kurashio as observed, through comparisons to observations. We also compare the output to that of a finely-resolved primitive equation model, in order to discern the importance of ageostrophic effects, and the errors incurred through the assumptions underlying quasigeostrophy.

PHOTOBIOGEOCHEMISTRY OF CARBON MONOXIDE (CO) IN THE COASTAL OCEAN: FROM GENES TO SPACE

Studies of CO in marine waters have confirmed its source (photochemistry) and sinks (bacterial consumption, air-sea exchange). Recent field studies have concluded that most CO in surface waters is recycled by CO-oxidizing marine bacteria, limiting atmospheric ventilation, consistent with studies showing that they are not a novelty; estimated at 1 in every 14 cells in the Sargasso Sea, with similarly high frequencies in US coastal waters. Our model on the model was implemented on the 10-yr SEWONS ocean-color record to esimate monthly averaged UV attenuation and CDOM absorbance for the Middle and South Atlantic Bights. Underwater scalar solar irradiance (STAR model), and published CO quantum yield spectra were used to generate depth-resolved CO production rates in the mixed layer. Assuming 80 percent of CO is consumed by bacteria, this model indicates that only a small fraction of the total bacterial production in the study area could be supported by CO oxidation (a maximum of only 0.2 percent in July and considerably less in colder months), an interesting paradox considering the apparently large number of marine bacterioplankton that maintain genes for CO oxidation.

QUANTIFICATION OF FUNCTIONAL GENE EXPRESSION OF FE(III) AND SULFATE REDUCING PROKARYOTES IN SALT MARSH SEDIMENTS

This study quantified the gene expression of functional targets for Fe(III)- and sulfate-reduction to investigate the competition between these terminal-electron-accepting processes in marine sediments. Citrate synthase (glaA) and dissimilatory sulfite reductase (dsrA) genes were examined as molecular proxies for iron and sulfur reducing prokaryotes, respectively. Sediment core samples with varying levels of reactive Fe(III) were used to construct microcosms with treatments that were unamended, amended with acetate, or amended with acetate plus molybdate (a specific inhibitor of sulfide reduction). In agreement with published work, rate measurements showed that the coupling of Fe(III) reduction to reorganize anaerobic respiration was dependent upon the abundance of Fe(III)-reducing communities. Quantitative transcription real time PCR of glaA and dsrA genes indicated copy numbers were positively correlated with Fe(III) and sulfate reduction rates, respectively. Site-specific variations in gene copy number supported rate measurements to indicate differences in microbial community structure/function. To our knowledge, we are the first to demonstrate that quantification of the in situ metabolism of known Fe(III)- and sulfate-reducers is possible in marine sediments using molecular proxies in conjunction with rate measurements.

GROWTH AND PRODUCTIVITY OF PHAEOCYSTIS ANTARCTICA AND FRAGILARIA CYPRIUS UNDER SIMULATED MIXED LAYER IRRADIANCE

The pyrmenophyete Phaeocystis antarctica dominates deep mixed environments in the Ross Sea while diatoms dominate shallow mixed layers. Understanding what controls the dynamics of these groups is essential because they utilize nutrients differently and support dissimilar food webs. We cultured P. antarctica and the diatom Fragilariopsis cylindrus under dynamic irradiances that simulated different mixed layer depths and measured their productivity in relation to irradiance (P vs. E). In both species, chlorophyll-a-normalized maximum CO$_2$ uptake ($P_{max}$) and growth were highest in the deeply mixed treatment that had a dark period. In all irradiance treatments, $P_{max}$ and the initial slope of the P vs. E curve
As the Quasi-renewable resource for nourishing the updrift barrier system, sediment composition around the Crozet Plateau reflects the dual control on input from the elevated export production and the proximity to the volcanic islands. The major lithogenic input is identified from bulk sediment geochemistry as Crozet island basalts. Significant heterogeneity in the distribution of biogenic and lithogenic phases occurs downslope. The sediments are characterised by a significant biogenic base sedimentary record and a mixed titanium-iron oxide of volcanic origin and there are multiple mass flow or turbidite events at the base. Meridional trends in $\delta^{18}O$-corrected Holocene mass accumulation rates of calcium carbonate, biogenic silica, lithogenic material, organic carbon, authigenic U, Ba$_{soil}$, and $^{210}$Pb/$^{234}$Th ratios are compared with published data for the Indian sector of the Southern Ocean. The core-top proxy records indicate that there is a significant enhancement of biogenic silica and organic carbon export both north and south of the Plateau and lower values east of the Plateau. The presence of the Crozet Plateau in the significant impact on organic carbon production and export throughout the Holocene corroborating shipboard and remote observations of enhanced productivity in this region.

CAPTURING AN EPISODIC FRESHWATER DISCHARGE EVENT BY COASTAL OCEAN MONITORING AT THE ARANAS PASS TIDAL INLET, SOUTH TEXAS

The coastal environment is a challenging place for oceanographic observations due to its dynamic nature and rapid response to external forcing. It is critical to conduct a continuous observation at strategic locations to detect episodic climate events and their impacts on the ecosystem. Multi-parameter observations were made throughout the water column at the U.S. Marine Science Pier at the Aransas Pass inlet during the July 2007 flood. The inlet is a major exchange pathway between the Gulf of Mexico and several bays in South Texas. Over several tidal cycles during the peak of the discharge event the upper water column was mostly occupied by colder and fresher water with higher oxygen and chlorophyll a content than offshore waters occurring near the bottom. These currents were stronger at the inlet than at the surface with occasional opposite flow, inducing strong vertical shear and mixing. More recent data from the automated profiling at the pier will also be presented. Continuous water column measurements at a local inlet show a potential to detect episodic events in the coastal environment.

Sediment Transport Trends Along the Chandeleur Islands, Louisiana: Implications for Island Sustainability and Barrier Island Management

Bathyetric analyses (1880-2006) for the Chandeleur Islands reveal long-term trends of barrier extension and retreat and recently, barrier disintegration, shoreface erosion (vertically 1-2 m), and mixed erosion and accretion on the backbarrier platform (0-4 m). Volume calculations indicate $\sim150\times10^6$ m$^3$ of sediment has been deposited downdrift (northward) and seaward of the northern terminal spit, whereas the southern end of the barrier has undergone long-term erosion. Bathyetric and shoreline analyses suggest that the islands are impacted primarily during major hurricanes, resulting in shoreline retreat in some sectors and shor development and in-place drowning in others. Katrina removed $>$90% of sand comprising the barriers exposing backbarrier marshes to wave attack. During the following year, $>$50% of the length of the northern Chandeleurs shoreline continued to erode $>(200$ m). However, during year two of recovery, marsh islands served as nucleation sites for sand accumulation along the northern arc. Incipient barrier islands now protect marshes. Contrastingly, southern segments of the chain, where marsh islands were absent, have undergone transgressive submergence. Downdrift sand reservoirs may provide a quasi-renewable resource for nourishing the updrift barrier system.
will be validated using quantitative real-time PCR (qRT-PCR). Results from qRT-PCR will be compared to the microarray data. Development of the protocols used will be presented and insights derived from preliminary results will be discussed.

A PARAMETER TO DESCRIBE INTERNAL GRAVITY WAVE SHOALING

We propose the use of an acceleration-based nondimensional number, γ, for parameterizing the shoaling behavior of internal gravity waves. It expresses the acceleration of wave excursion on the bottom slope relative to the gravitational acceleration projected onto the slope. Unlike the commonly used Iribarren number, which is based on wave geometry, γ may be calculated easily from velocity profiler data. The utilities of the two parameters are explored by examining the reflectance of three types of shoaling waves: sinusoidal surface waves, solitary internal waves, and coastal internal wave groups. We show that γ collapses reflection values of the different wave types. This result, combined with the ease of calculation from oceanographic measurements, suggests that γ may be useful in a wide range of applications.

LATERAL AND VERTICAL SEDIMENT HETEROGENEITY AND ITS RELATIONSHIP TO NEARSHORE MORPHOLOGY

Nearshore sediment heterogeneity enhances the already complex nature of the nearshore, defined here as the swash, surf, and breaker zones. In sediment-winged systems, the source of shoreline heterogeneity is often shallow, subtidal strata, which can become exposed/buried over relatively short time scales. Quantifying vertical heterogeneity of the nearshore may help us better predict sediment variability at the nearshore surface (or the lateral variability) and in turn, better understand the relationship between coastal morphology, stratigraphy, and lithology. To this end, eighteen vibracores were collected from the nearshore of the Outer Banks, North Carolina from within and outside a previously identified shore-parallel bar field. Cores from shore-parallel bars/troughs show greater variability in median grain size than those taken from a convex shoreline. Geophysical data show a coarser underlying stratum is exposed from the axis of the trough and on flanks of shore-parallel bar. Changes in the cross-sectional morphology of bars through time indicate a possible feedback between bar-associated sand and coarser, trough sediment. Observed lithologic heterogeneity is related to recent coastal stratigraphy and has implications for genetic analysis of shelf morphologies.

LARVAL DISPERSAL AND POPULATION DYNAMICS IN A TURBULENT COASTAL OCEAN

Larval dispersal occurs within a turbulent coastal ocean, where coastal eddies are ubiquitous and driving the stirring of water parcels. Hence, larval dispersal is strongly controlled by coastal eddying motions. In contemporary marine ecology however, a vast majority of models oversimplify larval dispersal by ignoring coastal eddying motions and describing it as a simple deterministic diffusion process. We assess the role of coastal eddying motions in larval dispersal and their consequences on nearshore marine population dynamics. The role of coastal eddying motions in larval dispersal is assessed using idealized simulations of time-evolving coastal circulations of the California Current and also using a simple scaling theory. It is found larval connectivity is stochastic on annual time scales, reflecting coastal eddying motions regardless of topographic, demographic, and climate variability. Eddy-induced stochasticity in larval dispersal can have important consequences in stock dynamics and community structures of nearshore marine populations. As an example, we demonstrate that coastal eddying motions can be a dominant mechanism enabling marine species co-existence in the nearshore turbulent environment.

PHOTOPROTECTION AGAINST UV-B RADIATION IN FRESHWATER PLANKTON: A COMPARATIVE APPROACH ACROSS A BROAD TROPHIC SPECTRUM

The ability to mitigate the amount of ultraviolet-B radiation absorbed by individual organisms was quantified in a broad spectrum of planktonic species commonly found in temperate fresh water lakes. Photoprotection was determined experimentally as the amount of DNA damage induced in different species compared with that induced in purified DNA donors exposed at the same time and under the same conditions. A total of fourteen species was examined and included various bacterioplankton, phytoplankton, protozoa, Daphnia and fish, both larval and adult. Damage was determined as the frequency of cyclobutane pyrimidine dimers per megabase DNA using a radioimmunoassay that specifically detects this lesion. We found that all of the organisms showed a high level of photoprotection, with reductions in potential CPD frequencies from ~80 to ~98%. Within this range, however, we found significant variation both between and within the major groups examined.

DMS & DMS LYSE LEVELS IN THE CORAL ALGAL SYMBIONTS, SYMBIODINIUM SP.

Dimethylsulfiniopropionate (DMS) is the precursor of DMS, a significant compound in the global sulfur cycle. Dinoflagellates are large producers of dimethylsulfiniopropionate and dinoflagellate symbionts produce among the highest levels. Various coral species contain DMS produced by resident symbiotic dinoflagellates (Symbiodinium sp.) and when under stress, release the odor of DMS. DMS is formed from DMS via the enzyme, DMS lyase, which some, though not all algae contain. Functions of DMS as an osmolyte, grazing deterrent, nitrogen storage molecule and antioxidant are proposed in algae other than Symbiodinium sp. It is unknown if the coral symbiotic algae (Symbiodinium sp.) or host tissues themselves contain DMS lyase. Current research is focusing on baseline DMSP in a variety of Symbiodinium sp. clades. These studies determine levels over a growth cycle, as DMS varies with growth cycle conditions in other species. DMSP levels varied among Symbiodinium sp. strains; maximal levels in all strains were in exponential growth phase Day 14. Symbiodinium algal strain 830 with antibiotic addition displayed DMS lyase.

Future work focuses on DMS lyase host involvement in tropical sea anemone, Aiptasia sp.

WEB ACCESS TO SATELLITE ALTIMETER CALIBRATIONS VIA THE GLOBAL TIDE GAUGE NETWORK

The methods for time-dependent errors in satellite altimetric data via comparisons with sea level time series from the global tide network have been described in multiple publications and presentations. These methods have been recently updated and extended and this work has been submitted for publication. More recently, with support from the NOAA and NASA we have created a web-based system to make these comparisons easily available to the wider community. Multiple versions of nearly all currently available altimeter datasets are currently available. The emphasis of this presentation is to illustrate what is available, how it can be accessed and used, and how other altimeter datasets could be added to the list of products.

REFRACTORY BLACK CARBON IN THE CHESAPEAKE BAY AND LOWER GANGES-BRAHMAPUTRA

The Chesapeake Bay (C. Bay) and Ganges-Brahmaputra River (G-B) complex represent two important coastal zones for carbon cycling. We isolated refractory BC in a core from the mainstem of C. Bay and in surface sediment of the lower G-B and Bay of Bengal using a chromic acid oxidation procedure. In the lower G-B and the Bay of Bengal, BC constituted 17-32% of the TOC and appears to have been derived from a mixture of sources including petrogenesis. In contrast, throughout the late Holocene, BC in C. Bay sediments represented 69-82% of the TOC and appears to have been derived from a mixture of sources including petrogenesis. In contrast, throughout the late Holocene, BC in C. Bay sediments represented 17-32% of the TOC and appears to have been derived from a mixture of sources including petrogenesis.
NUMERICAL MODELING AND PARAMETERIZATION OF DENSE SHELTER WATER FORMATION DUE TO BRINE REJECTION OVER A GENTLE SLOPE, WITH AN APPLICATION TO THE SEA OF OKhotsk

Eddy resolving simulation of dense shelter water formation over a gentle slope, due to brine rejection, is presented. The model configuration consists of a 200 m deep, 330 km by 330 km grid, centered on the northwestern shelf in the Sea of Okhotsk, where the heaviest water in the North Pacific region forms. The shelf water density is determined by a balance between surface salt flux and baroclinic-eddy flux offshore. It is found that the shelf water density varies sensitively with the slope inclination. If the inclination is smaller than 0.01, the density decreases with depth; the inclination becomes larger; however, the density is nearly invariant, or even increases slightly. This sensitivity comes from competing effects of the sloping bottom on baroclinic stability; one is a destabilizing effect due to increase of the density-interface inclination with the bottom slope, while the other is a stabilizing effect via potential vorticity distribution in the upper and lower layers. The destabilizing effect is important for the gentler slope. Eddy flux is parameterized including the effect of the slope, which evaluates the density of the shelf water very well.

A RECALIBRATION OF AVHRR: TOWARDS A HIGHER QUALITY AND ACCURATE DATASET FOR SST RETRIEVAL

Fundamental to accurate sea surface temperature measurements from space–borne observations is a proper understanding of the instrument calibration, particularly with the move towards physically based retrieval algorithms where absolute radiance accuracy is required. Perhaps the most widely used instrument is the AVHRR, which provides the longest continuous record of space–based observations of the SST currently available. However, while the instrument itself can be shown to be very stable, previous and current calibrations can only provide radiances accurate to 0.2-0.5K. We have derived a new physically based calibration based on the pre-launch data for the AVHRR instruments which addresses many of the problems with the previous calibration and can reduce the errors to ~0.05K. We also show that the old calibration is likely to have introduced both temporal and spatial (including latitudinal) biases into the AVHRR data, many of which cannot be fully accounted for by using Pathfinder–like running means to derive the SST retrieval coefficients. Finally, we discuss problems with the in–orbit calibration such as Earth shine and solar contamination which can be corrected for with our new calibration.

MOSO SCALE VARIATIONS REPRODUCED BY THE JCOP2 REANALYSIS

We have created the high-resolution reanalysis data in Japanese coastal ocean by using the 4th JCOP2 ocean forecast system, which has been developed to fully utilize the potential of various types of observations, as a part of a cooperative study between FRA and JAMSTEC (FRA-JCOP2). The reanalysis skill is evaluated by regional metrics defined by the in-situ temperature/salinity profiles and the surface velocity calculated from both the satellite altimetry and drifter buoy data. The intensive use of the various kinds of metrics is quite useful to determine unknown parameters built in the three-dimensional variational assimilation (3DVAR) system implemented in JCOP2. It is found that some parameters: 1) mean sea surface height (SSH) field required for derivation of the model SSH anomaly, 2) horizontal scales of background error covariance in the 3DVAR cost function, and 3) EOF modes representing waters property of the temperature/salinity in the 3DVAR system, significantly affect the reanalysis skill. Meso-scale events reproduced by the JCOP2 reanalysis path variations of the Kuroshio-Kuroshio Extension, southward intrusion of the Oyashio coastal branch, life histories of cyclonic/anticyclonic eddies east of the JCOPE2 reanalysis: path variations of the Kuroshio-Kuroshio Extension, southward intrusion of various types of observations, as a part of a cooperative study between FRA and JCOPE2 ocean forecast system, which has been developed to fully utilize the potential of various types of observations, as a part of a cooperative study between FRA and JCOPE2 reanalysis system, which has been developed to fully utilize the potential of various types of observations, as a part of a cooperative study between FRA and JCOPE2.
ably large potential dust sources, but recent models of Jerry Wiggert, using both GISS and GOCART-derived simulations to estimate dust fluxes, suggest that there is insufficient aeolian Fe to sustain high levels of monsoon-driven primary production and C export. A critical issue is how much interannual variability there is in air mass trajectories and Fe supply, and how the decade-scale increase in monsoon intensity reported elsewhere may be influencing these fluxes.

3D GRANULAR LANDSLIDE TSUNAMI EXPERIMENTS

Tsunamis are commonly associated with submarine earthquakes. However more than 10% of all tsunamis are generated by landslides or landslide like volcano collapses with subaerial, partially submersed or submarine origins. Landslide generated tsunamis were investigated in the easternmost circulation basin of the Baltic Sea on the basis of the geological similarity. The landslide emplacement characteristics were controlled by means of a novel pneumatic landslide generator. Deformable landslides of subaerial and submarine origin were modeled with granular materials. Measurement techniques such as particle image velocimetry (PIV), multiple above and underwater video cameras, multiple acoustic transducer arrays, as well as resistance wave and runup gauges were applied. The wave generation was characterized by an extremely unsteady three phase flow consisting of the slide granulate, water and air entrained into the flow. PIV provided instantaneous surface velocity vector fields, which gave insight into the kinematics of the wave generation process. At high impact velocities flow separation occurred on the slide shoulder resulting in a hydrodynamic impact crater. The recorded wave profiles were extremely directional, unsteady, non-linear and located in the intermediate water depth wave regime.

THE INTERCONNECTION BETWEEN THE FLINDERS CURRENT AND LEEUWIN UNDERCURRENT

The interconnection of the subsurface currents of the west and south coasts of Western Australia was documented through analysis of the water mass characteristics and vertical and horizontal velocity fields. Located around 250 m depth, the Flinders current (FC) and Leeuwin undercurrent (LU) are the two currents in this region—the Flinders current on the south coast and the Leeuwin undercurrent on the east coast of Australia (OSU) based on the generalised Froude similarity. The landslide emplacement characteristics were controlled by means of a novel pneumatic landslide generator. Deformable landslides of subaerial and submarine origin were modeled with granular materials. Measurement techniques such as particle image velocimetry (PIV), multiple above and underwater video cameras, multiple acoustic transducer arrays, as well as resistance wave and runup gauges were applied. The wave generation was characterized by an extremely unsteady three phase flow consisting of the slide granulate, water and air entrained into the flow. PIV provided instantaneous surface velocity vector fields, which gave insight into the kinematics of the wave generation process. At high impact velocities flow separation occurred on the slide shoulder resulting in a hydrodynamic impact crater. The recorded wave profiles were extremely directional, unsteady, non-linear and located in the intermediate water depth wave regime.

MOLECULAR APPROACH TO DETERMINE CONTRIBUTIONS OF EUKARYOTIC PROTISTS TO DOWNWARD PARTICLE FLUX

Under present conditions of increasing atmospheric CO2 and global ocean temperatures, a better understanding of the biological community involved in organic carbon flux, including the relative contributions of key taxonomic groups of eukaryotic phytoplankton as contributors to export production at a station in the eastern subtropical North Atlantic. Communities from various depths in the water column and from surface tethered particle traps below the water mixed layer were analyzed using a combination of molecular (18S rDNA clone libraries, DGGE) and traditional (epifluorescence and inverted microscopy) techniques. The application of molecular techniques to this question allows us to identify otherwise indistinguishable taxonomic groups (including the relative contributions of key taxa to particle export, will greatly contribute to this question allows us to identify otherwise indistinguishable taxonomic groups (including the relative contributions of key taxa to particle export, will greatly contribute to one of an uncultivated eubacterium that clustered with a alpha-Proteobacterium previ-
ously isolated from the North Pacific. Rarefaction analysis suggested that the major-
ity of the diversity was covered with 384 nIhU clones. Two new qPCR primer probe sets
were applied for dominant Proteobacterial sequence groups. Trichodesmium spp. was by far
the most abundant diazotroph, with up to 6x*10^6 gene copies L^-1. Cyanoabacteria Group
A, Group B, and symbionts were detected at low abundances. The microarray data mir-
rored trends in the clone libraries. qPCR results reproduced the microarray data for
Trichodesmium but not for the alpha-Proteobacteria that dominated the clone library.
Diazotroph community in South China Sea consists of both oceanic and estuarine compo-
nents with overall low diversity.

SPATIAL AND TEMPORAL COHERENCE OF PLANKTONIC LAYERS

The layering of planktonic organisms are a common occurrence in coastal systems.
These layers are formed by a combination of physical and biological forcing mechanisms
and depend largely on the characteristics of the organisms themselves. The coherence
of these layers and their duration at a given location are also dependent on many of the
same mechanisms, however it has only recently gained attention. As part of the Layered
Organization of the Coastal Ocean project, an autonomous underwater vehicle (AUV)
occupied the northeastern portion of Monterey Bay during 2006. Repeated missions over
the same location allowed for quantification of plankton layers and their coherence in
space and time. In addition to the AUV mission, recent data from a time series station in
San Luis Obispo Bay, CA will be shown to address these same questions from a temporal
perspective. These data highlight the potential to address the vertical interactions be-
tween planktonic groups and differential formation of layers between groups.

CHARACTERIZATION OF KA-BAND SWATH ALTIMETRY PERFORMANCE FOR SURFACE WATER HYDROLOGY

Traditional radar altimetry has demonstrated the ability to retrieve surface water heights
with decimeter accuracies along the nadir path. However, a profiling sensor is insufficient
to provide global monitoring of fresh water bodies. In response, the Water Vapor mission
proposes a swath-based imaging altimeter to provide the key hydrologic variables needed
for comprehensive river discharge and storage observations, specifically temporal height
count, slope and spatial extent. In addition, key imaging capabilities provide classification
and data for topographic corrections. Initially, we identify the error sources that a near-nadir synthetic aperture radar interferometer, such as the KaRIn instrument
proposed to meet the Water Vapor requirements, would incur. We then demonstrate that
with appropriate calibration techniques, measurements of river stage with an accuracy of ap-
proximately 5 cm and river slope with an accuracy of 1 cm/km are achievable. Finally, we
focus on methodologies for land/water and layover classification and limitations imposed
by temporal decorrelation of the water and local topography respectively.

THE ROLE OF BREAKING WAVES IN ENHANCING THE RATE OF CHEMICAL REACTIONS IN OCEANIC SURFACE WATERS: DEDUCTIONS FROM A TIPPING BUCKET EXPERIMENT

When ocean waves break a portion of their energy is converted to the production of new
bubble surfaces. These surfaces are sites at which naturally occurring dissolved organic
matter can collect. The energetic environments at the bubble–water boundary have been
postulated to be favored sites for chemical transformations to occur. A series of tipping
bucket experiments were conducted to test this hypothesis. Tryptophan was used as a
representative DOM compound. Within an enclosed space, a microprocessor-controlled
bucket of sea water was tipped into a tank of sea water every minute for days to generate
a bubble plume. Water samples were periodically taken through a port in the tank lid, and
the concentration of target chemical species were determined. In a number of experi-
ments the rate of specific transformations during tipping runs was seen to significantly
exceed the rate in control. The average bubble, or whitecap, coverage of the surface
in the water in the tank was determined so that the observed laboratory transformation rates
could be associated with a particular sea state, inferring rates for other whitecap cov-
erages.

ASSIMILATION OF AIRBORNE IMAGER WITH LIDAR FOR BATHYMETRIC ESTIMATION

One of the challenges to understanding coastal processes is overcoming the limitations of
methods for quantifying large scale coastal behavior. A particularly adaptive survey meth-
ood for use in regional nearshore studies is airborne Lidar (Light Detecting and Ranging),
which is able to densely sample both topographical and shallow bathymetric elevation
data over large geographical regions. Bathymetric Lidar is dependent on water clarity, and
in the surf zone sediment and air bubbles entrained in the water column by wave breaking
Photosynthesis produces biomass within the euphotic zone, which eventually sinks to the upper sedimentary layers of the ocean. This process is critical for the export of organic carbon from the surface waters to the deep ocean, contributing to the formation of the oceanic carbon reservoir. The study of benthic grazing and its role in the carbon cycle is essential for understanding marine productivity and the fate of organic matter at the sediment-water interface.

Benthic grazing is the process by which marine invertebrates consume organic material from the sediment surface. This includes pelagic organisms such as foraminifera and bivalves, as well as benthic filter feeders like amphipods and polychaetes. Benthic grazing is a fundamental process in marine ecosystems, influencing the flux of organic carbon from the sediment to the water column and affecting the structure of the benthic community.

The study of benthic grazing is crucial for understanding the role of the ocean in the carbon cycle and the fate of organic matter. This research can have implications for climate change, as changes in benthic grazing can affect the uptake and release of carbon dioxide from the ocean to the atmosphere. Additionally, understanding benthic grazing can help in the management of marine resources and the conservation of marine ecosystems.

Coastal sediments are source of dissolved organic carbon (DOC) to the overlying oceanic water column. Changes in coastal sedimentation, which are driven by physical processes such as tidal currents and wave action, can influence the amount of DOC exported to the ocean. This process is critical for understanding the carbon cycle and the budget of organic matter in coastal ecosystems.

The study of DOC export and its role in the carbon cycle is crucial for understanding the carbon budget of coastal ecosystems. This research can have implications for climate change, as changes in DOC export can affect the uptake and release of carbon dioxide from the ocean to the atmosphere. Additionally, understanding DOC export can help in the management of coastal ecosystems and the conservation of marine resources.
Dissolved hydrogen and of the potential of these measurements to aid the quantification of nitratation levels will be reported together with their relationship with isotopic measurements over the latitudinal surface ocean. Evidence of a correlation between hydrogen concentrations (or net degradation) and increased their APA in response to ATP but not inorganic P additions. However, whether Prochlorococcus populations (or some ecotypes) are P-limited or have become P-limited is a regular occurrence. It is not clear, how variations in iron inputs from the atmosphere. The BEC model includes multiple potential sources and in alkaline phosphatase activity (APA), and these differences are reflected in the typically assumed low, constant solubility of 1-2%) on phytoplankton community structure, nutrient limitation patterns, and the rates of nitrogen fixation, export production, and air-sea CO2 exchange.

PHYSIOLOGICAL RESPONSE OF PROCHLOROCOCCUS IN P-LIMITED CHEMOSTATS AND ON-DECK NUTRIENT ENRICHMENT EXPERIMENTS

In some regions of the world's oceans where marine cyanobacterium Prochlorococcus dominate, phosphorus (P)-limitation is a regular occurrence. It is not clear, however, whether Prochlorococcus populations (or some ecotypes) are P-limited or have a competitive advantage under P limitation. Studies on P stress response of various Prochlorococcus ecotypes revealed differences in their ability to utilize organic P sources and in alkaline phosphatase activity (APA), and these differences are reflected in genome content. This raises the question of what differentiates the P physiology of Prochlorococcus ecotypes and whether natural populations experience P limitation. To begin exploring these questions, P-limited chemostats of Prochlorococcus MED4 (HLI) were established and uptake kinetic experiments carried out. These results indicate that MED4 has a rapid uptake rate for P when grown under P-limiting conditions but is not more efficient at P uptake than other marine picophytoplankton ecotypes. Rates do not occur at the same time as increases in APA. On-deck nutrient enrichment studies in oligotrophic western Pacific indicate that Prochlorococcus populations grew and increased their APA in response to ATP but not inorganic P additions.

DISSOLVED HYDROGEN MEASUREMENTS AND THEIR RELATIONSHIP TO NITROGEN FIXATION IN THE EQUATORIAL PACIFIC: RESULTS FROM THE CMORE-BULA CRUISE

Dissolved hydrogen was measured in surface waters samples and vertical profiles during the CMORE-BULA cruise between Fiji and Hawaii in April 2007. The primary objective of this study was to determine whether nitrogen fixation is the main process responsible for the supersaturated levels of dissolved hydrogen that have been observed in the low-latitude surface ocean. Evidence of a correlation between hydrogen concentrations (or net production rates) and rates of nitrogen fixation as measured by NIF assimilation could offer the possibility of a near real-time measurement that would have value in mapping oceanic nitrogen fixation. Hydrogen proxy could assist in guiding isotopic measurements or in interpolating between such measurements. Hydrogen concentrations and isotope levels will be reported together with their relationship with isotopic measurements of nitrogen fixation rates. Assessments will be made of the sampling requirements for dissolved hydrogen and of the potential of these measurements to aid the quantification of nitrogen fixation.
We present a new approach for parameterizing dissolved organic matter (DOM) absorbance spectra. Two distinct spectral slope regions (275-295 nm and 350-400 nm) within log-linearized absorbance spectra were used to compare DOM from contrasting water types, ranging from wetlands (Great Dismal swamp and Swanneree River) to photobleached oceanic water (Sargasso Sea). Based on DOM size-fractionation studies (ultraltrafiltration and size exclusion chromatography), we found that the slope of the 275-295 nm region and the ratio of these slopes (Rs = 275-295 nm slope:350-400 nm slope) were related to DOM molecular weight (MW) and to photochemically-induced shifts in MW. Along an axial transect in the Delaware Estuary, large variations in Rs were measured, probably due to photo-degradation and microbial alteration of chromophoric DOM (CDOM) as terminally-dead DOM transits through the estuary. Further, Rs varied by over a factor of 14 between DOM-rich wetland waters and Sargasso Sea surface waters. Currently, there is no consensus on a wavelength range for log-linearized absorbance spectra. Based on our results, we suggest that the 275-295 nm slope be routinely reported in future DOM studies.

The Caribbean and Western Tropical Atlantic receive massive inputs of Orinoco and Amazon River water carrying a load of organic and inorganic materials into waters characteristically devoid of these. The magnitude of riverine impact became evident as remote sensing became an ocean color monitoring tool. These observations depict riverine plumes, containing dissolved organic matter and phytoplankton well above background concentrations, being advected into the oligotrophic ocean. Subsequent research revealed that riverine intrusions radically modulate trophic balance and activity through changes in plankton abundance, composition and size distribution and last but not least: availability of solar irradiance. Moreover, riverine influence responds to climate processes and oceanic mesoscale processes without significant spatial and temporal variability at annual and interannual scales. We discuss observations of physical and biogeochemical gradients in the Orinoco River Plume in the above context. Moret-Ferguson, S. E., Sea Education Association, Woods Hole, USA, s Ferguson@sea.edu; Sidla, A. N., Sea Education Association, Woods Hole, USA, asidla@sea.edu; Schell, J. M., Sea Education Association, Woods Hole, USA, jschell@sea.edu; Spatial and Temporal Variability in Zooplankton Density of East Pacific Surface Waters Zooplankton provide fundamental links in marine food webs, and their distributions have long been used to define biogeographic boundaries. For the past six years, Sea Education Association has traveled an annual cruise track in the East Pacific comprised of six regional transects: 1) San Diego, CA to Mexico, 2) Mexico to Tahiti, 3) Tahiti to Hawaii, 4) Hawaiian-Equatorial circuit, 5) Hawaii to West Coast, U.S. and 6) West Coast, U.S. track ending in San Diego, CA. Over 1200 netson net (1 x 0.5 meter, 333 um mesh) tows were conducted during 50 cruises from October 2001 through December 2007. Zooplankton trawl transects across the entire Pacific cruise track included a doubling of the mean from day to night, and positive correlations with extracted chlorophyll-α and phosphate concentrations. Highest densities were associated with frontal boundaries. However, differences among regional transects were observed in patterns of inter-annual and geographic variation. Morrey, S. L., Florida State University, Tallahassee, USA, morrey@coaps.fsu.edu; Dukhovskoy, D. S., Florida State University, Tallahassee, USA, dddmitry@coaps.fsu.edu; Bourassa, M. A., Florida State University, Tallahassee, USA, bourassa@coaps.fsu.edu; Connectivity Between Variability of the Apalachicola River Flow and the Biophysical Oceanic Properties of the Northern West Florida Shelf Maps of satellite-derived estimates of monthly-averaged chlorophyll-a concentration over the northern West Florida Shelf show high interannual variability concentrated near the coastline and extending at least 150 km offshore over this wide shelf in a tongue-like pattern from the Apalachicola River during the late winter through early spring. The spatial pattern of these anomalies encompasses clusters of spawning habitats for regionally important fisheries. The chlorophyll-a concentration anomalies are consistent with variations in the density of the Apalachicola River at interannual timescales. For instance, low chlorophyll-a offshore transport of the Apalachicola River plume across the inner shelf under upwelling-favorable winds provides the physical mechanism for connecting the variability of the river discharge with oceanic variability over the middle and outer shelf. Even though diatoms sink mostly in the form of aggregates and fecal pellets, bSiO2 dissolution rates used to reconstruct bSiO2 profiles are generally measured on free cells. Our experimental results show that in aggregates and in fecal pellets, initial dissolution rates of diatom frustules were 2 to 3 times lower than rates for free cells. Results from modelling experiments suggest that this is the result of high viability of diatoms and elevated dSi concentrations inside aggregates; the latter may in turn be due to dSi adsorption on the aggregate matrix. bSiO2 flux profiles at 8 sites in the global ocean were accurately reconstructed using bSiO2 dissolution rates and sinking rates of two classes of sinking particles: large particles (aggregates + fecal pellets), and small particles (free cells). A LONG-TERM REAL TIME SEAED MORPHOLOGY EVOLUTION MONITORING SYSTEM IN THE SOUTH ATLANTIC BIGHT

A long-term real sea bed morphology monitoring system has been established on the middle continental shelf in the South Atlantic Bight as part of the SEACOOS observation system and now in support of the BOTTOMS-UP project. The system is composed of an Imagexen Model 881 digital rotating imaging system (2.25 MHz) connected through 1.5 km of cable to a power and controller unit housed on the R2 Naval platform (SABSOON). The system collects high resolution images of the seabed composed of echo intensities along 6 meter long radials with resolution of 0.3 degrees. Data are acquired hourly, transmitted via microwave antenna to shore, to Skidaway Institute via T1 land line, and forwarded to the University of South Carolina over the internet. Raw images are rectified and processed using a 2-dimensional fast fourier transform algorithm providing wavelength and ripple orientation values. Post-data collection image processing allows evidence of bioturbation to be identified as well. The long-term data base (since April 2007) is used for evaluation of time-dependent ripple evolution models. System design, data analysis and example images will be presented.

VOLUME, HEAT AND SALT FLUXES IN THE NORWEGIAN SEA TOWARD THE ARCTIC DERIVED FROM ALTIMETER AND HYDROGRAPHIC DATA

The flow of the warm and saline water from the North Atlantic and into the Norwegian Sea is vital for the climate in the Nordic Seas and Arctic. The inflow in the Norwegian Sea, the Norwegian Atlantic Current, consists of two branches. While the variability and forcing of the inner branch has been resolved based on long-term current measurements, knowledge of the outer branch is poor. In this work we have estimated the total northward fluxes in the Norwegian Atlantic Current by combining altimetry, repeated hydrographic transect and new in situ data from the BOTTOMS-UP project. The total northward flux of water, heat and salt has increased from 1992 to present due to an increase in the outer branch. The different contributors to the fluxes such as sea surface level, bottom and baroclinic velocities are compared.

PENETRATION OF UV RADIATION IN STREAMS OF EASTERN PENNSYLVANIA, USA: TOPOGRAPHIC CONTROLS AND THE ROLE OF SUSPENDED PARTICULATES

Attenuation of UVR in stream is determined by the concentration and optical properties of suspended sediment and dissolved DOC. We document the baseflow optical environ- ment in the Fire hole and Little Juniata rivers that drain the Allegheny Plateau of central Pennsylvania. We observed a wide range of attenuation coefficients (Kd800: 0.68 - 151.1 m-1, Kd320: 0.95 - 316.2 m-1) and 1% transmission depths (2 cm - 147 cm). We also quantified the role of particulate material, which generally accounted for 20% ± 10% of the attenuation and DOM. We found a strong relationship between the concentration of DOC and DON with not dissipated by the blue light in 2005 as part of the Integrated Ocean Observing System (IOOS) to provide a comprehensive suite of observations. Buoy light attenuation measurements suggest that factors unresponsive to nutrient enrichment may be responsible for the major effect of the age grading (e.g., sediment resuspension and CDOM). Here we discuss how airborne hyper-spectral remotely sensed information collected during 2007 has been used to expand on the temporally rich buoy data to provide spatially rich information relevant to the goals of regional coastal managers.

DINOFLAGELLATE BLOOM DYNAMICS AND PATTERNS OF NUTRIENT UPTAKE IN A SHALLOW EUTROPHIC ESTUARY

The Lafayette River is a shallow eutrophic sub-estuary of Chesapeake Bay that frequently experiences algal blooms. We sampled the Lafayette River on a daily basis for a period of 54 days in fall 2005 and 34 days in spring 2006 to better understand the initiation and progression of dinoflagellate blooms. In September, little N uptake was measured as a Gymnodinium sp. bloom was forming despite high levels of DIN. Uptake rates increased from 1992 to present due to an increase in the outer branch. The different contributors to the fluxes such as sea surface level, bottom and baroclinic velocities are compared.

INTERANNUAL VARIABILITY OF PACIFIC WINTER WATER THROUGH THE BARRINGER CANYON FROM 2000 TO 2006

Time series of temperature, salinity and velocity from 2000 to 2006 at the Barrow Canyon, which is one of the major spreading pathway of Pacific Water into the Canada Basin, document significant year-to-year changes especially in salinity during winter. Interannual variability of Pacific Water (PWV) is well explained by the following two factors except 2004: 1) change in salinity in the upstream region, Bering Sea and Chukchi Sea, and 2) change in cold, saline polynya water input caused by the sea ice formation in the Barrow Canyon polynya, which is the largest coastal polynya in the Western Arctic Ocean. In 2004, saline PWW was rarely observed at the Barrow Canyon, although polynya often occurred. Barrow Cape polynya polynya was considered as latent heat polynya which was an active sea ice producer when polynya was maintained by offshore wind. However, subsurface temperature in 2004 was above freezing point due to reversing of warm Pacific Summer Water from the basin into the canyon, and it reduced sea ice formation in the polynya.

MECHANISMS OF WARM AND COLD WATER TEMPERATURE EVENTS IN THE FLORIDA KEYS BETWEEN 1988 AND 2003

The potential for thermal stresses on corals is evaluated from bottom temperatures for thirty-three stations in the Florida Keys National Marine Sanctuary. The ensemble annual mean water temperature was 26.5°C ± 2.5°C. The variability of temperature depends on the season and location within the Sanctuary. Temperature changes are small in summer with a standard deviation generally less than ±0.6°C due to weak temperature differences (< 2°C) in surrounding waters. However, water temperature greatly fluctuates during the winter (daily standard deviation of ±0.6 - 1.2°C) due to temperature differences of about 5°C on average between the Florida Current and Florida Bay. The primary mechanisms producing cold water temperature events is atmospheric cold fronts. Warm water temperature events were caused primarily by Florida Bay outflows, but also by locally generated wind forcing, or inshore positioning of the Florida Current. Eleven inshore stations, mainly in the Middle Keys, featured temperatures above 33°C or below 15°C, the thermal stress threshold temperatures harming the corals.

THE EXPLORATION OF ROUND REEF

In a time when fewer schools allow the students the opportunity to enter the water during school trips and with costs increasing to transport them to field trip sites, there is a challenge to expose young schoolchildren to coral reef biology. By bringing a simulated reef into the hands of a younger audience, this program allows early exposure to ocean literacy in an engaging way. The curriculum is flexible enough to be used from kindergarten through fifth grade and can be easily translated into opportunities for special-needs groups. At the core of the program is the understanding of one's importance in caring for - and taking responsibility for - our coral reefs. By using a simple child's toy we put the reef into the hands of a younger audience, this program allows early exposure to ocean literacy in an engaging way.
results show occasions of strong diurnal cycling of turbulence and intermittent internal wave bursts at frequencies near N, similar to previous intensive profiling observations in 1984, 1987 and 1991. But this is not always, or even typically, the case.

RECENT SALINITY VARIABILITY AND ASSOCIATED ECOSYSTEM CHANGES ON GEORGES BANK

The surface waters of the Gulf of Maine/Georges Bank region exhibited a large decrease in salinity during the 1990's relative to the 1980's. The decrease appeared to have originated at high latitude and been advected into the Gulf of Maine/Georges Bank region. Analysis of zooplankton data from Georges Bank indicates that a shift in the zooplankton community structure occurred in association with the salinity changes, resulting in higher abundance of smaller copepods during the 1990's. The survival rate from egg hatching to recruitment for the cod and haddock populations on Georges Bank also exhibited a shift between the two periods. Cod survival was three times higher than that for haddock dur- ing the 1980's, while the reverse was true during the 1995-1999 period sampled by the US GLOBEC program. Plausible mechanistic connections between the variability in salinity, zooplankton community structure and fish survival rates will be discussed.

ENSEMBLE-BASED MODEL SALINITY ERROR COVARIANCES INDUCED BY EXTERNAL FORCING UNCERTAINTIES IN THE EASTERN NORTH-ATLANTIC OCEAN

SMOS and Aquarius satellite missions, scheduled for launch in 2008 and 2009, will provide synoptic sea surface salinity observations at a global scale. These unprecedented data are expected to have a great potential to improve the mixed layer representation when assimilated into ocean models. This however will still require models to be able to faithfully represent the main processes affecting salinity, as well as a proper estimation of the associated model error. In this perspective, this study investigates model-SSS error covariances due to external forcing uncertainties using an ensemble approach. The model is a regional 1/3° configuration of the NEMO-OPA90 model implemented over the eastern subtropical North-Atlantic Ocean. Three 100-member ensemble of model simulations are generated, with perturbations of the wind stress forcing, the precipitations and the open boundary data respectively. The perturbations are linearly combined randomly selected leading EOFs of the fields under consideration. As initial conditions are the same for all experiments, the obtained ensemble covariances estimate the model error covariances induced by forcing errors. The spatio-temporal variability of SSS error variances is presented, as well as the 3-dimensional structure of the multivariate error covariances of salinity for different forcing conditions.

WHAT IS NORMAL? EXTREME TEMPERATURE VARIABILITY ON A HIGH LATITUDE, FRINGING RED SEA CORAL REEF

Corals in the Red Sea's Gulf of Suez live near the upper thermal tolerance limits, where corals regularly experience 2-4°C daily water temperature differences and seasonal variations that exceed 15-20°C. In this extremely harsh region, few, if any water temperature time series records exist. As part of a larger four year research project documenting a shallow fringing reef in the Gulf of Suez, water temperature observations were collected when mapped, temperature variability appears to be driven by small depth variations ranging from a low of 14°C in February to a maximum of 34°C in September. As part of a larger four year research project documenting a shallow fringing reef in the Gulf of Suez, water temperature observations were collected when mapped, temperature variability appears to be driven by small depth variations ranging from a low of 14°C in February to a maximum of 34°C in September.

PHOSPHATE AVAILABILITY AND NITROGEN FIXATION IN THE OLGOTROPHIC OCEAN: OVERVIEW AND OBJECTIVES OF THE BOUM CRUISE PROJECT

Oligotrophic marine areas are characterized by a thermal stratification of the water column. This delimits a warm surface mixed layer with high light intensity but depleted in nutrients, and a sub-superficial layer with low light levels and more nutrients. Tropical ar- eas, large anticyclonic gyres, the Sargasso Sea and the Mediterranean Sea (MS), have long been considered to be typical oligotrophic systems. Nitrate concentrations close to zero are generally observed in the upper surface waters of all these areas while large differences in phosphate similar to previous profiling observations in 1984, 1987 and 1991. But this is not always, or even typically, the case.

OPTICAL DETERMINATION OF PHYTOPLANKTON SIZE DISTRIBUTION FROM SATELLITE

Phytoplankton cell size is important to biogeochemical and food web processes. The goal is to determine the relative importance of phytoplankton cell size in remote sensing reflectance (Rrs) spectra in the presence of other optically active constituents. This is addressed through implementation of a forward optical model that incorporates the range of absorption and scattering variability due to phytoplankton and colored dissolved matter (CDM) in the global ocean from which Rrs is calculated by the radiative transfer software, Hydrolight. Spectral Rrs is investigated in terms of spectral shape and magnitude to ascertain changes in community size structure and the relative contribution of chlorophyll and CDM concentration to Rrs. Thresholds for chlorophyll and CDM concentration are determined, above which, any spectral changes are mainly due to any spectral shifting due to size. In certain situations of CDM values are used in conjunction with matched SeaWiFS Rrs spectra to determine if Rrs shifts can be discerned from a satellite platform. We seek to establish the role phytoplankton cell size has played in the observed change in chlorophyll concentration over the SeaWiFS mission.

CARBON ISOTOPES (δ13C & δ18O) IN CORALS AND ADJACENT NATURAL WATER AS RECORDERS OF CATCHMENT-TO-REEF REEFS TRANSFER

The terrestrial landscape of Puerto Rico has experienced major changes over the past 150 years, as the production of sugarcane crops dominated the landscape, while after 1960 agricultural practices diminished and many agricultural areas were gradually reforested. This land-use change has resulted in a shift in the average stable carbon isotopic composition of the living plant material (C4 to C3 plants) and surface soil organic matter. A similar isotopic shift may be recorded over the same time period in the skeletons of coastal corals influenced by river discharge. A 56 year record of δ13C in both coastal water samples and the coral skeleton. These data suggest that corals may provide a record of terrestrial influence on coral reefs.

MULTIDECADAL VARIABILITY OF THE ATLANTIC MOC AND ITS INFLUENCE ONTO THE ATMOSPHERE IN THE IPSL CLIMATE MODEL

The extent to which the climate is influenced by low-frequency changes in the Atlantic Meridional Overturning Circulation (AMOC) is investigated in a 500 year control simulation by the IPSL-CM4 coupled model. The multidecadal fluctuations of the AMOC are mostly sensitive to the deep convection in the subpolar gyre, which occurs South of Iceland in the model, and are primarily forced by salinity advection due to the East Atlantic Pattern (EAP). The North Atlantic Oscillation (NAO) plays a secondary role in the model. During summer, the AMOC variability is shown to have a significant impact on the atmosphere in the North Atlantic-European sector. This influence is due to an intrahemispheric Sea Surface Temperature (SST) anomaly pattern with opposite signs in the two hemispheres but largest amplitude in the north one. This mode corresponds to the model Atlantic Multidecadal Oscillation (AMO) and bears some similarity with the observed one. The atmospheric response is such that it induces a weak positive feedback on the AMOC.

Muñoz-Hincapié, M. E., University of Puerto Rico, Lajas, Puerto Rico, USA, milton.munozhincapi@gmail.com; Morell, J., University of Puerto Rico, Lajas, Puerto Rico, USA, oceanog@soqui.net; Corredor, J., University of Puerto Rico, Lajas, Puerto Rico, USA, quimocare@caribe.net

RESPIRATORY RATES AT THE CARIBBEAN TIME SERIES STATION (CATS)

Plankton community respiratory rates were quantified at the Caribbean Time Series station (CATS) on the AMOC. The changes in photosynthesis are mostly sensitive to the deep convection in the subpolar gyre, which occurs South of Iceland in the model, and are primarily forced by salinity advection due to the East Atlantic Pattern (EAP). The North Atlantic Oscillation (NAO) plays a secondary role in the model. During summer, the AMOC variability is shown to have a significant impact on the atmosphere in the North Atlantic-European sector. This influence is due to an intrahemispheric Sea Surface Temperature (SST) anomaly pattern with opposite signs in the two hemispheres but largest amplitude in the north one. This mode corresponds to the model Atlantic Multidecadal Oscillation (AMO) and bears some similarity with the observed one. The atmospheric response is such that it induces a weak positive feedback on the AMOC.
five to thirteen representative depths between the surface and 1000 m. Over this depth span, the different water masses were sampled in the Caribbean Surface Waters, Subtropical Underwater, Mode water, the tropical Atlantic Central Water and the Antarctic Intermediate Water. Comparison of ET8-derived respiration rates to primary production determinations revealed that the P/R ratio was less than 1 in 64 % of the sample dates showing predominance of heterotrophic metabolism. The remaining 36 % of the cases exhibits a P/R ratio higher than 1 in a minor tendency for predominance of autotrophic metabolism. Respiratory rates, integrated to 1000 m, ranged from 512 to 1922 mg C m-2 d-1. Rates in the euphotic layer (CSW) averaged 373 mg C m-2 d-1 representing 29 % of the total water column respiration. Integrated respiration below the surface mass (SWU, MODE, and ACW water masses) accounted for the remaining 71 %. Heterotrophic communities of the mesopelagic layer (150 - 1000m) thus account for the bulk of respiratory activity in this region. Our results indicate that despite large export of organic matter from surface waters, additional allochthonous inputs of organic matter must be considered.

RISING CO2 DISSIPROPORTIONATELY AFFECTS EXTENSION RATES VERSUS MASS DEPOSITION RATES IN REEF CORALS

Although ocean acidification is known to decrease calcification in corals, such effects have been measured almost exclusively in terms of the mass deposition of aragonite. This study used manipulative experiments to test the hypothesis that increasing pCO2 has unequal effects on different components of growth that contribute to colony size and morphology. First, increased levels of CO2 (700 vs. 350 ppm) were tested for effects on the mass deposition (mg cm-2 day-1) and linear extension (µm day-1) of Acropora hyacinthus and A. pulchra from French Polynesia, and second, the results were used to explore the covariance between each growth component. Overall, mass deposition and linear extension were significantly reduced by high pCO2, and in both species the linear extension was reduced more than twice as much (52%) as mass deposition (26%). For these species, the inhibitory effects of elevated pCO2 on aragonite deposition apparently were modulated by changes in skeletal density and/or shape. These results are important as they reveal the potential role of morphological plasticity in translating the effects of ocean acidification into coral reef acroporids.

CHARACTERIZING POLLUTION PLUME DYNAMICS USING CLOSTRIDIUM PERFRINGENS DISTRIBUTION AND MOLECULAR DIVERSITY.

Clostridium perfringens is a common member of the intestinal tract of many animals and a long-lived fecal pollution marker due to spore forming capabilities. Particle attached C. perfringens was enumerated in sediments captured at three nearshore locations at varying distances from the Milwaukee harbor. Samples collected within the harbor contained an average of 16000 CFU g substrate-1. Particles collected ~200 m from the harbor had concentrations eight times lower than the harbor. C. perfringens was repeatedly recovered from the other locations, but levels fluctuated drastically, which may be due to the influence of current and wind direction on plume dispersion. This organism was also recovered from the other locations, but levels fluctuated drastically, which may be due to the influence of current and wind direction on plume dispersion. This organism was also recovered from the other locations, but levels fluctuated drastically, which may be due to the influence of current and wind direction on plume dispersion. This organism was also recovered from the other locations, but levels fluctuated drastically, which may be due to the influence of current and wind direction on plume dispersion. This organism was also recovered from the other locations, but levels fluctuated drastically, which may be due to the influence of current and wind direction on plume dispersion. This organism was also recovered from the other locations, but levels fluctuated drastically, which may be due to the influence of current and wind direction on plume dispersion.
than elsewhere in the bay. Large eddies form at the jet’s edge and it serves as an important mechanism for stirring and mixing throughout the bay. We report observational data from a field experiment examining the circulation. The jet exhibits a variety of flow structures and appears to be strongly influenced by winds over the bay. The velocity signal of the jet generally appears first at around mid-depth of the water column and evolves until it is confined to the top 2-3 m below the surface with a slow counter flow underneath. However, the jet sometimes spans the full water column. These deeper jet events appear to be associated with the sudden relaxation of wind forcing. The observations, in particular drifter paths, are compared with model results from the hydrodynamic model Dell3d.

COMPARISON OF EXTENDED RANGE UNDERWATER IMAGING TECHNIQUES

Optical imaging in turbid ocean water is a challenge due to the high probability that light will scatter multiple times as it propagates to and from the object of interest. Techniques that have been developed to suppress the contribution from scattered light and increase the image contrast include those using a pulsed source with a range-gated receiver or a modulated continuous wave source with an coherent RF receiver. The main disadvantage of the continuous wave, amplitude modulated system is that it is impossible to 4f gate out the volumetric backscatter signal as can be done in the pulsed, range-gated system. Therefore, the concept of a modulated pulse, range-gated system is currently being evaluated to understand the benefits and limitations of this approach relative to existing techniques. A theoretical performance prediction model is currently being used to compare these three different underwater imaging approaches. Laboratory tank experiments are also being conducted to validate theoretical predictions and to determine what hardware limitations must be considered when comparing these techniques. Results from both model predictions and laboratory experiments will be presented.

PROCESSING THE DEEP-BIOSPHERE

Precondition to achieve environmentally relevant results is research in pristine habitat. Benthic in-situ conditions have to be maintained during the sequences of retrieval, transfer, storage and downstream analysis. TUB developed PRESS (Pressurized Core Sub-sampling and Extrusion System) in the EU project HYACE/HYACINTH which enables sterile, anaerobic and well defined sectioning of drilled pressure-cores (HYACE Rotary- and Fugro Percussion Cores) into transportation and investigation chambers. When coupled with DeepSoilBug (University Cardiff) it allows sub-sampling and incubation of coaxial core-sections to examine high-pressure adapted bacteria or remote biogeochemical processes in defined research conditions of the laboratory. A joint project of the Deutsche Forschungsgemeinschaft (DFG) PRESS was successfully deployed in the Gulf of Mexico, on IODP Expedition 311, and as part of the NGHP expedition 01-TUB currently works on concepts to scale down the system, reducing logistical and financial expenses and likewise on the feedback its implementation - requiring less operating space. Redesigning the cutting mechanism simultaneously adjusts the system to harder cores (e.g., ICDP). Novel transportation chambers for processed sub-samples intend to make the system more attractive for a broad spectrum of users and reduce their interdependence.

THE CARIACO OCEAN TIME SERIES PROGRAM

The CARIACO program has conducted monthly oceanographic cruises to the Cariaco Basin (10°30’N, 64°40’W, SE Caribbean Sea) since November 1995. One mooring with five sediment traps and one with two ADCPs are in place. This basin is open to the Caribbean Sea in the upper 140 m and is well ventilated above this sill depth, but waters below about 250 m are anoxic. The objective of the series is to understand the relationship between hydrography, community composition, primary production, microbially mediated processes and trace inputs, sediment fluxes, and element cycling in the water column, and how changes in these processes are preserved in seafloor sediments. These sediments are one of the most important paleoclimate records available, and the series is designed to link knowledge about modern physical and biogeochemical processes with ancient regional oceanography. We discuss apparent changes in nutrient availability observed over the short life of the time series that have resulted in these ecosystems. These are reflected in the chemistry, amount of sinking particles, and other processes that seem to have affected even the important regional sardine fisheries.

WAVE-DRIVEN CIRCULATION AND FLUSHING OF A COASTAL BAY

A coupled numerical model is used to simulate the waves and currents in a coastal bay during the landfall of a hurricane with offshore significant wave heights of up to 9.1 m. Extensive wave breaking along the shoreline and over a mid-bay shoal induced the development of a strong mean circulation in the bay, in combination with currents forced by wind, tide and storm surge. The general circulation pattern consisted of inflows along the shoreline and over the shoal region, and outflows that were observed in deeper channels near the shoal. The predicted currents agree with observations of 0.4 m/s mean flows only when wave-forcing is included in the circulation model. Wave-driven flows accounted for over 50% of the high flushing rates during the storm and induced strong velocity gradients over short (~200 m) horizontal length scales.

RECENT AQUATIC ECOSYSTEM RESPONSE TO ENVIRONMENTAL EVENTS REVEALED FROM 210Pb SEDIMENT PROFILES

The power of the sediment-water interface to record ecological events, anthropogenic impacts as well as catastrophic episodes is unquestionable. However, the reading of the record requires an accurate and well calibrated record on sediment cores collected in several depositional environments that may bring some light on the usefulness of 210Pb as tracer rather than only a geochronological tool. In the Mediterranean sediment cores (Morocco, Algeria), 210Pb as well as its isotopic signature, clearly depicts the origin of heavy metals contents. In another coastal aquatic system, 210Pb, is unable to represent sediment accretion and time, but rather a biogeochemical shift on the sediment water interface that took place few decades ago as a result of aquaculture (Southern Chile). In two different set of sediment cores, one from the Chilean Lake district, and the others from the Argentinean Pampa plains, depict similarly, on the 210Pb record sudden catastrophic events. We discuss the use of 210Pb sediment profiles not only as a timing tool, but also as a tracer of environmental changes both natural and anthropogenic in aquatic ecosystems.

MODELING THE FLOW PAST ISLANDS USING THE FINE ELEMENT METHOD

Observations of flow past islands have shown a variety of behaviour bearing a resemblance to the classical fluid dynamics problem of flow past a cylinder. Observations have also elucidated the presence of intense shear layers, along the edge of the separation bubble, and the presence of vertical motions and secondary circulations. We report on the results of some simple experiments on flow past a cylinder on which the traditional 2D domain has been expanded to three dimensions with a no-slip bottom boundary condition, the domain is then suitable for the study of idealised flow past islands. By using the Imperial College Ocean Model in a dynamically adaptive mode, we are able to explicitly resolve the shear layers that form in the event of flow separation. The results, at a range of parameter values, reveal complex secondary circulations and vertical motions both up- and down-stream of the cylinder. Those in the wake can be attributed to Ekman spin-down processes. However, those upstream of the cylinder are more likely to be due to the combined effects of shear and flow curvature. In the past, it has been argued that island wakes are closed and cut off from any exchange with the free stream. We present evidence contrary to this and show flow configurations in which the flow crosses the shear layers to enter the wake. We also examine the changes that moving to a domain in which the depth is shallow, with respect to the cylinder diameter, brings to the resulting flow.

INTER-DECADAL CHANGES OF THE SUMMER CARIBBEAN LOW-LEVEL JET

The summer Caribbean low-level jet (CBNLLJ) has an onset in June, a maximum in July and decay in August. The inter-annual variability of the summer CBNLLJ responds to sea level pressure (SLP) and sea surface temperature (SST) gradients between the tropical Pacific and the tropical Atlantic. The objective of this study is to determine if the CBNLLJ has changed its intensity and persistence in different decades and what conditions have triggered these changes. This is important with respect to the climate conditions that triggered these changes. This is important with respect to the climate conditions that influenced extreme intra American monsoon events. To determine the changes, statistical diagnostics of summer CBNLLJ anomalies are analyzed for different periods, in particular 1958-1978 and 1979-2001. Also analyzed were inter-basin SLP and SST gradient indices. The CBNLLJ showed more intense events and greater persistence during
VARIABILITY IN PRIMARY PRODUCTION RATES OFF THE SOUTHERN CALIFORNIA COAST: APPLICATION OF THE OXYGEN TRIPLE ISOTOPE METHOD

Delphi's fundamental importance of primary production (PP) to marine ecosystems and carbon cycle dynamics, large scale PP estimates remain poorly constrained, particularly for dynamic coastal regions. Conversion of satellite data to quantitative PP estimates requires algorithms that, to date, have relied on in vitro 14C PP measurements. A relatively new in situ technique for estimation of gross primary production (GPP) based on precise measurements of the three stable oxygen isotopes in dissolved O2 provides expanded spatiotemporal resolution and avoids in vitro effects associated with 14C PP. Contemporaneous measurement of O2/Ar gas ratio provides an estimate of the biological oxygen saturation state. Together, these measurements yield the ratio of net community production (NCP) to GPP, or NG, an indicator of carbon export efficiency. We measured the oxygen triple isotopic composition of dissolved O2 and the dissolved O2/Ar gas ratio of seawater samples on five CalCOFI cruises between November 2005 and January 2007 and calculated mixed layer GPP and NCP rates. We will discuss the variability of GPP and NG in the study region and compare these in situ rates to 14C PP rates routinely measured on CalCOFI cruises.

NON-REDFIELD TYPE BEHAVIOR OF DINOFLAGELLATE ALEXANDRIUM TAMARENSE IN RELATION TO NITROGEN AND PHOSPHORUS LIMITATION IN COASTAL WATER

Dissolved inorganic nitrogen (DIN) occupied 90% by nitrate (NO3-) and dissolved inorganic phosphorus (PO43-) are primary nutrients in coastal ecosystems in Kure Bay, Hiroshima. Their concentrations were significantly and systematically different from sea surface conditions. Furthermore, the data suggested that Alexandrium tamarense is bioconcentrating these nutrients to be exposed to variable nutrient concentrations and ratios. The present study investigated the nutrient dynamics of A. tamarense based on natural environment studies and controlled laboratory experiments. The cells seemed to take up the nutrients with non-Redfield DIN:PO4 ratio ≤ 8, and P-limitation at NO3:PO4 ratio ≥ 16. Under P-limitation, A. tamarense accumulated more paralytic shellfish poison (PSP) than N-limitation. Therefore, DIN:PO4 ratio might be important factor to determine the nutrient limitation and PSP production of A. tamarense, and then shellfish poisoning in a coastal ecosystem.

ASSESSING THE PERFORMANCE AND OPERATIONAL IMPACTS OF THE OCEAN SCIENCE, TECHNOLOGY, AND OPERATIONS WORKFORCE

One of the major goals of ocean science, technology, and operations (OSTO) workforce is to produce products that enable better management and use of the ocean environment. For example, ocean observing, analysis, and forecasting systems generate products for monitoring and predicting ocean conditions that are used in a wide range of applications (e.g., environmental management, ocean policy, resource extraction, national defense). For many reasons, it is important to objectively and quantitatively assess the performance of these products and their operational impacts (e.g., the accuracy of ocean forecasts and the impacts of these forecasts on the decisions made by end users of the forecasts). A major motivation for conducting such assessments is that they provide valuable feedback to the OSTO workforce on how to improve the quality and effectiveness of its products. For end users, these assessments can lead to improved understanding and application of the products (e.g., increased awareness of ocean forecast uncertainties and how to account for those uncertainties in decision making). We will present examples of online systems for developing these assessments, plus sample product assessments.

VARIABILITY AND CHANGE IN SOUTHERN OCEAN ECOSYSTEMS: THE EFFECTS OF CLIMATE FLUCTUATIONS AND BIOLOGICAL INTERACTIONS ON THE DYNAMICS OF SCOTIA SEA ECOSYSTEMS

Determining the factors generating change in ocean ecosystems requires an understanding of how biological and physical processes interact across a wide range of scales. Here we consider the Scotia Sea ecosystem and highlight the role of biological and physical interactions in generating large-scale ecosystem structure. We then examine the factors generating coherent variability in the ecosystem between years. In particular, we examine the effects of physical variations (sea surface temperature and sea ice) on the dynamics of the regional populations of Antarctic krill and their predators. We further consider how these fluctuations are linked to climate related variation through the El Nino-Southern Oscillation, the Southern Annular Mode variation and the Antarctic Circumpolar Current. On the basis of these analyses of sub-decadal variation we then consider the factors generating longer-term change (over the last 200 years) in this ecosystem. Finally, we discuss the development of predictions of future change in a system subject to both climate and harvested driving changes.

TIDAL AND RESIDUAL CIRCULATION IN ST. ANDREW BAY, FL

The St. Andrew Bay System, Florida, consists of four sub-estuaries: North Bay, West Bay, East Bay, and St. Andrew Bay. The system has limited freshwater input and is the only major drainage basin located entirely in the Florida Panhandle. The tide is diurnal with a range of 0.3 m. Two 24-hour surveys were conducted during spring and neap tides to understand the roles of different forces on the residual flow under differing tidal regimes. Observed velocities were fitted to diurnal and semidiurnal harmonics separating tidal from subtidal motions. The results indicate that freshwater input was the main driving force during the measurement periods. The residual flow is compared to an analytic model that allows variations in the relative contributions from Coriolis accelerations and friction through the Ekman number. A solution with an Ekman number of 0.045 makes the observations best. This indicates that the overall dynamics are governed by pressure gradient, Coriolis and friction. Locally, advective accelerations become important, like around a cape at the intersection of West Bay and St. Andrew Bay.

DIFFERENT APPROACHES TO MODELING INNER-SHELF ÅE SORTED BEDFORMS AND THEIR RESPONSES TO COMPLEX FORCING SCENARIOS

Numerous observations have revealed that a striking type of large-scale pattern adorns many inner continental shelves, in which the sediment is sharply segregated into swaths of coarse material separated by domains of fine sand. Coarse swaths, usually on the order of 100 m wide, often extend kilometers in the offshore direction. Previous work offered a hypothesis for the formation of these Åe-sorted bedforms, and an exploratory numerical model to test its plausibility. The hypothesis and model involve a grain-size sorting feedback and subsequent emergent interactions that lead to an unusual kind of large-scale bedform. The previous exploratory numerical model represented the key relationship between bed composition and sediment flux with simple parameterizations that lump together ripple growth and the effects on sediment and current profiles. A recent model reproduces those results using more explicit representations of relatively small- and fast-scale processes. This new model also allows an exploration of diverse geometries that result under complex wave- and current-forcing scenarios. However, using different parameters does not produce the individual processes produces qualitatively different results. Our attempts to use both top-down models and more explicit numerical reductionist models provide an instructive case study highlighting the advantages and pitfalls of different modeling strategies for dealing with interactions spanning a range of scales.
THERE IS THE DRAMATIC CHANGE IN THE TERMINATION OF THE EUC AND THE ASSOCIATED CASCADES
middle to late Holocene palynomorph assemblages (MW-1 P-4 and IL-2 P-3), the palynomorph assemblages are represented by sudden increase in Pinus pollen and abrupt decrease in Quercus pollen in comparison with the earlier zones. There is also a notable rise in the amount of Gramineae and Artemisia. These assemblages record the onset of more unstable forest condition, and the climatic degradation and forest regression at that time can be presumed. During the deposition of MW-1 P-4 and IL-2 P-3, the climate was probably moister and drier. Radiocarbon dates in the lower part of IL-2 P-3 (-6.543 m) indicate the deposition initiated from 4,470 ± 140 yr BP. The increase in spores from Peridoliophsida (Laevigatosporites, Polyphidioporsides) and the first appearance of spores from Bryophyta (Spinifexes) are another features of MW-1 P-4 and IL-2 P-3. These variations are probably related to increased fluvial activities. The high freshwater input to the coring sites could have also caused the stronger water stratification, favoring the development of fine stratification with very low degree of bioturbation in the upper parts of MW-1 unit-5 and IL-2 unit-3.

USE OF PASSIVE INTEGRATED TRANSPONDER TAG FOR ASSESSING THE ALONGSHORE TRANSPORT RATE OF GRAVEL, NORTH ARCTIC ALASKA

The seasonal alongshore transport direction and rate was monitored of gravel tagged with 12mm-long passive integrated transponder (PIT). In June 2006 fifty-tagged gravels were injected at each of two seaward MTL sites on Narwhal Island, a sand-gravel barrier in Arctic Alaska. In July 50 gravels were injected at two additional sites. In July, 35-50% of gravels which were identified from the first site, had drifted alongshore up to 3m, and by August this drift had extended up to 8m westward. In mid-October 2006 none of the tagged gravels was identified, while in July 2007 subsequent to the 8-month winter only one of the original 200 tagged gravels was detected. The sole gravel had moved 35m west of the June injection point. The post-winter poor detection of the tagged gravels at beach surface is likely to their burial under ice-pushed sediment mounds (up to 3m high), and their loss to subtidal zone by shoreface ice and meltwater. Thus, PIT tag use to assess the annual alongshore transport rate of gravel in Alaskan arctic can be complicated by ice action.

BIODIVERSITY OF CHAETOGNATHS OF THE ANDAMAN SEA, INDIAN OCEAN

Andaman Sea is one of the prominent biodiversity hotspots in the Indian Ocean. Stratified zooplankton collections were made at 32 locations during 2003-2006. Average density of chaetognaths was 8.5/m³ in open ocean and 41.6/m³ in coastal waters. Twenty species of chaetognaths including two new species occur in the area. In the oceanic sector Sagitta enflata predominated the layer above thermocline followed by S. neglecta, S. bipunctata, S. crinata, S. pacifica, Pterosagitta draco and S. regularis. In the 500m to thermocline S. decipiens dominated followed by Eukrohnia fowleri. Congregations of S. decipiens, a mesopelagic species was occasionally found in the mixed layer (upto 9.9 m) during NE monsoon associated with the upward movement of species due to recurrent severe cyclones in the Bay of Bengal. In the coastal waters either S. enflata or S. neglecta predominated. Krohnitta balogapali and Sagitta meenakshi are endemic to the area. Maximum species diversity was observed above thermocline. Invariably two clusters were found along each stratum accounting 70% similarity. Latitudinal species diversity increases towards south. Variability in chaetognath community is influenced by unique physical features of the area.

CLIMATE FORCING OF MID-ATLANTIC ESTUARIES IN THE 20TH CENTURY

To better understand the implications of anthropogenic climate change for three major Mid-Atlantic estuaries (Chesapeake Bay, Delaware Bay, and the Hudson River Estuary), we (1) analyzed the regional output of seven global climate models and (2) estimated the impact of sea-level rise on estuarine salinity. The climate simulation given by the average of the models was generally superior to individual models, which differed dramatically in their ability to simulate 20th-century climate. All models warmed over the 21st century under the six greenhouse gas scenarios considered, with an increase of 4.7 ± 2.0°C (model
mean ± 1 standard deviation) for the A2 scenario (a medium-high emission scenario) over the Chesapeake Bay watershed by 2070-2099. Precipitation projections had much weaker consensus, with a corresponding increase of 3 ± 12% for the A2 scenario, but in winter there was a more consistent increase of 8 ± 7%. Precipitation projections were within the range of interannual variability but temperature projections were not. Streamflow-adjusted salinity variations were analyzed in Delaware and Chesapeake Bay during the past several decades in order to isolate the influence of sea-level rise. Both time series show long-term increases that are somewhat larger than hydrodynamic models forced with increasing sea level predict.

BATHYMETRY INVERSION BY SEQUENTIAL DATA ASSIMILATION OF TSUNAMI SIMULATION MODEL

We demonstrate the framework of sequential data assimilation for correcting bottom topography which can be regarded as boundary condition of various simulation models. We used shallow water equations model and tide gauge data of tsunami in this assimilation. Not of our concerns are paid to validate information on depths of sea bottom. The reason is that bottom topography data sets are erroneous and correction of depths can make simulation results more accurate. The particle filter is used as assimilation method because of the computational reason. In this study, we conducted two types of numerical experiment and analysis: twin experiment of bottom topography correction and bottom topography estimation in the Japan Sea. The result of twin experiment shows the efficiency of our sequential data assimilation approach. It also shows the guideline on the noise term of simulation model. The result of assimilation to real data suggests that almost all of Yamoto Rises is shallower than the average of available data sets.

SMALL-SCALE EDDIES AROUND THE KURIL STRAITS GENERATED BY BAROTROPIC TIDAL FLOW

Numerous small-scale eddies have been found from LANDSAT infra-red imagery around the Kuril Straits, which are located between the Okhotsk Sea and the North Pacific Ocean, whose ventilation is deeply affected by the transport and mixing at the Kuril Straits (Nakamura et al., 2006). The diameters of the observed eddies range from 2 to 30 km, much smaller than those of eddies previously found in this region (50 to 400 km). Our tidal simulations show that small-scale eddies similar to those observed can be generated by diurnal barotropic tides, particularly the K1 tide, and induce mixing and transport of water. The eddy generation is caused through the effects of both the coastal boundary and the vorticity generation due to the stretching of water columns. The latter effect causes the eddy growth even after eddies leave the coast. Interestingly, anticlockwise eddies are larger due to the dynamical balance and the advection by the tidal flow whose direction rotates clockwise in the straits. The latter advection moves anticlockwise eddies offshore but clockwise eddies onshore, which is unfavorable for the growth of clockwise eddies. Such eddy generation varies greatly with tidal modulation in terms of both their number and intensity.
VARIAIBILITY OF NONLINEAR INTERNAL WAVES ON THE CONTINENTAL SHELF

Nonlinear Internal Wave (NLIW) packets are pervasive features in the coastal ocean. Yet while they arrive like clockwork in some regions like the South China Sea, they occur with a high degree of variability on most continental shelves. Here we explore their variability using moored observations from the New Jersey Shelf obtained during the ONR Shallow Water '06 (SW06) experiment. During a 50-day period, NLIW activity was found to be both spatially inhomogeneous and temporally intermittent. Wave packets propagated in many different directions, producing highly 3D wave fields and irregular wave timing. Initial results indicate that NLIW energy levels do not scale with the strength of the barotropic tide. Instead, NLIW activity is found to be linked to the strength of the internal tide, with greater activity occurring during the neap barotropic tide. While topographic forcing and, seasonal stratification are certainly important, sudden changes in the location of shelfbreak fronts and mesoscale motions must play a role in setting the strength of the internal tide, its nonlinear steepening, and subsequent propagation of NLIWs.

LONG-TERM (1992-2007) CHANGES IN DIATOM AND PHAEOCYSTIS GLOBOSA SPRING BLOOM DYNAMICS IN COASTAL WATERS OF THE EASTERN ENGLISH CHANNEL.

Massive Phaeocystis globosa and diatom spring blooms succession occur each year in coastal waters of the eastern English Channel. The present study aimed to determine the long-term trends of phytoplankton dynamics from 1992 to 2007 with special emphasis on community composition. The correlations observed between the North Atlantic Oscillation (NAO), nutrient loads and phytoplankton species dynamics were similar to those recorded at a long-term scale (1988-2001) in the Southern Bight of the North Sea. Drastic changes in diatom biomass and composition appeared in 1994 and 2004. They consisted in a shift between a Guinardiaceae assemblage (Rhizosolenia spp. and Guinardia spp.) and potentially toxic species of the genus Pseudonitzschia. The first assemblage is probably related to the intensity of the North Atlantic inflow into the English Channel, the second one seems to be linked to changes in nutrient ratios. Moreover, these Pseudonitzschia spp. blooms concomitantly increased with the dominance of Phaeocystis globosa. We suggest that these pennate microzoic diatoms could develop on organic components produced by Phaeocystis colonies.

LATERAL MIXING BY INTERLEAVING IN THE EQUATORIAL THERMOCLINE

The observation of interleaving of water masses within the thermocline of the equatorial Pacific raises questions as to why the interleaving is present and what impact it has on mixing and the broader scale structure of the flow and tracer fields. Individual layers are of order 10m thick and stretch for order 200 km and 1000 km in the meridional and zonal directions, respectively. Numerical experiments which reproduce the interleaving suggest that the interleaving can have a large impact on both vertical and lateral mixing of momentum, potential vorticity and tracers. Here we report on theoretical and numerical work on the stability of steady and time dependent background flows and the subsequent equilibration of the flow. We contrast freely evolving and forced flows as well as 2D versus 3D disturbances. The relative roles of inertial and parametric subharmonic instabilities change depending on the flow configuration and as the flow evolves. The implications for lateral mixing in the equatorial thermocline and its impact on ocean dynamics will be discussed. The inference is that scale interactions involving interleaving may link mixing in the equatorial thermocline to variations of the larger scale flow on interannual to interseasonal timescales.

INFRASONIC PRECURSOR OF TROPICAL CYCLONE

Intense infrasonic emission was observed prior to the birth of a tropical cyclone (Netrava, 1999). It is connected apparently with instability of atmospheric layers in cyclone area. There are different mechanisms of this effect, the condensation instability is considered in the present paper. The Cooling of air in upward convection flow makes water vapor supersaturated. This is a nonequilibrium state of fluid where effect of instability can be developed in the process of infrasonic precursor. Solution of initial equation indicates the effect of infrasonic wave amplification and its nonlinear evolution. Corresponding analyses of them make it possible to clarify the principally important aspects of cyclone infrasonic precursors.

VARIAIBILITY OF MODE AND INTERMEDIATE WATERS IN DRAKE PASSAGE DURING THE LATE 20TH AND EARLY 21ST CENTURIES

The variability of the Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW) flowing through Drake Passage in the last four decades is examined using 24 hydrographic and tracer sections and over 400 Argo hydrographic profiles. SAMW exhibits a decadal trend toward increasing potential temperature and salinity during the 1970s and a reverse decreasing tendency between 1990 and 2005, at which point the coldest and freshest SAMW on record is encountered. In contrast, AAIW undergoes a steady freshening between the 1970s and the 21st century. Both SAMW and AAIW experience marked interannual changes in their thermohaline properties, potential vorticity, and oxygen and nutrient concentrations that co-vary differently for each water mass. The contrasting evolutions of SAMW and AAIW over the study period are interpreted in terms of distinct formation areas and mechanisms. These reveal that SAMW variability is predominantly controlled by tropical modulation of air-sea interaction in the Southeast Pacific, and that AAIW changes are more closely linked to the rapid climate change west of the Antarctic Peninsula. The likelihood of an anthropogenic influence in the observed variability is discussed.

PLANKTONIC RESPONSE TO UV IN A CHANGING ENVIRONMENT: EFFECTS OF ACUTE AND CHRONIC UV-B INFRARED WARMING AND OTHER STRESSORS ON THE FUNCTIONAL RESPONSES

Planktonic sensitivity to UV is affected by climate change through variations in UV exposure (modulated by surface irradiance, CDOM and vertical mixing), temperature, and CO2. Warming can enhance repair of UV damage, especially important when the UV temperature ratio is high in the early spring. We manipulated temperature and UV exposure of natural microbial assemblages from Lake Giles, PA during April when surface temperature is rapidly increasing. Biological weighting functions for UV inhibition of photosynthesis and bacterial incorporation of leucine were estimated based on polychromatic exposures to filtered xenon lamp irradiance. At the initial temperature (5.5°C), surface UV 2

SHORELINE ANALYSIS AND BARRIER ISLAND DYNAMICS: EVENT TO DECADECAL SCALE PATTERNS FROM CEDAR AND PARRAMORE ISLANDS, VIRGINIA

Data from aerial photographs and topographic maps have been analyzed in tandem with aerial LiDAR and high-resolution GPS surveys to determine decadal-scale and event-scale coastal retreat rates and patterns on Cedar and Parramore Islands. In past literature, it
was suggested that Cedar and Parramore lie in two distinct erosional zones (threshold retreat and moderate to high rates). Periodically, the islands are geographically neighbors, exposed to the same general forcing processes and conditions. Cedar Island is prone to parallel beach erosion while Parramore Island undergoes clockwise rotational erosion. The current data, however, suggest that Cedar Island has undergone some degree of clockwise rotation and is eroding at an average island rate of 5.3 m/yr (1852-2002) while Parramore experienced parallel beach retreat of about 12.6 m/yr (1994-2007) based on end-point measurements. The data further indicate that there has been acceleration in erosion rates over the past decade.

ROSE: COINCIDENT SEISMIC AND HYDROGRAPHIC SURVEY OF THE GULF STREAM AND SLOW WATERS SOUTHEAST OF NOVA SCOTIA

In the summer of 2007, the Government of Canada contracted a large-scale multi-channel seismic (MCS) survey southeast of Nova Scotia with the intent to extend Canadian jurisdiction of the seabed and its natural resources under the United Nations Convention on the Law of the Sea (UNCLOS). The survey lines crossed a major oceanographic boundary between the Gulf Stream and the slope waters. The primary goal of our research undertaken on R/V Endeavor during the 2007 cruise EN438 was to collect a hydrographic dataset coincident with a part of the UNCLOS MCS survey. We collected ~350 km of hydrographic data at a spatial density ~500-1000 m using shipboard XBTs and CTDs. In addition to analyzing the MCS data to gain quantitative understanding about the recorded water column reflux, we plan to use XBT/CTD data to produce reflectivity sections and carry out waveform modelling to study spatial resolution limits of seismic oceanography. We also recorded repeat and reverse profile XBT/CTD data to investigate short period temporal effects on seismic imaging in this dynamic environment.

VIRUS AND BACTERIA DISTRIBUTION AND ABUNDANCE ALONG A EUTROPHICATION GRADIENT IN THE COASTAL BAYS OF MARYLAND, USA

Anthropogenic activities including increased use of fertilizers, poor sewage treatment, and watershed development have increased nutrient input in estuaries worldwide. The Coastal Bays of Maryland are characterized by high nutrients, long water residence times, and decreasing water quality. This study explored how different land uses in these coastal bays impact virus and bacterial distribution and abundance. Bacteria concentrations ranged from 10^{9}-10^{10} m^{-3} and VLP concentrations ranged from 10^{-10}-10^{9} m^{-3}. Bacteria abundance was significantly positively correlated (p < 0.05) with VLP abundance, salinity, chlorophyll and total nitrogen (predominantly organic), total phosphorus, and temperature. The patterns emphasize the importance of the microbial loop in estuarine nutrient processing.

SYNTHESIS AND APPLICATIONS OF THE MULTI-YEAR TIME SERIES DATA FROM THE LOBO SENSOR NETWORK IN ELKHORN SLOUGH, CA

The Land/Ocean Biogeochemical Observatory (LOBO) in Elkhorn Slough, CA has operated since 2001; a period sufficient to resolve the seasonal variability in nutrient fluxes and metabolic processes of the estuary. The combination of chemical, biological, and physical measurements from the LOBO network allowed extensive characterization of complex ecosystem processes related to nutrient cycling and primary productivity in the coastal environment. The extended high resolution time-series using shipboard XBTs revealed important relationships between climate, tides, and anthropogenic activity on estuarine nutrient levels and primary productivity. As a whole, the observations from the LOBO network have contributed to the conservation of this important ecosystem through: 1) scientific understanding, 2) effective management decisions, and 3) public outreach and education. We will describe these contributions with an emphasis on how the capabilities of the network could not be duplicated with traditional sampling methods.

SEASONAL VARIABILITY OF OCEANIC ORGANIC SULFUR COMPOUNDS IN THE SUBTROPICAL GYRE OF THE NORTH ATLANTIC OCEAN: DMS, DMSP AND DMSO

Monthly vertical profiles of dimethylsulfide (DMS), particulate and dissolved dimethyl-sulfoniopropionate (DMSPp and DMSp), and dimethylsulfoxide (DMSO) are sampled in the North Atlantic Ocean at the Bermuda Atlantic Time-series Study (BATS) site from March 2005 to September 2005. Clear seasonal cycles are evident in the distributions of DMS and DMSP. DMS displays the so-called summer-paradox with increased concentrations (up to 4 nM) during the summer-stratified period in the subtropical gyre surface waters. DMSP concentrations show complex variability with concentrations typically <1 nM. DMSPp routinely is the largest reservoir of dimethylated sulfur with concentrations ranging from 10^{-7}-10^{-4} nM. Correlations between the sulfur compounds and the extensive time-series data sets collected from the Sargasso Sea are expected to address the sources of this seasonal variability.

THE INFLUENCE OF MESOSCALE EDDIES ON INORGANIC CARBON CYCLING AND AIR-SEA CO2 GAS EXCHANGE IN THE NORTH ATLANTIC OCEAN

In the subtropical gyre of the North Atlantic Ocean, recent studies have shown that mesoscale eddies have an important role in modulating nutrient supply, new production and export production. Mesoscale eddies may also have an important role in controlling the inorganic carbon cycle of the upper ocean and influencing air-sea carbon dioxide gas exchange. As part of the EDDIES project in 2004 and 2005, and from earlier studies in the late 1990s, we examine how mesoscale eddies influence inorganic carbon distributions and carbon dioxide dynamics in the upper ocean. We find that the influence and response is different for a variety of mesoscale eddy features, from cyclonic eddies to Eighteen Degree Mode Water eddies, and also dependent on the age and evolving nature of the feature. For example, the wind-driven mesoscale eddy resulted in excess inorganic carbon relative to nitrate and canonical C:N elemental stoichiometry in the surface with subsequent enhancement of sea-to-air carbon dioxide flux. With field and model understanding of eddy type and frequency, we examine their contribution to the carbon dioxide sink and sources.

COUPLING AN IN SITU AUTONOMOUS PLATFORM AND A MONITORING PROGRAM IN THE CALOOSAHATCHEE RIVER, FL TO UNDERSTAND NUTRIENT DYNAMICS OF COASTAL HABS

The primary objective of this project was to assess potential links between Kariena brevis blooms in southwest Florida ocean waters and changes in Caloosahatchee river flow and nutrient inputs into this region. Two continuously moored MARVIN platforms were used with a traditional field sampling approach. DMSP to survey the un gated portion of the river for various water quality and nutrient parameters since 2005. Results indicate significant amounts of nitrogen and phosphorus, in both organic and inorganic forms, enter the Caloosahatchee River at different locations, but were not easily correlated with changes in river flow. The fate of these nutrients entering the West Florida Shelf depends upon the complex physico-chemical and biological parameters present in various regions of the river. These include: prevailing coastal current direction and velocity, optical properties of the water, the phytoplankton community structure and nutrient needs at the time of nutrient delivery, short- and long-term climatological events like the passage of fronts.
or droughts. The paradox of certain historical water quality parameters improving while others decline underscores the need for high frequency measurements provided by autonomous platforms.

HYDROCARBONS AND METALS IN TISSUES OF BENTHIC CRUSTACEANS AND MOLLUSCS FROM THE NEAR-SHORE BEAUFORT SEA: POSSIBLE EFFECTS OF OIL AND GAS DEVELOPMENT

Concentrations of saturated and aromatic hydrocarbons and 18 metals were measured in soft tissues of benthic crustaceans (amphipods, isoports, and mysids) and bivalve molluscs collected from the near-shore Alaskan Beaufort Sea during the summers of 2004, 2005, and 2006. In order to do so, offshore oil and gas development were accumulating in the coastal marine food chain. This study was part of the cANIMI-DA Project, sponsored by the Minerals Management Service. All species of benthic invertebrates sampled contained low concentrations of polycyclic aromatic hydrocarbons (PAH) and metals, similar to concentrations in similar species from uncontaminated environments. The PAH assemblage was consistent with mixed petrogenic, pyrogenic, and biogenic sources. Concentrations of PAH and saturated hydrocarbons were not higher near oil and gas operations. The saturated hydrocarbon assemblage in crustaceans was dominated by pristine, probably derived from consumption of phytoplankton or peat eroding from coastal sediments. Lead concentrations were higher in amphipods from the Northwestern facility than in those from nearby undeveloped locations in 2004 and 2005, but not in 2006. Benthic invertebrates are not bioaccumulating hydrocarbons and metals from oil and gas development activities.

MOTION OF DISCRETE PARTICLES ON A PLANE SLOPE UNDER REGULAR BREAKING WAVES

The motion of solid spheres and the corresponding fluid velocity fields under regular breaking waves were measured on a plane slope using particle image velocimetry (PIV). The two-phase measurements were separated into the fluid phase and solid phase by morphological operation. The fluid velocity field was decomposed into a wave component and a turbulence component by ensemble averaging. The particulate phase was tracked as individual trajectories to determine their dispersion, velocity and acceleration. sediment sizes and wave conditions investigated, the glass spheres moved along the bottom and did not suspend. Breaking-wave-generated coherent structures were characterized by individual downstreams of turbulence impinging on the bed. The net motion of the sediment particles over a wave cycle was typically offshore and dominated by the undertow. Because the turbulence velocities in the downwash were larger than the wave velocity and undertow velocity, a sediment particle trapped in a downburst could occasionally overcome the effect of the undertow and be transported onshore. The frequency of occurrence of onshore transport was found to be higher in plunging breakers than in spilling breakers.

SATELLITE OCEAN COLOR RECORD OF SEASONAL AND INTER-ANNUAL VARIABILITY IN CDOM DYNAMICS IN THE SOUTH ATLANTIC BIGHT

Ocean color satellite imagery from SeaWIFS and MODIS Aqua has been obtained from the late fall of 1998 to present. Here we examine inter-annual variability in the CDOM-associated signal in ocean color imagery on the South Atlantic Bight continental shelf, focusing on winter-spring, along with regional rainfall, river discharge, hydrographic conditions and possible modes of cross-shelf exchange. Cruise data and time series measurements at offshore towers are consistent with high CDOM absorption in lower salinity surface water masses on the shelf and a terrestrial/riverine origin for highly colored CDOM on the shelf. However, accurate retrieval of CDOM absorption coefficients from satellite ocean color measurements remains challenging, and is discussed in relation to in situ data obtained from several cruises (hydrographic properties, absorption measurements, optical profiles). Despite these uncertainties, CDOM-related products provide a useful tracer of terrestrial-derived DOM and where and when cross-shelf transport of coastal-derived water masses occurs. Examples compare CDOM from satellite ocean color between low, average and anomalously high FW discharge years and case studies where in situ data were available during CDOM events.

CDOM IN THE DEEP SEA: DISTRIBUTION AND DYNAMICS FROM TRANS-OCEANIC SECTIONS

Chromophoric DOM (CDOM) is a ubiquitous component of ocean waters, found at all depths in all ocean basins. Our ongoing project is studying the distribution and dynamics of CDOM in the surface and deep seas, using meridional sections of the CO2/CLIVAR Repeat Hydrography Project in the Atlantic, Pacific, and Indian Oceans. Lack of correlation with DOC indicates that CDOM in the open ocean has local sources and sinks and represents a very small portion of the DOM on a carbon basis. Ventilation supplies CDOM at low concentrations to intermediate and deep water masses, but CDOM in slowly ventilating water masses is well correlated with AOU, indicating a slow microbial source for CDOM in the ocean interior. Comparison of CDOM in deep ocean water masses to ventilation age tracers indicate that there is no significant microbial consumption of CDOM in the deep ocean, leaving slow blooming to be the only known source. Systematic changes in CDOM:DOC relationships, DOM quality indices, and optical characteristics of CDOM in the deep ocean give tantalizing hints of the chemical transformations involved in DOM diagenesis.

GENETICS OF PACIFIC ZOOPLANKTON INVASION OF THE ARCTIC OCEAN.

Climate change will increase opportunities for southern marine organisms to become established in the Arctic Ocean. The study of intraspecific genetic variation across oceanic transition zones holds great potential for early detection of such invasions and of ecological change. Using molecular genetic analysis of the 16S rRNA gene, we find that Calanus glacialis from the Bering Sea and the Arctic Ocean are genetically distinct from each other. Further, we find that C. glacialis from the Bering Sea is advected into the Arctic with the northward flow of Pacific water but is not observed outside areas of recent Pacific water inflow. This suggests that Bering Sea C. glacialis is not reproductively established in the Arctic Ocean at present. We conclude that the restriction of gene flow across the Pacific Arctic boundary has been sufficient to allow for molecular and phenotypic divergence of C. glacialis. The genetic assay and baseline study we report provides a sensitive tool to monitor Arctic marine ecosystem change.

USING UNDERWATER VIDEO TO EXAMINE THE OCCURRENCE OF GREEN MACROALGAL BLOOMS ON A REGIONAL SCALE IN WASHINGTON STATE, USA.

Green macroalgal blooms are a threat to marine ecosystems, can release toxic compounds, and are thought to be increasing worldwide. These blooms have not been as well-studied in the Northeast Pacific as in other areas. We used underwater video surveys conducted by the Washington State Department of Natural Resources (WADNR), originally intended to determine seagrass cover, as a means to examine the abundance and geographic distribution of green macroalgal blooms over the regional scale. We have completed analysis for sites sampled in 2004 and 2005 and are beginning analysis for 2006. Seasonal regional trends, in particular the variability on spatial scales, are noted. We have also identified several strengths and weaknesses of this approach for both scientific and management purposes. The advantages of this technique over more traditional alternatives include the large sample size (per site and number of sites), the ability to digitally archive the original video, safety to personnel, and low cost. Disadvantages are primarily related to the use of video originally intended for examining other species, in particular times delays from sampling until videos are available for analysis. The likelihood of underestimating green algal abundance when water clarity is low and other primary producers are abundant is also problematic, although green macroalgal blooms that are sufficient to have substantial ecosystem consequences would not likely be missed.

Nelson, T. R., University of South Carolina, Columbia, South Carolina, USA, tnelson@geol.sc.edu; Voulgaris, G., University of South Carolina, Columbia, South Carolina, USA, gvoulgaris@geol.sc.edu; Warner, J. C., U.S. Geological Survey, Woods Hole, Massachusetts, USA TEMPORAL AND SPATIAL EVOLUTION OF SMALL SCALE RIPPLES ON THE INNER SHELF

Bedforms on the inner shelf were observed from October 2003, until March 2004, off Long Bay, South Carolina. During this period waves propagated to the northwest with an average significant wave height of 0.6 m and period of 4.8 s. The site was composed of fine-medium sand (D50 =177 microns). The geometry of the bedforms (wavelength, orientation, and plan-view shape) was determined using spectral and visual analysis of sonar images produced by an Imagenex rotating sonar system. This analysis focuses on the temporal and spatial evolution of continuous and discontinuous linear, wavy, bifurcating, and irregular ripples with 6-26 cm wavelengths. The analysis includes a time series com-

M., University of Hawaii at Manoa, Honolulu, USA, shimi@hawaii.edu; Bidigare, R. R., University of Hawaii at Manoa, Honolulu, USA, bidigare@hawaii.edu; MESOSCOPIC EDDIES IN THE LEE OF HAWAII: CLOSED OR OPEN SYSTEMS? Mesoscale eddies are often treated as closed systems with respect to horizontal exchanges with the surrounding waters. Therefore, nutrient injections into the euphotic zone are assumed to occur only during the time of eddy formation. On March 2005, the cyclonic cold-core eddy Opal was sampled during the E-Flux III field experiment in the lee of Hawaii. Analysis of physical and biogeochemical data revealed a well developed, fairly circular eddy. Opal's core region was characterized by an intense doming of isopycnal surfaces and enhanced nutrient and chlorophyll concentrations. Vertical profiles of density show that the anomalies associated with the eddy extend to ~700 m. However, Opal's cyclonic circulation is primarily limited within the upper mixed layer. Analysis of the potential vorticity field suggests that the portion of Opal isolated from the surrounding waters is relatively shallow, and that radial exchanges of water might occur before this portion, as the eddy migrates. We therefore hypothesize a conceptual model in which nutrient inputs are not limited to a single injection, but can occur more or less continuously during the eddy's lifetime.

ESTIMATION OF MODEL BIAS BY THE ASSIMILATION OF SATELLITE CHLOROPHYLL DATA INTO A GLOBAL MODEL OCEAN Chlorophyll concentration estimates by ocean-biogeochemical models show typically significant errors. Data assimilation algorithms based on the Kalman filter can be applied to improve the model state. However, these algorithms do usually not account for possible biases in the model prediction. Taking model bias explicitly into account can improve the assimilation estimates. Here, the effect of bias estimation is studied with the assimilation of chlorophyll data from the Sea-viewing Wide-Field-of-view Sensor (SeaWIFS) into the NASA Ocean Biogeochemical Model (NOBM). The ensemble-based SEIK filter has been combined with an online bias correction scheme. A static error covariance matrix is used for simplicity. The performance of the filter algorithm is assessed by comparison with independent in situ data over the 7-year period 1998–2004. Compared to the assimilation without bias estimation, the bias correction results in significant improvements of the surface chlorophyll. With bias estimation, the daily surface chlorophyll estimates from the assimilation show a 3.3% lower error than SeaWIFS data. In contrast, without the bias estimation, the global surface chlorophyll estimate without bias estimation is 10.9%. Next to the improvement of the estimated chlorophyll concentrations, the estimated biases indicate regions with systemic errors in the model-represented chlorophyll.

THE ROLE OF CARBONATE IN INFLUENCING PARTICULATE ORGANIC CARBON EXPORT IN THE SUBTROPICAL NORTH ATLANTIC GYRE Long term time series data offer the opportunity to test hypotheses regarding our current paradigms in ocean biogeochemistry. Here we investigate the cause of the observed difference in export production between the two subtropical North Atlantic gyre time series stations, BATs and EOSTOC, situated at about the same latitude but on opposite sides of the gyre. The two stations exhibit similar seasonality in phytoplankton biomass and productivity but export production measured with free-drifting and moored traps is higher by a factor of 2-4 at BATs. Gianca et al. (2007) found that nutrient availability is slightly higher at BATs which could partially explain the higher export production. But calcium carbonate sedimentation is also higher by about a factor of 1.5 at BATs, as is the slope and correlation coefficient of the flux of particulate organic carbon vs calcium carbonate; indicating that POC sedimentation is also linked to calcium carbonate sedimentation at BATs compared to EOSTOC. This may partially explain a higher POC export in the western compared to the eastern NA gyre because of the greater carrying capacity associated with calcium carbonate.

NAT-WORKING MARINE RESEARCH - A SCHOOL ENCOUNTER BEYOND LAB EDUCATION Stimulating young talents at school to join the natural sciences appears to be a task of modern societies poor in other resources. As there is no silver bullet for this age old conundrum, students, scientists and teachers joined in a project, "Nat-Working - Ocean Sciences" funded by the Robert-Bosch Foundation/Germany. To meet various demands of the students various opportunities can be chosen. The range covers almost the entire scale of scientific work from a laboratory - work to group work or excursions as well as a many kinds of demonstration like student symposia, single or group lectures or posters. Symposia and teacher training courses complement the practical work by providing the scientific background. Contributing to research work teaches scientific thinking and methodology in a more sustainable fashion than standardized exercises in a school setting. Science careers can thus be accelerated in general, as students already know basic scientific capabilities at the very beginning of their university studies. Students however learn in a framework of curricula which potentially limit their own as well as scientific engagement in such a cooperation.

THE INFLUENCE OF HEAT AND FRESHWATER FLUXES ON CONVECTIVE ACTIVITY IN THE CENTRAL IRMINGER SEA The temporal evolution of the hydrographic structure of the Central Irminger Sea from 2002 to 2006 is investigated. Particular attention has been drawn to the mixed-layer depth as the region has been suggested to be a deep water ventilation site. During the period we report here a maximum mixed-layer depth of about 500m was found in winter 2000/2005, while shallower measured winter depth of 350m was found in winter 2002/2003 (no data in 2003/04). In the past convection activity has been related to the intensity (strength, frequency and direction) of the Greenland Icecap Jet (GIJ). As the GIJ intensity was rather similar in 2002/03 and 2004/05 it can not explain the difference in mixed-layer depth. However, in 2002/2003 a buoyancy gain through an anomalous high freshwater content was observed which may explain the difference in mixed-layer depth. During all times the mixed-layer did not reach into the stratum of the upper Labrador Sea Water and thus no renewal took place, at least at the mooring site. The highest depth that has been reached was 27.68 kg/m² during winter 2004/2005.

THE SPATIAL-TEMPORAL DISTRIBUTION OF NEARSHORE MYSIS SWARMS AND THEIR PRIMARY PREDATOR, GRAY WHALES The spatial-temporal variability in the nearshore (10 m isobath) distribution of mysw swarms and their predator, gray whales, was examined along a 12.5 km stretch of the Oregon coast. Summer surveys were conducted from 2003-2007. Acoustic transects were conducted to estimate the thickness and distribution of the mysw swarms, while net tows, underwater imaging and direct observations (SCUBA) provided confirmation of acoustic observations. Ten recurring swarm sites were documented and mysw swarm thicknesses varied annually at these sites from 0.5 m to 6 m. A three-week deployment of a 1-MHz Nortek Aquadopp (TM) documented changing patterns in the distribution and biomass of the mysws during late summer. Residence time of gray whales within the region of the swarms varied from two to 112 days. The predation pressure from the whales and changing environmental conditions played an important role in the structuring of this nearshore ecosystem.

AN EVALUATION OF VARIOUS DRIVERS FOR INCREASING HYPOXIA IN HOOD CANAL, WASHINGTON

Hood Canal (Washington State) is a classic fjord estuary with a shallow sill and sluggish circulation. It receives direct input from the Pacific Ocean via the Strait of Juan de Fuca. Increasing persistence and distribution of low dissolved oxygen concentrations in Hood Canal observed during the 1990-2000’s and repetitive fish kills during the 2000’s have galvanized interest to better understand the drivers of the hypoxia and, specifically, to assess whether human activity is involved. The situation is complex because several factors could be driving the present situation, including natural factors (e.g., climate, ocean, and freshwater dynamics), as well as human factors (e.g., carbon and nutrient loadings from a variety of sources). The Hood Canal Dissolved Oxygen Program-Integrated Assessment and Modeling study is a three-year effort to use observations and models to quantitatively evaluate possible causes for the increasing hypoxia. Emerging results from the study, begun in 2005, will be presented and discussed. While natural factors appear to be involved, the role of human loads of nitrogen cannot be ruled out.
Mesoscale activity has been hypothesized to be an important source of nutrients to base plankton growth in the Gulf. These factors resulted in a pronounced CHL maximum, suggesting aeolian deposition of micronutrients (seemingly iron) as a crucial factor regulating phytoplankton growth in the Gulf.

4DVAR ASSIMILATION USING THE NAVY COASTAL OCEAN MODEL IN THE MONTEREY BAY

The recently developed 3DVAR and 4DVAR systems based on the Navy Coastal Ocean model will be used for data assimilation experiments in the Monterey Bay area. The high resolution limited area model will be nested into a regional model which in turn will be nested into the global model. Ocean observations from moored buoys, gliders, high frequency coastal radars and satellites will be assimilated in order to obtain a model solution that best fits the data and model dynamics with minimal errors. Assimilation results from 3DVAR and 4DVAR will be compared to each other and to independent observations in an attempt to evaluate the accuracy and efficiency of each method. Preliminary results will be presented.

ASSESSMENT OF THE ECCO2 COUPLED OCEAN AND SEA ICE SOLUTION IN THE ARCTIC

One of the primary objectives of the Estimating the Circulation and Climate of the Ocean, Phase II (ECCO2) project is to realistically estimate the Arctic ocean circulation and sea ice distribution during the ocean satellite era (1978-present). ECCO2 state estimates are obtained by fitting a high-resolution (18-km horizontal grid spacing) global-ocean and sea ice configuration of the Massachusetts Institute of Technology general circulation model (MITgcm) to the available ocean and sea ice data. Towards ECCO2 Release Candidate 1 (RC1), an optimized solution has been obtained by (i) computing 70 forward-model sensitivity experiments and (ii) using a Green's function approach to minimize model/data misfits. Here we present a comprehensive assessment of ECCO2 RC1 in the Arctic Ocean using satellite and in-situ measurements of sea ice, freshwater fluxes, and temperature and salinity profiles. In addition, we assess ECCO2 RC1's ability to reproduce and to maintain important water mass properties, e.g., the Arctic halocline and the warm Atlantic layer. The purpose of this assessment is both to evaluate ECCO2 RC1 as well as to suggest improvements for the representation of the Arctic Ocean in future ECCO2 solutions.

DEEP EUPHOTIC ZONE NET COMMUNITY PRODUCTION IN THE SUBTROPICAL NORTH PACIFIC GYRE FROM AUTONOMOUS GLIDER MEASUREMENTS

Mesoscale activity has been hypothesized to be an important source of nutrients to base plankton growth in the deep euphotic zone and hence a driver of net community production. We use the signature of biologically produced oxygen measured by autonomous gliders as a geochemical tracer of net community production. Seagliders, deployed through most of 2005 in the subtropical North Pacific gyre, made measurements of temperature, salinity and dissolved oxygen using both Aanderaa optode and Seabird Electronics SBE43 oxygen sensors. A simple mass balance model was used with objectively mapped Seaglider data to calculate net biological oxygen production in the deep euphotic zone, beneath the mixed layer. We find that productivity in the deep euphotic zone, beneath the mixed layer is strongly influenced by the vertical movement of isopycnals driven by Rossby waves and other mesoscale events. Net biological oxygen production in the deep euphotic zone was 0.9 – 1.5 mol O2 m−2 yr−1. This production rate accounts for 17 – 25 percent of net community production at Station ALOHA in 2005.

NEARSHORE FLOWS IN CALIFORNIA: THE PRESENCE OF A COASTAL BOUNDARY LAYER

Nearshore flow is one of the most important and understudied issues in physical oceanography. The movement of ocean waters near the coast has important implications for larval recruitment and other ecological processes. Of particular interest are velocity gradients caused by the interactions of the coastline and alongshore flow, referred to as the Coastal Boundary Layer (CBL). Here, we examine the presence of a CBL at multiple sites on the South and Central California coast. We deployed Acoustic Doppler Current Profilers in transects perpendicular to the shore to measure velocity gradients in the nearshore waters. Data indicate the presence of a CBL whose characteristics reflect interactions of flow with the shoreline and the shallow seabed nearshore. Slower flows nearshore due to the presence of a CBL may be responsible for decreased alongshore transport and increased local retention of certain waterborne constituents, such as larvae and pollutants.

Nield, G. D., Stanford University, Stanford, USA, nield@stanford.edu
LATERAL CIRCULATION IN STRATIFIED AND WELL-MIXED ESTUARINE FLOWS WITH CURVATURE

We will present observations of density, velocity, and turbulent stress under varying stratification conditions in an estuarine channel with significant curvature. Instrumentation was deployed in the Seal Bend region of Elkhorn Slough, in Monterey Bay, California, that permitted of all the terms in the lateral momentum balance to be calculated. Classical helical (two-layer) flow occurs only when stratification and lateral density gradients are weak; lateral Reynolds stresses balance the centrifugal acceleration. In contrast, stratified conditions produce strong streamwise velocity shear that results in a three-layer lateral velocity profile that is balanced primarily by lateral density gradients. We will discuss the relative balance between density gradients, vertical mixing, and lateral velocity in relation to the redistribution of salt in the channel cross-section and the concomitant effects on longitudinal dispersion.

Nilsen, T., Norwegian University of Science and Technology, Trondheim, Norway, tsagn@ntnu.no
IRON LIMITATION OF RESIDUAL PHYTOPLANKTON COMMUNITIES IN THE ICELAND BASIN

The high latitude (≈55°N) North Atlantic Ocean is a highly productive region with deep winter overturning and intense spring blooms. Residual nitrate concentrations of 3-5 μM, low chlorophyll concentrations (≤0.5 μg chl a l-1), and low photochemical quantum yields (Fv/Fm) have been observed in mid-late summer (2004-2007) in the Iceland Basin. These results indicate the potential for seasonal iron limitation. During cruise D321 in late summer dissolved iron concentrations in the surface waters ranged from 20-80 pM. In vitro iron addition experiments carried out during this cruise demonstrated enhanced chlorophyll accumulation in treatments amended with 2 nM Fe, compared to controls. Phytoplankton photophysiology also differed between control and Fe amended treatments with increased (Fv/Fm) observed following Fe amendments. The results imply that the iron supply to the region is sub-optimal for complete macronutrient utilization suggesting that the seasonal HNLc condition developed in response to iron limitation. This can be rationalised by a sub-optimal Fe/N ratio in winter overturned deep water.

BENTHIC MICROBIAL FUEL CELLS AT COLD SEEPS REFLECT VARIABLE TRANSPORT PROCESSES AND MICROBIAL COMMUNITIES

A benthic microbial fuel cell (BMFC) was deployed at cold seeps in Monterey Canyon, CA. The BMFC included a chamber that enclosed a carbon-fiber brush anode above the sediment-water interface. Repeat deployments at one seep used different valve technologies so that in one deployment flow through the anode chamber was occluded while in a
second, flow was possible. Assuming that hydrogen sulfide was the major electron donor, power records from the first deployment were consistent with a diffusive flux of sulfide to the anode chamber (31 mmol m\(^{-2}\) d\(^{-1}\)). With different valves, power increased by a factor of five, showed tidal variability, and was consistent with a dominantly advective flux of sulfide (157 mmol m\(^{-2}\) d\(^{-1}\)). The change in transport regime coincided with a significant change in microbial community from one dominated by epsilonproteobacteria (93% of phylotypes found) under diffusive conditions to a diverse community with representatives from deltaproteobacteria (23%), epsilonproteobacteria (23%), firmicutes (11%) and flavobacterium-cytophaga-bacteroides (17%) groups under advective conditions. These fuel cells delivered usable levels of power (40-80 mW) and did not exhibit signs of electrochemical passivation.

WHERE STREAMS COMMINGLE WITH THE SEA: ENVIRONMENTAL CONTRIBUTIONS OF PATHOGENIC BACTERIA IN COASTAL WATERS

Human pathogens in the genus Vibrio (e.g. V. cholerae, parahaemolyticus, and vulnificus) thrive in warm brackish coastal waters. Because these pathogens are natural estuarine flora, rather than being simply washed into the coastal zone as pollutants, understanding the infection risk that they pose is complicated by myriad ecological interactions. Temperature and salinity tolerance appear to be major influences on the autecology of pathogenic Vibrio spp., but their relative importance is context dependent. In Lake Pontchatrain, Louisiana, for example, we found that V. vulnificus abundance was strongly correlated with lake temperature over a seasonal cycle. In coastal waters of Hawaii, on the other hand, variability in abundance was best explained by changes in salinity. Multiple strains of the same vibrio species were frequently isolated from a given sample, but which controls the balance of viable and avirulent strains in the environment is not known. We propose that bacteriophages, which infect selectively, mediate horizontal gene transfer, and contribute to virulence through lytic conversion, will be key to better understanding the synergy, evolution, and changing virulence potential of pathogenic Vibrios in the environment.

“UPPER OCEAN & EDDY MOMENTUM, VORTICITY AND THERMAL ENERGY CONVERGENCES COMPUTED FROM LAGRANGIAN OBSERVATIONS”

Since 1985, drifting buoys have been built to accurately follow the horizontal trajectories of water parcels at 15m depth below the ocean surface. These data are used to calculate the Lagrangian acceleration of water particles and the rate of change of mixed layer temperature. The ensemble average in a spatial domain over many observations of the Lagrangian acceleration is the sum of the mean and eddies convergences of momentum and is used to also calculate the mean and eddies convergence of vorticity. The ensemble average of the Lagrangian acceleration is the sum of the mean and eddies convergences of vorticity. In a similar fashion, the sum of the mean eddies convergences of thermal energy is computed from the ensemble average time rate of change of temperature following the drifter tracks. These ensemble averages are robust in the tropical Pacific where over 4000 drifters have been deployed since 1988. The eddy flux of the tropical Pacific in relation to the time mean vorticity gradient is discussed in light of the common use of horizontal eddy viscosity parametrizations in models that do not resolve the eddy vorticity fields directly.

RADIATION AND DISSIPATION OF INTERNAL WAVES IN THE SOUTHERN OCEAN.

Direct observations and inverse models suggest that small-scale turbulent mixing is enhanced in the Southern Ocean above bottom topography. The eddy enstrophy spectrum, directly related to the PDI, has been obtained for each study’s variable. Singularity spectra are shown to be scale-invariant and so fully describe changes in scale of the observed PDFs. We have compared the singularity spectra obtained from some altimeter-derived maps (SLA, velocity and vorticity) and those obtained from the PDFs of the spatial variation of SST and Chlorophyll concentration satellite gridded maps, in order to determine the scaling properties which are common to the different variables and hence improve our understanding of oceanic turbulence.

SCALE ANALYSIS OF NON-GAUSSIAN PROPERTIES OF ALTIMETER-DERIVED VARIABLES

Velocity probability density functions (PDFs) derived from scalars such as Sea Level Anomalies (SLA) have been studied in the past to analyze ocean turbulence. It has been argued that the non-Gaussian character of velocity PDFs is mainly due to the presence of intense vortices. However, the influence of changes in scale in those non-Gaussian properties has not been fully described. In this work, we will show that velocity PDFs, as well as other satellite-derived scalar PDFs, present scalar invariance properties but with a non-trivial dependence on the observation scale. We will show that these properties are related to the multifractal behavior of the variables under study, intimately connected with the action of ocean turbulence. The singularity spectrum, directly related to the PDFs, has been obtained for each study’s variable. Singularity spectra are shown to be scale-invariant and so fully describe changes in scale of the observed PDFs. We have compared the singularity spectra obtained from some altimeter-derived maps (SLA, velocity and vorticity) and those obtained from the PDFs of the spatial variation of SST and Chlorophyll concentration satellite gridded maps, in order to determine the scaling properties which are common to the different variables and hence improve our understanding of oceanic turbulence.

DNA BARCODING OF MARINE PLANKTONIC OXACILLARIA (ARThROPODA; CRUStacea) FROM THE SARGASSO SEA, NORTH ATLANTIC OCEAN.

Oxacillaria (Arthropoda; Crustacea) are an important but little-known component of the marine holozooplankton assemblage. During a cruise to the Sargasso Sea (western North Atlantic Ocean) in April 2006, 65 species of oxacillaria – of 140 species known from the North Atlantic – were identified from samples obtained from 5,000 m to the surface at five stations spread between 33.5°N and 14°N. A portion of the mitochondrial cytochrome oxidase I (mtCOI) gene was sequenced for identified specimens at sea for multiple individuals of 38 species. Patterns of variation of this gene fragment were suitable for use as a DNA barcode (i.e., short DNA sequence for species recognition and discovery), with low intraspecific variation (1% to 3%) and diagnostic differences between species (12% to 26%). mtCOI can be used as an accurate and reliable tool for taxonomic identification of known oxacillaria species and for revealing cryptic taxa within geographically widespread species, but does not resolve deeper phylogenetic relationships above the genus level.

A CONCEPTUAL DESIGN FOR BOREHOLE OBSERVATORIES OF GAS HYDRATES BURIED IN OCEANIC SEDIMENTS
Most of gas hydrates are buried stably in the sediments which are located in 0-1000m depth below seafloor. The climate, oceanographic and tectonic processes can affect gas hydrate stability conditions, resulting in highly dynamic changes of subsurface environments (GH05S, 2007). A coupled seafloor/borehole gas hydrates observatories can be used to monitor the chemical, microbiological and physical data to understand the dynamic changes, the carbon cycling in gas hydrate- bearing continental margin and serve for exploration and exploitation of gas hydrate as an energy in the future. It is more difficult to deploy the borehole gas hydrates observatory than the seafloor’s because of the former needing drilling. Borrowing ideas from the experiences of operating CORK or ACCC in OD and MOWD or LWD in oil drilling, this paper develops a conceptual model of borehole gas hydrates observatory. The model mainly includes borehole instruments, data recorder and power module, shrinking cables and data transmission unit. Sensors integration and the mode of data transmission may be the primary problems of carrying out the borehole observatory of gas hydrates buried in the oceanic sediments.

SPECIES DIVERSITY IN THE MESOPELAGIC ZONE: IMPLICATIONS FROM MULTI-SPECIES SYMMETRIC ASSEMBLAGES OF CONGENIC COPEPODS
The mesopelagic zone of the oceans is among the largest biospheres on earth and with moderate vertical gradient of environment that is highly stable compared with coastal waters and epipelagic zones. Zooplankton assemblages in the mesopelagic zones commonly exhibit highest species diversity at a local scale among various marine pelagic habitats, but detailed patterns and possible mechanisms for generation and maintenance of species diversity have rarely been addressed. An examination of the patterns of species diversity in mesopelagic copepods indicated correspondence of morphological/functionspecialization in feeding appendages with high species richness, e.g., in Scoleicirrhitidae (modified chormoraptors, ca. 160 nominal species), Eucryptidae (sucker-like appendages, ca. 70 spp.) and Heterorhabdus (poison-fang, 31 spp.). Also noted is co-existence of extremely large number of congenic or closely-related species occurring in the local waters, e.g., in Scoleicirrhitidae (43 spp. in Sagami Bay, 57 spp. in Celebes Sea) and Eucryptidae (35 spp. in Celebes Sea), in both of which vertical segregation and food-resource partitioning appear to be major, if not all, mechanisms for the species co-existence, but necessitating further evidences of feeding specificity.

IMPROVED REPRESENTATION OF MIXED LAYER DEPTH AND MODE WATERS IN THE HIGH-RESOLUTION MODELS OF THE WESTERN NORTH PACIFIC
A series of high-resolution simulations of the western North Pacific is performed changing the horizontal resolution. Two basin scale eddy-resolving models, whose horizontal resolutions are about 7.5 km and 2.5 km, are nested within a control eddy-permitting (about 22.5 km) North Pacific model. These models basically reproduce important features of the western North Pacific, such as separation of Kuroshio/thermocline structure of the upper ocean (mode waters) and salinity minimum of North Pacific Intermediate Water. But the representation of these features is highly improved in the eddy-resolving models from the eddy-permitting model. We focus on the representation of the subtropical mode water, where mixed layer, subduction, and circulation are involved. As a first step, we investigate the representation of the mixed layer depth (MLD) distribution in these models, comparing with observational data. The five-year mean March MLD distribution of the eddy-resolving model is similar to the HydroBase climatology of February-March MLD from Suga et al. (2004, JPO). On the other hand, the fact that the eddy-permitting model shows an overestimation of MLD in the northern deep mixed layer region. The general features of the seasonal variation of the mixed layer, which have been shown from recent analyses of the Argo profiling floats (e.g. Oka et al. 2007, JO), are also reproduced in the eddy-resolving model.

THE VALUE OF TEMPORAL PERSPECTIVE FOR UNDERSTANDING COASTAL SEDIMENTATION: THIRTY YEARS ON THE WESTERN NORTH AMERICAN SHELF
Quantitative studies of sedimentary change in various regions have focused on 30-40 years ago, and environmental changes over that period can be evaluated by comparisons with the earlier observations. A recent study examined sediment accumulation on the Washington continental shelf, through measurements of Pb-210 geochronology and grain size. These observations were contrasted with similar measurements made thirty years ago. Sixteen stations were reoccupied, triplicate cores were collected at some stations, and consistent analytical techniques were used. Across- and along-shelf trends in accumulation rate and sediment texture have remained the same. Despite potential impacts from land use (log-ging), damming, and the Mt. St. Helens eruption, Pb-210 profiles are very similar today to those thirty years ago. Consequently, sediment accumulation rates have not changed significantly, likely attributing to the modulating effects of terrestrial and marine portions of sediment dispersal systems. However, grain size of the accumulating sediment is significantly coarser (~10 % more sand) at most sites reoccupied, and may reflect intensified wave activity. A likely source of sand is from shallow-shelf and coastal locations, where erosion has been observed.

OLIGOTROPHICATION - COMING TO AN ESTUARY NEAR YOU?
Just as limnologists perceived the threat of eutrophication ahead of marine ecologists, they have also taken the lead in studying the reversal of that process, oligotrophication - a decrease in the supply of organic matter to an ecosystem. Decreases in the supply or production of organic matter in aquatic systems can come about for a variety of reasons, including the introduction of herbivorous animals, reductions in the numbers of predators on herbivores, management or climate induced reduction of nutrient inputs, and climate induced changes in phenology. The impact of oligotrophication resulting from various causes has so far received very little attention in marine ecology, though the growing success of nutrient management programs in some parts of the world suggests that the phenomenon will become increasingly important, at least in Europe and North America. In some areas, such as Narragansett Bay, ongoing management interventions will be interacting with a climate-driven oligotrophication that has been underway for decades. The process deserves our attention, though we should not forget that eutrophication will likely continue to intensify in much of the world.

UNDERSTANDING THE IMPACT OF STORMWATER ON THE COAST OF NORTH CAROLINA, USA
Microbial contaminants from stormwater runoff negatively impact the water quality along the North Carolina (NC) coast, and have the potential to adversely affect public health through both water contact and consumption of shellfish. The extent and nature of microbial contamination of stormwater runoff in NC has not been adequately characterized. We studied a total of 123 runoff samples and found that 79% were contaminated with Bacteroides sensu lato, a generic marker for fecal contamination. We document a large difference in the composition of these bacteria, with changes in composition corresponding to fundamental downstream processes. Barometric influence, along with proximity to dominant wind direction, may be the primary reasons for changes in contamination levels. Our results may be the first to document the potential impact of changes in climatic patterns on microbial contamination of stormwater runoff.

INCREASED FRESH WATER FLUX AND THE SLOWING OF THE MOC -- WILL IT WARM OR COOL EUROPE?
We were motivated by Bryden et al. (2005) analysis which implies that the MOC has slowed down significantly (20%) during the past 50 years and that, as a result, Europe should have cooled during this period. Although the article has been subject to strong criticism, and, although there have been claims in various blogs (e.g., www.realclimate.com) that Bryden himself retracted at least some of his conclusions, his results are consistent with recent observations of an increased fresh water flux into the Atlantic. And yet, western Europe "failed" to cool during the past 50 years. To examine this issue, we considered a coupled analytical model where the MOC responds to increased fresh water fluxes and altered salinity. Convective, heat exchange and Ekman layers are all parts of the model dynamics corresponding to fundamental counter-intuitive heat-flow processes. On the basis of that model, we suggest that, in contrast to what the global numerical climate models predict, a slow down of the MOC will cause Europe to warm, not cool. As in the numerical models, the analytically modeled slow-down is accompanied by a reduced heat flux to the North Atlantic, damming, and the Mt. St. Helens eruption, Pb-210 profiles are very similar today to those thirty years ago. Consequently, sediment accumulation rates have not changed significantly, likely attributing to the modulating effects of terrestrial and marine portions of sediment dispersal systems. However, grain size of the accumulating sediment is significantly coarser (~10 % more sand) at most sites reoccupied, and may reflect intensified wave activity. A likely source of sand is from shallow-shelf and coastal locations, where erosion has been observed.
AUTOTROPHIC PICOCYANOTON DISTRIBUTION IN THE WESTERN PACIFIC
- FROM CHUK LAGOON TO EAST CHINA SEA

Autootrophic picocyanoton distribution was investigated from Chuk Lagoon (FSM) to the coastal waters of Korea (Inner Chuk Lagoon (IC), outer Chuk Lagoon (OC), North Equatorial Current (NEC), Kuroshio current (KC), East China Sea (ECS)). Prochlorococcus (PRO), Synechococcus (SYN), picocyanotones (PEUK) were both enumerated using FlowCytometry. Diversity and type distribution of picocyanotones were analyzed through 18SrRNA gene sequencing. Importance of autootrophic picocyanotone biomass was assessed using size fractionated chlorophyll a analyses. Summer size fractionated chlorophyll a contributed more than 50% for most part indicating their importance as primary producers in these regions. PRO were the most abundant autootrophic picocyanotone in the surface waters but not observed in the IC and ESC shelf waters. High abundances of surface SYN were observed in IC and ECS, but lower abundances were enumerated in NEC and KC. PEUK in OC and ECS showed a characteristics of having abundance maximum whereas NEC showed mixed surface layer. PEUK showed that the whole study area have novel picocyanotone group and picotyposome as a dominant group. The current study tries to understand how the changes in environmental variables effect autootrophic picocyanotone distribution in the Western Pacific.

EVOLUTION OF TURBULENCE IN THE OCEAN MIXED LAYER RESPONDING TO THE STABILIZING BUOANCY FLOW SIMULATED BY LES

The formation of a diurnal thermocline in the ocean mixed layer under the stabilizing buoyancy flow was simulated successfully by large eddy simulation, reproducing various features consistent with observations. It was found that wave breaking and Langmuir circulation play a critical role in the formation of a diurnal thermocline. The TKE flux dominates TKE production within the mixed layer, while turbulence maintained by shear production at the thermocline causes restratification in the remnant layer. The depth of a diurnal thermocline is determined by both the Monin-Obukhov length scale and the Ekman length scale. Further, the effects of stratification on turbulence were investigated for the sake of parameterizing the vertical mixing process.

THE STABILIZING BUOANCY FLUX SIMULATED BY LES

This study examined the effect of the environmental conditions of temperature, salinity and light on germination of south Florida Vallisneria americana in a controlled setting. A randomized block split-plot design was used in a controlled growth chamber study; the main plot was temperature (30, 24, 18°C) with sub plots of salinity (0, 5, 10, 15psu) and light (presence, absence). Increased temperature significantly increased the final percent germinated (p<0.001). Across all salinity and light levels, final percent germinated was always highest in 30°C (p<0.001). The three-way interaction of temperature, salinity and light significantly affected germination rate (p<0.001), where germination rate was directly related to temperature and light but inversely related to salinity. Overall, the rate was fastest in 30°C, 15psu and light and slowed in 18°C, 15psu and light. Increased temperature significantly increased the number of days until last germination (p<0.001). None of the main effects (p>0.05) nor their interactions (p>0.05) had a significant effect on time to first germination. Placing V. americana seeds in water of 30°C with a salinity of <5psu and in the presence of light will maximize germination. Applying these conclusions to south Florida populations will assist in restoration and sustainability of V. americana and help determine environmental tolerances and thresholds for the long term management of this species and the Caloosahatchee River.

HYPERPYCNAL FLOW WITHIN LOW GRADIENT RIVER DELTAS AND IMPLICATIONS FOR SEDIMENT TRANSPORT TO THE SHELF: BRAZOS RIVER

Hyperpycnal flow is a well documented process for high gradient rivers, but is not generally accepted as a common phenomenon in low gradient rivers. The Brazos River provides an example of such a low gradient system. The Brazos River Delta and proximal shelf were sampled during the July 2007 floods with a CTD, equipped with a turbidity sensor, and a short gravity core on transects running the 8m isobath along shelf and across shelf from the river mouth. A turbid hypopycnal river plume as well as a turbid bottom layer was found emanating from the river. Brazos River mud is characteristically red, while marine sediment is olive-grey. Preliminary result reveal a distinctively red, porous storm layer, composed of up to 30% sand, material coarser than would be carried in the suspended load, that extends from the river mouth. The strong layer suggests hypopycnal transport during the flood discharge. If this is the case, hyperpycnal flow may occur regularly on the Brazos River, providing an important mechanism for transporting sand and mud across the inner shelf.
ABUNDANCE AND TOXICITY OF A KARLODINIUM VENEFICUM BLOOM IN THE WEEKS BAY NATIONAL EUTRIFIED RESEARCH RESERVE, ALABAMA. Weeks Bay NERR experienced multiple dinoflagellate blooms in 2007. The phytoplankton community was dominated by a bloom of Prorocentrum minimum in February followed by Kryptoperidinium foliaceum and Karloidiurn veneficum in July - October. Five fish kills occurred within Weeks Bay and its tributaries during the summer. Analyses of the water and the dead fish indicated that karlotoxin contributed to these. We mapped phytoplankton community structure, toxin levels and a range of environmental and optical variables repeatedly during the Karlotium bloom. Karlotium formed spatially localized peaks of cell density and cell toxicity. The highest abundance was 120 million cells/liter (466 &micro;mol/l Chla) in the upper reach of the estuary. High cell densities reflected elevated nutrient loading. Toxicity reached 1 ng cell in the bloom, 67% of the variability in the environmental data (T, S, DIN, DIP and kd) was explained by the first 2 PCs in a principle components analysis. Per-cell toxin concentration was highly correlated with PC2, which was correlated (p<0.05) with DIP (R = 0.91) and kd (R = 0.81): toxicity was highest at low DIP/high water clarity.

ROLE OF UPPER TROPHIC LEVELS ON SILICON, NITROGEN AND PHOSPHORUS CYCLING IN THE OCEAN: A BOX-MODEL STUDY

Robust estimates of biologically-mediated fluxes are critical to our understanding of nutrient cycling in the ocean. The magnitude of these fluxes is partly driven by spatial and temporal variability in the structure and the dynamics of the marine food web. To date the potential influence of upper trophic levels, i.e. organisms larger than mesozooplankton, on nutrients cycling has been seldom considered. Here we examine their potential influence on silicon, nitrogen and phosphorus cycling using different global ocean models, which differ by their horizontal resolution (Southern Oceans, Low-latitude Oceans and Northern Oceans). In all case, the vertical resolution considers an epipelagic (0-200 m), mesopelagic (200-1000 m) and bathypelagic (> 1000 m) layer. The biological model is derived from Tye's (Nature, 400, 525-531, 1999) with inclusion of the silica cycle, and a simple description of upper trophic levels. The biological parameters are constrained using alometric laws. Afterward, the role of large organisms is examined through a model sensitivity analysis to nutrients stoichiometry, food-web structure, or biomass size spectra. At the end, the results will help to answer how large the impact of higher trophic levels in nutrient cycle and how big the different of nutrient concentration among horizontal and vertical resolution.

A NEW SAMPLING DEVICE FOR COLLECTING ZOOPLANKTON WITH EASE AND ACCURACY

Numerous different devices are employed for sampling zooplankton. Every sampler has its advantages and limitations in terms of sampling ease, adaptability and efficiency. Because of these considerations researchers are always in search of samplers that increase efficiency and decrease human effort. In this study we compared zooplankton densities and composition obtained from sampling with a new sampling device, the Nunez sampler, and three long-standing vertical sampling devices, an integrated tube sampler, a plankton tow, and a Van Dorn bottle. The results of this experiment indicate that the zooplankton communities observed using the Nunez sampler were statistically similar to the results obtained using the integrated tube sampler and the Van Dorn. All three of the devices had statistically higher quantitative values than the plankton tow. The advantages of the Nunez sampler for zooplankton collection principally relate to its relative ease of use and its fast mode of operation, particularly compared to the Van Dorn bottle and plankton nets. The Nunez sampler also provides easy quantification of zooplankton densities for entire water columns, thereby avoiding biases related to vertical stratification of plankton.

THERMODYNAMIC ANALYSIS OF OCEAN CIRCULATION

Calculating a stream function as function of depth and density is proposed as a new way of analysing the thermodynamic character of the overturning circulation in the global ocean. The sign of an overturning cell in this stream function directly shows whether it is driven mechanically by large-scale wind stress, or “thermally” by heat conduction and small scale mixing. It is shown that the integral of this stream function gives the thermodynamic work performed by the fluid. The proposed method is applied both to an idealized coarse-resolution three-dimensional physical ocean model, to the ECCO GODAE model, and to the real-time resolution OCCAM model. The overturning circulation in OCCAM between 200 m and 1000 m depth is dominated by a thermally induced cell of 25 Sv, forced by Ekman pumping. In the deepest and deepest waters there is a thermally direct cell of 18 Sv, which requires a forcing by around 100 GW of parameterized small-scale mixing.

A MODEL OF WINTER GROWTH FOR ANTARCTIC KRILL (EUPHASIA SUPERBA) DURING THEIR FIRST AND SECOND YEAR

A model to predict growth of individual Antarctic krill (Euphausia superba) during their first and second winters was constructed with experimentally-derived estimates of winter ingestion of water column and sea ice associated food, assimilation efficiency, and respiration. Environmental variables included chlorophyll concentration both in the water column and sea ice, and carbon to chlorophyll ratio of the food. Krill feeding in the water column or at the sea-ice surface was predicted by day length. Net growth rates for individuals were positive or negative depending on initial food conditions. Daily growth rates were consistent with published rates. Model results indicated that while krill can survive or grow under a variety of food conditions, when sea ice is absent krill in their second winter would not survive or grow at low water column food concentrations that would not support krill in their first winter. Linking physiological growth models to dynamic models of winter primary productivity would allow prediction of the impact of future changes in annual sea ice production on winter survival of krill.

SOLITON PACKET IMPACT ON ACOUSTIC PROPAGATION AND ARRAY PERFORMANCE DURING ASIAEx2001

During ASIAEx 2001, SAR imagery and temperature strings showed a strong soliton packet passing along an acoustic path from a 300 Hz source to a bottomed horizontal array. Observed array performance was degraded during the soliton passage. Performance degradation due to acoustic variability is being related to oceanographic features by an integrated modeling effort and resultant data/model comparisons. The ASIAEx oceanographic data forms a basis for initial and boundary conditions in sub-mesoscale hydrodynamic computational models (EULAG, NMCO, and NRL-MIT) to simulate the evolution and propagation of such internal soliton packets with external forcing, stratified flow, and variable bathymetry. The resulting temperature and salinity distributions are mapped to the time updates of sound speed field. Those sound speed fields are input to a 3D acoustic code, which computes the acoustic field at the array. The modeled acoustic array performance is then computed and compared to the observed array performance, using measures related to array performance. [This research is supported by ONR and has the support of HPC time grants from the DoD HPCMP!].

A SEQUENTIAL CLEAN FILTERING SYSTEM FOR PARTICULATE TRACER METALS IN OCEANIC SURFACE WATER (GE0SS/BIOCARBON)

Iron and several other trace metals in seawater play crucial roles in cell physiology and in biochemical reactions of marine organisms in many oceanic regions. For our better understanding of the trace metals role on oceanic ecosystem, a composition of suspended particle matter gives us essential information on phytoplankton, biogenic particles and mineral dusts. In order to correspond to time and spatial variations of biological activities at the surface layer, we present here an in-line clean filtering system for surface seawaters. Using the system, whose flow lines were made of Teflon, polyethylene and polycarbonate, eight of surface samples (1.5 - 3.2 L) can be filtered sequentially. This filtering system is
CABRON THE LOWER MISSISSIPPI RIVER: TYPES, TRANSFORMATIONS, TRANSPORT

The Lower Mississippi River collects water from 41% of the contiguous U.S. before entering the Gulf of Mexico. Particulate and dissolved materials transported by the river are critical to biological and chemical processes occurring both in the river and in the Gulf. For approximately two years, we have measured quantities and fluxes of various materials, including organic carbon, transported in the main channel of the Lower Mississippi River. Additionally, we have made the most detailed measurements to date for this system of primary and secondary microbial production, respiration, and biomass. Our objectives in this presentation are to describe temporal patterns in the quantities of organic carbon in various living and non-living components, rates of carbon fluxes within the microbial food web, and the magnitudes of different forms of organic carbon transported by the Mississippi River during 2006-07.

AN ARTIFICIAL FISHERY? THE RECOVERY OF THE NILE DELTA FISHERY VIEWED THROUGH A STABLE ISOTOPIC LENS

After the closure of the Aswan High Dam in 1965, the coastal fishery off of Egypt's Nile Delta collapsed. While this consequence was unexpected, the real surprise came later; in the mid-1980's, when landings of marine and estuarine fish began to rise again and then exceed landings prior to the dam's closure. A hypothesis has been advanced that nutrients (N and P) from agricultural runoff and sewage are artificially supporting this rebounded fishery. We have made a first test of this hypothesis by measuring the stable isotopic signatures of fish, plants, particulate matter, and water from the Nile River, agricultural drains and offshore. There are significant differences between inshore and offshore samples and fish caught from across the delta. Also interesting is the evolution of the N isotopic signature of the water and fish in the Nile River and its distributaries as it flows north to the Mediterranean Sea.

SURFACE CURRENTS AND BOTTOM OXYGEN VARIATIONS IN WESTERN LONG ISLAND SOUND

The bottom waters of western end of Long Island Sound experiences hypoxia each summer. Moored CTD and DO sensors revealed intermittent ventilation events during the transition to hypoxia. We hypothesize that the mechanism that controls the ventilation is the wind induced modulation of the re-stratification rate by principal tidal currents. This is quite different from the variability observed in the Narragansett Bay which has been associated with spring-neap changes in the amplitude of the tidal currents. Surface currents in the Narragansett Bay system as determined by an HF RADAR system reveal significant correlation with the rate of change of DO at the bottom and support the hypothesis. These results suggest that subtle variations in the wind statistics can have substantial influence on the seasonal variability of the duration and extent of hypoxia.

CENSUSING MARINE LIFE - DIVERSITY, DISTRIBUTION AND ABUNDANCE

The Census of Marine Life (COML) is a global ten-year initiative by over 2000 researchers from 80 countries to assess and explain the diversity, distribution, and abundance of life in the oceans – past, present, and future. The History of Marine Populations analyses sea life diversity retrospectively as historians and biologists trace life before significant human exploitation. The Ocean Realm Projects demonstrate standardized protocols and novel technologies for observing marine organisms, yielding new biodiversity data ranging from the global intertidal to the abyssal plains, earth’s largest habitat. The Future of Marine Populations integrates biogeographic data in models for statistical analyses and forecasting, providing a wide synthesis of data types. All data are available online in the Ocean Biogeographic Information System. In 2003, COML summarized known marine biodiversity globally, characterizing life on the planet.

TEMPORAL VARIATION PROPERTY OF DISSOLVED ORGANIC CARBON, NITROGEN AND PHOSPHORUS IN SURFACE OF THE WESTERN SUBARCTIC PACIFIC

The temporal variations of dissolved organic carbon (DOC), nitrogen (DON) and phosphorus (DOP) in surface waters of the Western Subarctic Pacific were investigated along the different two timescales. One is the seasonal changes found in time series observations at KNOT stations (44N, 155E) during 1999-2000. The other is the daily changes on the inside of diatom-blooming water mass induced by the mesoscale iron enrichment of SEEDS I (48N, 16E). The elemental composition of dissolved organic matter (DOM) at KNOT showed the seasonal change from C-rich ratio (C/N=19, C/P=380) in the pre-bloom (May) to relatively N-rich ratio (C/N=14, C/P=310) in the post-bloom (July). Also in SEEDS I (13 days after enrichment), the accumulation of relatively N-rich DOM (C/N=16, C/P=310) was observed with diatom bloom compared with pre-bloom (C/N=18, C/P=410). These suggest that relatively N-rich DOM are supplied through phytoplankton bloom and they are preferentially decomposed within the surface, consequently C-rich DOM remain.

ASLO/AGU/TOS/ERF 2008 Ocean Sciences Meeting
Marine dissolved organic matter (DOM) is likely transformed from photosynthetic products of phytoplankton through microbial degradation processes. However, changes in the chemical composition and biogeochemical properties during transformation processes are still unknown. Here, we followed the fates of major biogenic compounds of photosynthetic products such as neutral aldehydes, amino acids and fatty acids using gas chromatography/carbon isotope mass spectrometry (GC/C/IRMS) combined with $^{13}$C as a tracer. We incubated natural phytoplankton populations with addition of NaH$^{13}$CO$_3$ by simulated in situ method for 36 hours, and labeled photosynthetic products with $^{13}$C. After the subsample was recovered at the end of the light period, the samples were incubated in the dark for 150 days. The concentration of organic carbon in photosynthetic products decreased only by 9.0% of the maximum concentration which we observed at the end of the light period, remained on day 30. The contribution of dissolved fraction to total products increased from 10 to 32% in the first 30 days. The analyses using GC/C/IRMS was able to determine the $^{13}$C content precisely and elucidate the degradation process from biochemical composition.

With a population dynamics model the influence of environmental factors on the distribution of anchovy eggs and larvae in the Black Sea is studied. The model is initialized by specifying the location of eggs with a given individual weight at different spawning areas indicated by the available observations. Zooplankton biomass within the sea is computed by a lower trophic food web model. Spawning is considered to begin in early June and last for 90 days when mixed layer temperatures are greater than 20°C. Each cohort of daily spawned eggs is subject to natural and predation mortalities, as well as somatic growth and metabolic demands which are all dependent on zooplankton biomass and temperature. They are advected by current fields provided by daily circulation model (POM) predictions which involve the assimilation of alimter data for 1992-1994. The present version of the model includes neither active swimming of juvenile and adults, nor fishing mortality. These simplifications are introduced to isolate the effect of life cycle characteristics as well as environmental influences on anchovy dynamics. Model results indicate that individuals are strongly controlled by advection through the Rim Current circulation around the periphery of the basin and are locally controlled by mesoscale eddies. It is found that the coastaly attached anticyclones are more preferential foraging grounds of anchovy. Future plans are to couple the model dynamically with the lower trophic food web model.

PARTICLE BACKSCATTERING, ABSORPTION AND BIOGEOCHEMICAL PROPERTIES IN THE MID-ATLANTIC BIGHT We examined the relationships among inherent optical properties and remotely sensed quantities in the Mid-Atlantic Bight. Surface particulate backscattering $b_p$ (442) was more strongly correlated with non-algal particulate absorption $a_{ph}$ (443) ($r = 0.80$) than the phytoplankton absorption $a_p$ (443) ($r = 0.69$). These results, along with the $a_{ph}$ ($r = 0.43$)/$POC$ indicated that suspended non-algal particles with high inorganic content are the major water constituents regulating $b_p$ (442) variability. Surface $b_p$ (660, 676) and $a_p$ (660, 676) were significantly correlated with $POC$ ($p < 0.001$ at 660 and 676 nm) and Chl a ($p < 0.001$ at 660 and 676 nm), respectively. Variation in remote sensing reflectance R$_{665}$, which is a function of $b_p$ (660) and $a_p$ (660) ($p < 0.001$), was correlated with POC/Chl a ($p < 0.05$). These relationships could provide an algorithm for estimating surface $a_{ph}$ (443) from $b_p$ (442) and POC/Chl a from $R_{665}$ (in the Mid-Atlantic Bight).

CLIMATOLOGICALLY DRIVEN VARIATION IN PHYTOPLANKTON COMMUNITY COMPOSITION AT A COASTAL STATION IN THE NORTHERN CALIFORNIA CURRENT Strong seasonal upwelling in the Northern California Coastal Current promotes the rapid proliferation of a predictable suite of chain forming diatoms during spring and early summer off the central Oregon coast. Variations in both the strength and duration of upwelling, increasing thermal stratification and uptake by diatoms results in the rapid depletion of surface nutrients and a transition to a dinoflagellate dominated community as summer progresses. A final fall diatom bloom generally marks the close of the growth season after which inshore transport of high abundances of relatively low biomass oceanic nanoflagellate species results in a complete turnover of the phytoplankton community. Variations to this paradigm however are known to occur in response to local, basin-scale forcing (e.g. Pacific Decadal Oscillation) and more remote climate phenomena such as the El Nino Southern Oscillation. Here we examine the effects of such events on the structure and composition of the phytoplankton community between 1998 and 2007 and assess their influence on higher trophic level dynamics in particular, copepod and euphausiid egg production rates, at a coastal station off the central Oregon coast.

SURFACE CURRENT TRAJECTORIES FROM HF RADAR; PARAMETERIZING SUBGRID SCALE MOTIONS Lagrangian trajectory information in the coastal ocean is important for a variety of applied and purely scientific problems. Improving trajectories from high frequency (HF) radar observations requires knowledge of time-space averaged velocities and unresolved eddy velocities. Pathways of surface drifter triplets from the Santa Barbara Channel demonstrate
that eddy diffusivities for scales of $O(10-100)$ m range from $10^{-7}$ to $10^{-9}$ m$^2$/s. These values agree with Richardson's $1/4$ power law scaling and Okubo's empirical fits. They relate the idea that realistic sub-grid scale parameterizations must be scale dependent. HF radar trajectories from a random walk Lagrangian stochastic model agree poorly with drifter observations despite incorporation of observed sub-grid scale information. Large differences ($\sim 15$ cm/s) in mean velocities between drifters and HF radar occasionally occur, causing rapid divergence of modeled and observed trajectories. Possible sources include artificial sub-grid scale energy for an enlarged PDF of HF radar derived trajectories, and incorporation of numerical model output to constrain HF radar observations.

Meso Zooplankton Grazing Pressure in Different Spatial Domains in the California Current System

The CCEE LTER (California Current Ecosystem-Long Term Ecological Research) site is exploring the use of spatial differences within the CCEE site as a surrogate measure of how ecosystem characteristics may change over time. As one component of this study, we have measured mesozooplankton grazing pressure in 8 different regions of the southern sector of the California Current System, in conditions ranging from vigorous upwelling to a strongly stratified water column. All measurements are made with a Lagrangian design, in which we follow water parcels for 4-5 days at a time using Globalstar-track drifter. Meso zooplankton grazing pressure was measured using gut fluorescence in 5 size fractions ranging from 200 $\mu$m to $5 \text{ mm}$. Four replicate day-night sequences of gut fluorescence, together with one more intensive study of diel periodicity, were conducted at each of the experimental cycles. Specific grazing rates varied from 0.02 to 0.17 d$^{-1}$ in May 2006 and 0.06 to 0.54 d$^{-1}$ in April 2007, with a disproportionate share of mesozooplankton grazing in the two smallest size fractions. Rates decline monotonically from inshore to offshore in both years.

STUDY ON VERTICAL PROFILES OF RARE EARTH ELEMENTS BY USING AN OCEAN GENERAL CIRCULATION MODEL

Observations of rare earth elements (REEs) in the North Pacific suggest that vertical profiles of their concentrations in water are dramatically different from lighter to heavier REEs. In this study, in order to evaluate role of each source and sink in controlling the vertical profiles of REEs, we conduct numerical simulations of REEs by an ocean general circulation model (OGCM). In the first experiments, external fluxes such as river runoff, atmospheric dust deposition, and flux from coastal regions are given individually as a source of REEs. In the second experiments, we focus on internal recycling associated with reversible scavenging process onto particles where a scavenging parameterization is incorporated into an OGCM. The model clearly demonstrates that vertical transport of REEs by reversible scavenging process is essential for reproducing the observed vertical profiles of REEs. The model successfully reproduces the observed difference in vertical profiles among REEs, where adsorption reactivity of REEs on particles controls it. This study also suggests that external flux from river transported sediments at river mouth plays a role in the observed inter-basin difference of REEs concentration between the Atlantic and Pacific. In the case of Nd, our simulations suggest that about half of Nd of deep water in the North Pacific originates from external flux given in the other basins.

SEASONAL AND INTERANNUAL VARIATIONS OF THE NORTH PACIFIC SUBTROPICAL MODE WATER IN 2003-2006

Seasonal and interannual variations of the North Pacific Subtropical Mode Water (STMW) over its entire distribution region were examined by using Argo profiling float data during 2003-2006. In 2008, STMW is formed in late winter in the recirculation gyre of the Kuroshio/Kuroshio Extension, which extends north of about $28^\circ$ N, from $136^\circ$ E to near the date line. The recirculation gyre consists of several anticyclonic subgyres, in each of which thick STMW with a characteristic temperature is formed. After spring, STMW with each temperature tends to be continually trapped in the respective subgyre, remaining in the formation region, while part of it leaves the subgyre, entering the region south of $28^\circ$ N where the surface current transports relatively thin STMW southwestward. The temperature of STMW formed in the recirculation gyre increases by about $1^\circ$ C from 2001 to 2006, and the salinity also increases by 0.05 from 2003 to 2005, with eastward decreases of both temperature and salinity in each year. These interannual changes are clearly detected in the downstream region south of $28^\circ$ N, with time lags consistent with the estimated geostrophic flow speed.

FLORIDA BAY CORALS: RESILIENT TO STRESS?

Significant experimental evidence suggests increases in $pCO_2$ can cause a decrease in the calcification and ultimately the health of corals, a finding which has particular significance in view of the increase in the global $CO_2$ by ~100 ppm since 1800. Despite these findings, corals such as Solenastrea sp. and Siderastrea sp. have been observed growing in extreme environmental such as Florida Bay where the $pCO_2$ varies by 100s of ppm from year to year without having any demonstrable effect on the coral growth and health. In order to assess whether these corals have adapted to variations in $pCO_2$, a series of experiments are being carried out in which the rates of calcification are being measured as the corals respond to these natural variations and variations which we impose on the corals through artificially lowering the pH. These studies will assess whether naturally occurring corals can and have already adapted to changing $pCO_2$.

TIME SERIES OBSERVATIONS, 1983-2006, OF INORGANIC CARBON AND NUTRIENTS IN HIGH LATITUDE NORTH ATLANTIC

We present results of observations of ocean CO$_2$ partial pressure, total dissolved inorganic carbon and nutrients from two hydrographically different regions: The northern Irminger Sea and the Iceland Sea. The former represents relatively warm and saline Modified North Atlantic Water derived from the North Atlantic Current. The latter is dominated by the cold Arctic Water and Atlantic Water formed at high latitude Polar Water with varying proportions. These regions not only constitute significant North Atlantic CO$_2$ sink areas, but also represent important source areas for the North Atlantic Deep Water (NADW). Therefore, pronounced hydrographic changes that have induced significant biogeochemical changes in these regions, but at different rates, must be taken into account in evaluating the future course of ocean CO$_2$ uptake in response to increasing atmospheric CO$_2$.

AN APPLICATION OF LAGRANGIAN COHERENT STRUCTURES TO HARMFUL ALGAL BLOOMS

The largest and most frequent harmful algal blooms (HABs) caused by the toxic dinoflagellate Karenia brevis tend to occur along the southern portion of the West Florida Shelf (WFS). A necessary condition for achieving a high population density is that stretching and folding of fluid elements do not act to significantly reduce the population during the growth phase. It is argued that the presence of a cross-shelf transport barrier may provide favorable conditions for the development of HABs on the WFS by inhibiting exhausitively losses and allowing for a greater nutrient buildup on the shoreface of the barrier. The barrier is characterized as a Lagrangian coherent structure (LCS), which is a material line that separates fluid domains with different advection properties. Because the early stages of HABs are usually not detected, there is limited understanding of the environmental conditions that lead to their development. We employed simulated LCSs to trace the early location of a HAB before it was transported to an area where it could be detected by satellite imagery. Then a population dynamics model is used to infer the factors that may have led to its development. Two nearshore nutrient sources are identified, one associated with a coastal upwelling event and the other produced by river run off. These results show that the use of simulated LCSs and a population dynamics model can enhance our understanding of the early stages of HAB development.

CHEMICAL AND ISOTOPIC CHARACTERIZATION OF PRODUCTS FROM RUTHENIUM TETRIOXIDE OXIDATION OF MACROMOLECULAR ORGANIC MATTER IN MARINE SEDIMENTS

The majority of organic matter in marine sediments is insoluble, macromolecular, and poorly characterized. While novel analytical techniques shed light on the molecular level composition of these refractory materials, understanding their origin and deposition requires additional information. Age and isotopic composition of macromolecular organic matter may vary due to source(s) and pre-depositional history. Deconvolving inputs is important for understanding organic matter cycling within a specific environment, and for constraining global carbon cycling budgets. Ruthenium tetroxide (Ru4O4), a relatively mild chemolytic agent, selectively oxidizes aromatic units, un saturated moieties, and ether bonds. The aliphatic and alicyclic compounds liberated from the macromolecular matrix using a mild chemolytic agent, selectively oxidizes aromatic units, unsaturated moieties, and ether bonds. The aliphatic and alicyclic compounds identified, one associated with a coastal upwelling event and the other produced by river run off. These results show that the use of simulated LCSs and a population dynamics model can enhance our understanding of the early stages of HAB development.
face that was repeatedly forced to the surface by internal oscillations. Striking cross-shore variation in phytoplankton abundance and community composition were observed, with dinoflagellates dominating onshore of the 15 m depth contour, and diatoms dominating in deeper areas over a cross-shore distance of 8 km. This integrated cross-shore perspective indicates that these shallow-water events may carry significant implications for the growth and success of phytoplankton taxa commonly associated with shelf waters. Funded by CA Seagrant, ONR, SCoCOn, CA Coastal Conservancy, and NOAA.© Mori, Y., University of Tsukuba, Tsukuba, Japan, mori.327@eisei.tsukuba.ac.jp; Hama, T., University of Tsukuba, Tsukuba, Japan, thama@biol.tsukuba.ac.jp; Ishii, M., Geophysical Research Department, Meteorological Research Institute, Tsukuba, Japan; Saito, S., Geophysical Research Department, Meteorological Research Institute, Tsukuba, Japan

MOLECULAR WEIGHT COMPOSITION OF MARINE HUMIC SUBSTANCES IN THE SUBTROPICAL WESTERN NORTH PACIFIC

Marine humic substances (MHS) are one of the main components of marine dissolved organic matter. However, molecular weight (MW) composition of MHS, which is closely related to dynamics of MHS, is largely unknown. In the present study, we measured the depth and spatial changes in MW composition of MHS in the subtropical western North Pacific. Samples were collected between 15–30ºN along 137ºE. We extracted MHS by solid phase extraction using ODS cartridges. MW compositions of ODS-MHS (O-MHS) were fractionated by high-performance size-exclusion chromatography. O-MHS was composed of three MW groups: high, middle and low MW, in all samples, and the vertical profiles of these groups were different each other. In surface mixed layer, the concentration of the high and middle MW groups were lower than those in deeper layer, suggesting that UV-light damage these two groups was more severe for irradiated. In intermediate waters, on the other hand, the concentration of high MW group substantially increased relative to surface layer. This increase in high MW group likely reflects the production of high MW O-MHS as by-products of the microbial decomposition processes.

HYDROGRAPHIC AND MICROBIAL VARIABILITY IN SURFACE WATERS OF THE HUDSON RIVER ESTUARY

The lower Hudson River is a well-flushed temperate estuary influenced by substantial urban discharges. Continuous underway surface water sampling was performed during twelve monthly surveys of the lower Hudson River Estuary to determine the spatial and temporal variability of hydrographic variables and microbial metabolism. When combined with discrete samples of microbial diversity and abundance, observations reveal both spatial and temporal transitions in River metabolism that occur at a variety of scales. Temperature stratification was observed both seasonally and during short term wet weather events. Spatial variability was observed along the estuarine salinity gradient but also at smaller scales due to tributary and urban inputs and cross-river variability in production and respiration. While expansive regions of the River were relatively homogeneous in the well flushed mid-channel, comparatively large changes in microbial abundance, diversity and activity were observed at mixing interfaces and along the shallow edges of the river.

NEAR IR WATER-LEAVING RADIANCE MEASUREMENTS IN TURBID WATERS

We have recently developed a new technique for measuring near-IR bands using a modified Saltic HypOCR Hyperspectral Radiometer. The typical HypPro radiometer is only calibrated by Satlantic to measures from 350 to 800 nm. Our HypPro is custom built with a fiber optic coupling instead of a collector head and has been calibrated out to 1100 nm. The new technique includes reprogramming the instrument to turn off the automatic gain and manually setting the integration times, thus allowing visible bands to saturate and maximizing the signal in the near-IR. A 25 mm fiber optic cable is attached to the coupling input and is attached to a buoy for deployment from a boat. These near-IR measurements have become part of our routine sampling techniques in the Chesapeake Bay and are used to validate ocean color atmospheric correction techniques. The new instruments and sampling techniques are described and preliminary results presented.

TIME-RESOLVED DETECTION, VALIDATION AND QUANTIFICATION OF GLOBAL OCEAN BIOMASS/WATER MASS BOUNDARIES

We have developed an objective classification algorithm that detects global ocean biomes and water masses based on statistical concepts developed in bioinformatics. The predicted boundaries of the detected biomes and water masses are quantitatively accurate according to the upwelling radiance and temperature measured within each water mass or biome. In addition, boundaries of water masses and biomes are independently validated by in-situ ship track data from several different regions and time periods of the global ocean. This results presented here are based on the MODIS-Aqua mission, but this technique has been used with other satellite data sets of ocean color and sea surface temperature originating from OCM, AVHRR and SeaWIFS. Most importantly, this technique is time-resolved allowing for detection of local, regional and global changes in water mass and biome distributions. Applications of this technique include i) the tracking of river plumes and associated pollutants ii) establishing long-term baselines of water mass distributions and iii) detecting climate induced, large scale secular change in ocean biomes.

SUBMARINE GROUNDWATER INPUTS TO GULF OF LION (FRANCE) REVEALED BY 226Ra AND 228Ra ENRICHMENTS.

Here we propose to use 226Ra and 228Ra as tracers of submarine groundwater (SGW) inputs to the Gulf of Lion. We measured the radionuclide isotopes activities by thermal ionization mass spectrometry (TIMS) in coastal waters and in the aquifer waters of the Rhone deltaic plain. Radium isotopes have the capacity to repair that damage. Exposure experiments conducted on other taxa suggest that UV affect trout survival through a feedback loop wherein UV both damages DNA and reduces the capacity to repair that damage. Exposure experiments conducted on other taxa suggests that UV both damages DNA and reduces the capacity to repair that damage. Tributaries of the Chesapeake Bay including the Sassafras and Potomac Rivers, have been experiencing seasonal cyanobacterial blooms (e.g., Anabaena, Oscillatoria (Planktothrix), Lyngbya and Microcystis). These water column blooms, as well as macrophytes (e.g Lema n Uva), subemerged aquatic vegetation, and sediments (which often have associated ni-

trogen-fixers), were sampled during the summers of 2005-2006 and assayed for nitrogen fixation using the acetylene reduction assay. All had measurable rates of nitrogen fixation, with cyanobacteria having highest rates, followed by macrophytes and then sediments.

That significant rates of N fixation were measured despite high ambient N concentra-
tions, suggests that this nitrogen input term may be more important, particularly on seasonal and local scales in Chesapeake tributaries, than previously thought. Furthermore, cyanobacterial blooms appear to be increasing spatially and temporally in the bay and therefore N fixation may be on the increase in these systems and should be captured in mechanistic and statistical models.

MAPPING BENTHIC SUBSTRATES IN WESTERN CANADIAN COASTAL WATERS USING HYPER SPECTRAL IMAGERY

Eelgrass, an important component of inter- and sub-tidal ecosystems, has exhibited worldwide community decline in hypothesized response to light attenuation imposed by eutrophication and sedimentation. Therefore to assess the status of this valuable coastal ecosystem, there is a growing need to know cost- and time-effective monitoring methods. The goal of this study is to determine the optimum spectral resolution for accurately mapping eelgrass distribution around Sidney Island, British Columbia. Two-metre resolu-
tion hyperspectral imagery was acquired over Sidney Island with airborne sensor AISA, as well as 30-metre resolution Landsat 7 data. Concurrently, in situ above-water hyperspec-
ral remote sensing was conducted, underwater videography, and water samples for optical-

constituent analysis were collected. The Empirical Line Calibration method was used to minimize atmospheric effect on the airborne imagery. Various spectral resolutions were simulated from the dataset, and the Spectral Angle Mapper classification technique was applied to each product. The study resulted in recommendations for remote ecosystem integrity monitoring and park management.

GENERATION AND DISSIPATION OF THE DIURNAL COASTAL-TRAPPED CURRENTS (CTWs) OVER THE SAKHALIN SHELF IN THE OKHOTSK SEA

Numerical experiments with a three-dimensional tidal model were conducted to examine the generation and dissipation mechanisms of the diurnal coastal-trapped waves (CTWs) over the Sakhalin shelf. The model implies that the CTWs are mainly generated at the northern corner of Sakhalin, where the shelf bends sharply, and are amplified by the influ-

ences from Sakhalin Bay and Khashevarov Bank. The observations showed that the CTWs are dissipated by the strong spin-down due to the bottom friction. The conventional turbulent closure model cannot reproduce the observed damping, which overestimates the tidal currents associated with the CTWs. Given the vertical eddy viscosity value esti-
mated from the observations in advance, the model roughly reproduces the damping of the CTWs. The conventional turbulent closure scheme should be modified in modeling the tidal fields in high-latitude regions where the CTWs exist. The model also suggests that the spin-down effects due to the friction associated with the sea-ice cover as well as ocean bottom play important role on the tidal currents reduction in the region where the CTWs exist. The ice concentration is high, as observed.

METABOLIC MEASUREMENTS OF ENERGY FLOW THROUGH OCTOPUS RUBESCENTS

Cephalopods form a unique and important link in the food webs of the oceans. Virtually all convert a high percentage of the food they consume into body mass (gross conversion efficiency, GCE). In their, their soft bodies without shells or bones make them favored prey items of many higher predators. This suggests that cephalopods, including the oct-
opuses, play a disproportionately larger role in the energy flow of their food webs than their biomass would indicate. To date little work has been done to explore this ecological role. The first step in evaluating octopus role in energy flow is to make careful metabolic measurements under controlled conditions. 17 male Octopus rubescents were collected from Admiralty Inlet, Washington and their metabolic rate measured around the clock by respirometry. Stepwise multiple regression was used to determine correlation between metabolic rate and other factors. Octopus mass and time of day were found to have the strongest correlation with metabolic rate while diet and amount of time spent in the respi-

rometer were found to have weaker yet still significant correlation.

GLOBAL OCEAN OBSERVATIONS - GOVERNMENT AND INDUSTRY ROLE

Industry has potentially large roles in enabling and exploiting ocean science and engi-

neering conducted at oceanographic institutions and can complement support from the federal government and states. This includes the research and development appropriate for both aspects. The Center for Earth Observations & Applications (CEOA) held a sym-

posium at UCD and Scripps in August 2007 entitled: The Integrated Ocean Observing System and the Ocean Observatories Initiative (OOI): The Role of Industry. This sym-

posium brought together leaders from academic, industry, and government agencies to highlight current ocean research efforts and applications, and to explore opportunities for fostering new, innovative collaborations in ocean observing. 22 senior executives in indus-

try attended the symposium with approximately equal numbers from each of academia and
government. While the symposium was directly related to observatories, the issues covered were broadly applicable to ocean sciences and engineering/technology. Questions and subjects addressed included public/private partnerships: why they succeed, why they fail; what is industry’s role within impact/outcome driven systems; research to operations: the view from industry; Intellectual property rights were a substantial topic of discussion, but were not seen as fundamental impediments to academic-industry partnerships.

SHOTGUN PROTEOMICS AND BIOMARKERS FOR DISSOLVED ORGANIC CARBON (DOC) IN THE OCEANS

There are 730 GT of DOC sequestered in the world’s oceans, however, its composition, sources and fate remain mostly unknown. Protein biomarkers provide a window to under-

standing the complex sources and dynamics of DOC. We studied the relationship be-

tween downstream water DOC environmental samples and those in a model phyto-

plankton cell using mass-spectrometry-based proteomics. We investigated how environ-

mentally induced changes in the proteome of Thalassiosira pseudonana can influence the composition/reactivity of marine DOC. T. pseudonana was grown under different sources of nitrogen and whole-cell qualitative and quantitative (ICAT: isotope-coded affinity tag) experiments were conducted. MS/MS data was searched using the Trans-Proteomic Pipeline and channeled into Gaggle, a bioinformatics platform allowing visualization and analysis of proteomic data in context of metabolic pathways, and genome annotations. We identified 1350 proteins in T. pseudonana: 530 have functional annotations; 674 have matches into protein family signatures (Interpro/COG); 1 predicted; 141 hypothetical protein. Cyanobacterial blooms appear to be increasing spatially and temporally in the bay and seasonal and local scales in Chesapeake tributaries, than previously thought. Furthermore, the view from industry; Intellectual property rights were a substantial topic of discussion, but were not seen as fundamental impediments to academic-industry partnerships.

OBSERVATION AND MODELING OF PERIODIC UPWELLING/DOWNWELLING IN THE ADRIATIC SEA

An experiment, carried out in the Adriatic between February and September 2006, showed that subsurface temperature oscillations, characterized by the 24, 12 and 8 h periods, were strong at the Lastovo island thermistor station and that this corresponding baroclinic current variability was largest at a nearby ADCP station. Wavelet spectral analy-

sis of meteorological and oceanographic time series revealed that the sea/land breezes were responsible for the periodic interchange of upwelling and downwelling in mid-July 2006, with the relatively weak morning breeze corresponding to thermocline reaching the deepest point, the relatively strong (up to 10 m/s) afternoon breeze coinciding with thermocline being close to the sea surface. The range of thermocline variability surpassed 20 m. A simple straight-coast, reduced-gravity model reproduced the observed phases but underestimated the corresponding amplitudes, probably because it did not allow for the resonant excitation of internal Kelvin waves traveling around the island and the nonlinear interaction of various wind-driven constituents. Further modeling addressed these issues, and also enabled the other spots at which diurnal upwelling/downwelling occurs and from which higher frequency inertia-gravity waves emanate to be detected.

MARGIN-WIDE HOLOCENE SEDIMENT DISPERSAL ADJACENT TO THE MUDDY WAIPAOA RIVER, NORTHEASTERN NEW ZEALAND

At the muddy Waipaoa River margin of northeastern New Zealand, rapid erosion of fri-

able catchment lithologies has resulted in thick mid-outer shelf sediment depocentres, and
localised thick deposits on the upperslope. New data from a suite of 0.7-3.2 m-long cores document millennial-scale pattern of sediment dispersal. Tephra and radiocarbon ages afford accumulation rate estimates for the outer shelf and intercanyon areas. Down-core measurements show broad changes around 600,000 yr BP, coincident with the Kahanaro tephra and Polynesian settlement, which persisted for ~200 yrs. Over longer time scales, the seaward-tapering edge of the shelf deposit yields a relatively condensed, 1.8 m-long 16 kyr sequence. Here, the deep-water surface current correlates to a strong seafloor current. Millennial accumulation rates are ~0.3 cm/yr over the mid-late Holocene. The consistency of these Holocene rates with modern radiochemical estimates described in partnering studies suggests that significant mid and outer-shelf sediment transport pre-dates the increase in sedimentation resulting from colonization. Collectively these imply pre-colonization sedimentation was not supply limited. The efficiency these rivers transport fine sediments are dispersed is longstanding and suggests strong oceanic drivers.

CONNECTIVITY AMONG RESTORED OYSTER BARS IN THE SEVERN RIVER ESTUARY

In the effort to restore eastern oysters (Crassostrea virginica) in the Chesapeake Bay, oyster bars have been placed in numerous locations. One such bar exists in College Creek, a tributary of the Severn River (Annapolis, Maryland USA). To place oyster bars in the most optimal positions, the circulation patterns of the Chesapeake Bay and its sub-estuarine system was used (Jaccard et al., 2014). Extensive studies have been carried out in the Iceland-Faroe Front (IFF) over the past two decades. A field experiment was conducted along a broad 5 m deep section of the Hudson over one month in fall, 2007. An autonomous instrumented catamaran was used to observe density stratification. Of particular interest are the effects of tidal currents and a superimposed along-estuary wind (e.g., a seabreeze) on upper water column turbulence. The overriding goal of this research is to address how simplified models may be broadly used to predict upper water column turbulent kinetic energy dissipation and air-sea exchange in an estuary.

TIDE AND WIND FORCING OF ESTUARINE UPPER WATER COLUMN TURBULENCE

Upper water column turbulence is often important to estuarine dynamics and constituent transport, yet our lack of comprehensive observations limits our understanding, and its prediction is a weakness of numerical models. Here, we describe observations of turbulence over a range of wind and tidal forcing in the Hudson River estuary and preliminary comparisons of the observations against a series of empirical and theoretical models of increasing complexity. A field experiment was conducted along a broad 5 m deep section of the Hudson over one month in fall, 2007. An autonomous instrumented catamaran was anchored near a bottom-mounted 1200 kHz acoustic Doppler current profiler that was measuring vertical profiles of velocity and several turbulence parameters using the variance method. The catamaran was fitted with an acoustic Doppler velocimeter, a sonic anemometer, an inertial sensor, and other instrumentation (e.g. carbon dioxide air-sea fluxes). Anchor stations (12-hour) and along- and across-channel transects were conducted from a small boat with CTD profiling to observe density stratification. Of particular interest are the effects of tidal currents and a superimposed along-estuary wind (e.g., a seabreeze) on upper water column turbulence. The overriding goal of this research is to address how simplified models may be broadly used to predict upper water column turbulent kinetic energy dissipation and air-sea exchange in an estuary.

Extended studies have been carried out in the Iceland-Faroe Front (IFF) over the past decades. This study deals with the dynamics of the extension of the IFF, the polar front in the southern Norwegian Sea. The eastward flow of North Atlantic water associated with the IFF bifurcates north of the Faroes and partly continues into the Norwegian Sea as the western branch of the Norwegian Atlantic Current. This study is based on a series of SEASoAR-Soar-CTD and VM-ADCP transects across the polar front, from the bifurcation zone and about 300 km downstream into the Norwegian Sea. The flow shows a meandering and eddy structure, with cold-core cyclonic eddies and warm-core anti-cyclonic eddies. The most prominent features are the warm-core eddies on the cold side of the front and transporting warm water into the Norwegian Sea. An almost 100 km wide anti-cyclone with current speeds up to 100 cm/s in the bifurcation zone. The Norwegian Sea. We investigate the meandering eddy field in light of topographic effects, eddy shedding and lateral mixing.

RESOLVING OPTICAL AND CHEMICAL MEASUREMENTS OF TERRESTRIAL DOM FLUX IN THE NORTH SEA-BALTIC SEA MIXING ZONE

In the Kattegat-Belt Sea region, territorially-dominated brackish Baltic Sea water mixes with saline North Sea water. Few studies have examined the terrestrial flux of Baltic Sea DOM in this region. We report seasonal surveys of key DOM measurements such as UV-vis absorption and excitation-emission (EEM) fluorescence, dissolved inorganic and organic carbon (DIC and DOC) stable isotopes, and dissolved lignin. The distribution of terrestrial DOM in this region appears to be driven by influx of saline North Sea water below the outflow of brackish Baltic Sea surface water. In terms of water mass mixing, we have found excellent agreement between qualitative DOM optical measurements such as spectral slope and qualitative chemical measurements such as carbon stable isotope values. Further, the quantity of ocean color measured as absorption at 375 nm was well-correlated to both DOC concentration and dissolved lignin concentration. Terrestrial DOM flux in this region is conservative and may be scalable to remote sensing measurements through its optical properties.

Cont. Shell Res., 26(17-18). Because most transport of such mudflow occurs within the wave boundary layer, typical coastal models cannot directly resolve such transport and effective parameterization is required (Harris et al. J. Geophys. Res., 110). In this study, the behavior of such downslope transport due to various wave-current forcing, sediment parameters and bed erodibility is investigated by a high resolution numerical model for near-bed fluid mud transport (Hsu et al. 2007, J. Geophys. Res., 112). The model results are first verified by field data observed in Po Delta (Trezkorkis et al., Cont. Shell Res., 27(3-4)). Model results are further analyzed to study the variation of drag coefficient and Bilk Richardson number with respect to wave and alongshore current velocities. The limiting conditions for auto-suspension are also investigated.

ECCOLOGICAL RESPONSES AND RECOVERY OF THE PAMLICO SOUND SYSTEM DURING A PERIOD OF ELEVATED HURRICANE ACTIVITY: WHAT’S MANAGEABLE AND WHAT’S NOT? Since the mid-1990’s, the Atlantic Basin has experienced elevated hurricane and tropical storm activity. During this time frame, coastal North Carolina has been impacted by 10 major storms, and this frequency is forecast to continue for the next several decades. Storms exhibited individualistic hydrologic and nutrient impacts. In the Pamlico Sound (PS), the second largest estuary, different rainfall amounts among hurricanes led to variable freshwater, sediment, organic matter and nutrient (N and P) inputs. This variability differentially affected physical-chemical properties and ultimately biotic properties such as primary production, phytoplankton composition, dissolved oxygen and higher trophic levels (zooplankton to fish). Floodwaters from the two largest hurricanes, Fran (1996) and Floyd (1999), exerted multi-month to multi-annual hydrologic and biogenic-chemical effects. In contrast, the PS showed a rapid recovery in ecosystem properties following relatively low rainfall hurricanes (Isabel 2003, Ophelia 2005). Freshwater discharge and physical forcing are important drivers and must be integrated with nutrient loading in assessing and managing ecological impacts and recovery to these storms during a period of elevated hurricane frequency and intensity.

AN 18-YEAR TIME SERIES OF CORAL REEF DECLINE IN THE FLORIDA KEYS NATIONAL MARINE SANCTUARY FROM SATELLITE DATA

The decline of coral reef habitats has been witnessed at a global scale. Here, we utilize an 18-year time series of Landsat satellite images to assess changes in eight coral reef sites in the Florida Keys National Marine Sanctuary. Twenty Landsat images (1984-2002) were used, with imagery every two years. The image dataset was georectified, calibrated to remote sensing reflectance and corrected for atmospheric and water-column effects. A Multivariate Distance Classification was trained for four classes using in situ coral-truthing data collected in 2003-2004 and using the spectral statistics from a 2002 image. The habitat classes are 'coral', 'sand', 'bare hardbottom' and 'covered hardbottom'. Overall mean coral habitat decline for all sites was 61% (3.4%/y), from 1984% to 7.6% (2002). In situ monitoring data acquired by the Coral Reef Evaluation and Monitoring Project (CREMP) for the eight reef sites between 1996 and 2002 showed a loss in coral cover of 52% (6.7%/y). A direct trend comparison between the full CREMP percent coral cover data (1996-2004) and the full Landsat-derived coral habitat class showed no significant difference between the two time series (ANOVA, p = 0.303, n = 32), despite the different scales of measurements. This dataset provides a relatively long-term continuous time series showing a significant decline in coral reef habitat.

A TALE OF TWO HOT SPOTS: AT-SEA SEGREGATION IN HAWAIIAN ALBATROSSES

Laysan and black-footed albatrosses breed sympatrically at Terr Island (23.87°N, 166.28°W), Northwest Hawaiian Islands. When breeding, tracking studies reveal that Laysans forage north and west of Terr Island, and black-foots forage northeast. Post-breeding distributions are not well defined, but we hypothesize that habitat segregation is less distinct because adults are no longer tied to the breeding colony. We tagged 42 albatrosses with geolocator loggers in 2004 (4 Laysan, 2005) (10 Laysan, 9 black-foot), and 2006 (7 Laysan, 12 black-foot). Time at sea ranged from 128-160 days and albatrosses traveled up to 4,500 km from Terr Island, covering 35,000-43,000 km for Laysans and 50,000-68,000 km for black-foots. Laysans traveled to oceanic waters with a narrow temperature range (12-14°C), whereas black-foots occurred in a broader temperature range (12-20°C). Home-range analysis revealed that Laysan hotspots occurred north-northwest of Terr Island, in the Subarctic Gyre, whereas black-foot hotspots occurred along the coast of central California, north to British Columbia. These results indicate that both species segregate at sea year round. Habitat modeling efforts are underway to unravel species-environment relationships using remotely-sensed oceanographic variables.

OPTICAL DETECTION OF A DINOFLAGELLATE BLOOM IN MONTEREY BAY, CA

A massive red-tide in Monterey Bay, CA was extensively sampled during the GOES-R COAST cruise in September 2006. The bloom occurred in the northeastern region of the bay known as the ‘red-tide incubator’ and persisted until November 2006. The dominant species was the dinoflagellate, Akashiwo sanguinea with chlorophyll concentrations exceeding 500 mg m⁻³. During periods of stress, dinoflagellates may produce UV light-absorbing compounds, such as mycosporine-like amino acids (MAAs), found both inside the cell and released into surrounding water. Presence of UV compounds, characteristic of red-tide forming dinoflagellates, has motivated the ocean color community to request UV sensor bands on future airborne and satellite sensors. Our objectives were (1) to develop a method to discriminate UV-absorbing MAAs from other absorbing compounds, such as chlorophyll a, and (2) to evaluate this method to be effective in categorizing different vegetation communities than direct unsupervised classification. We evaluated the capabilities of the NASA Experimental Advanced Airborne Research Lidar (EAARL) to delineate vegetation communities in Jean Lafitte National Park (JLP); Louisiana, using a hierarchical approach. Five-meter-resolution grids of bare earth, canopy height (CH), canopy reflectance ratio (CRR), and height of the median energy (HOME) were derived. We used a statistical-based approach to divide the CH in 5 distinct classes and for each height class we carried out a principal component analysis (PCA) and an independent component analysis (ICA). Within each height class, original principal components (PC) and independent components (IC) were sub-classified in 4 groups either by k-means or neural-gas algorithms. Unsupervised original metrics classifications and PCA- and ICA-based classifications were compared with JELA infrared aerial photography. Ground-truth data are being acquired at two test sites to assess species composition, canopy cover, and to identify biologically consistent vegetation patches. Our study reveals that neural-gas PCA- and ICA-based classifications performed better in categorizing different vegetation communities than direct unsupervised classification of the four metrics or k-means based classifications of PC and IC.

LINKAGE OF SEABED AND WATER-COLUMN OBSERVATIONS TO QUANTIFY EVENT-SCALE SEDIMENT DEPOSITION AND EROSION

A new approach to examine event-scale sedimentation is described that establishes a connection between water-column signals and changes in the seabed. The Po River (Italy) shelf is used as a case study due to the dominance of winter storms on events sediment transport and the availability of coincident measurements necessary for the analysis. Repeated deployments of an instrumented bottom-boundary layer tripod at a site on the shelf have produced a nearly continuous record of sediment transport over ~35 yr. Sediment cores were collected every ~3 mo during this time, and seabed inventories of ‘Be (half-life 53.3 d) were used to determine net sediment deposition or erosion during each deployment. Comparison of these values with the net elevation change obtained from the tripod altimeter over a deployment agrees well, varying from ~2 cm deposition to ~1 cm erosion. Within each event, analysis of the altimeter record has proved challenging due to changes in sediment porosity that likely occur during a storm event. However, the maximum erosion occurring at the peak of storm events can be evaluated with suspended-sediment data and bottom shear stress calculations.

A SATELLITE-BASED ASSESSMENT OF SEASONAL AND INTERANNUAL CHANGES IN BIOLOGICAL PRODUCTIVITY OF THE BEAUFORT SEA, CANADIAN ARCTIC

The Arctic Ocean is currently experiencing unprecedented changes in sea ice extent and sea surface temperatures, both of which affect biological productivity. However, not all areas of the Arctic are responding in the same way. We used satellite remote sensing of chlorophyll from SeaWIFS and MODIS-Aqua to investigate seasonal to interannual changes in phytoplankton production of the Beaufort Sea (215W-155W), from 1997-2007. The Beaufort Sea, unlike most of the Arctic, has decreased in open water extent and phytoplankton productivity since reaching maximum values for both in 1998, when temperatures were anomalously warm. Annual production decreased by almost half of its 1998 maximum to a minimum in 2000 and has remained relatively constant since then. The flow polynya generally exhibited two distinct phytoplankton blooms, which varied in intensity and timing due to interannual differences in both the onset of polynya formation and the extent of open water. Our results suggest that although temperatures are warming over the entire Arctic region, smaller scale changes may not be as easy to predict and may follow local patterns more than previously assumed.

INTENSE MIXING OVER MODERATE SHELF TOPOGRAPHY

Stratified flow over shelf sea banks have been shown to result in enhanced levels of turbulent mixing most commonly linked to the breaking of locally generated internal waves. Invariably such studies have focused on steep topography where the existence of such waves is predictable. In contrast, Jones Bank rises only 30m above the seafloor over 40km in 120m of water. It is situated over 10km from the continental shelf break in the middle of the Celtic Sea, which is predominantly strongly stratified throughout the summer months. We present a new series of measurements of current and temperature structure on the slope of Jones Bank during the summer of 2003 that demonstrates intense internal wave activity. Additionally, measurements of TKE dissipation identifies regular bursts of intense turbulent mixing occurring in the bottom mixed layer following off bank flow, suggesting this is the work of locally generated lee waves. Our measurements are compared to the results from a non-hydrostatic model to investigate the generation and timing of these mixing events.

HORIZONTAL PRESSURE GRADIENTS IN THE SWASH ZONE

Stockdon et al. (2007) developed a morphological response model for hurricanes requiring the results from a non-hydrostatic model to investigate the generation and timing of these mixing events. Our measurements are compared to the results from a non-hydrostatic model to investigate the generation and timing of these mixing events.

ON THE SOURCE OF GULF STREAM NUTRIENTS

Along density surfaces, nutrient concentrations in the Gulf Stream are elevated relative to concentrations to either side of the current. We assess the source of these elevated nutrient concentrations in the Western Boundary Current using historical hydrographic data. The analysis is extended to the separated Gulf Stream with four hydrographic sections recently occupied as part of the Clivar Mode Water Dynamics Experiment. The results of this analysis suggest that imported, extra-tropical waters are the primary source of the elevated nutrient concentrations. Because the high nutrient signature is likely imported, dacypral mixing need not be invoked to explain the Gulf Stream’s high nutrient concentrations, as had been proposed in the past. Moreover, nutrients do not increase along the length of the Stream, further suggesting that the Stream’s high nutrient signature is imported rather than manufactured by processes within the current. The imported nutrients are likely advected into the North Atlantic within the low salinity water masses that contribute to the shallow limb of the meridional overturning circulation. Thus, the availability of nutrients to the North Atlantic may be linked to upstream processes in the tropics and possibly the Southern hemisphere, as well as variability in the volume of imported water and its distribution in density space.

VARIABILITY OF LIPIDS AND THEIR DELTA-C13 COMPOSITIONS OF DIATOM (THALASSISORIA PSEUDONANA) DURING CELL GROWTH, AUTO-METABOLISM, AND MICROBIAL DEGRADATION

Phytoplanktonic lipid biomarkers and their compound-specific delta-C13 ratios have been used to study OC cycling in marine systems. However, it remains unclear how the biomarker compositions and isotopic signatures vary from formation stage to recycling phase. We conducted laboratory experiments to examine variability of lipids (phystol, sterol, fatty acids) and their compound-specific delta-C13 during cell growth (exponential and stationary phases), auto-metabolism, and microbial degradation. Our results showed: (1) the cells synthesized more lipids (as energy storage component) during stationary phase than in exponential growth stage (as membrane component); (2) lipid compositions remained relatively stable until microbial degrada- tion; (3) auto-metabolism consumed more fatty acids than neutral lipids; (4) microbial degradation dragged almost all algal fatty acids but partial neutral lipids; (5) lipid delta-C13 ratios varied in a larger range (~6-9‰ of enrichment) during exponential growth stage than in other processes; and (6) variability of delta-C13 of lipids during auto-metabolism and microbial degradation were diversified, depending on individual compounds. This study implies that phytoplanktonic biomarkers and their delta-C13 signatures can be altered in different ways during cycling.

SATELLITE REMOTE SENSING RETRIEvals OF INHERENT OPTICAL PROPERTIES WITHIN U.S. SOUTHERN MIDDLE ATLANTIC BIGHT

In coastal waters, bio-optical properties are typically complicated due to seasonal river discharge, shallow bathymetry, anthropogenic impacts, and so on. At present, satellite remote sensing of coastal water quality and constituent quantity is subject to large errors as compared to its capability for oceanic waters. In this study, we have conducted a series of efforts since 2004 to detect improvements in satellite retrievals of various optical and biogeochemical products. Algorithms were developed to retrieve the inherent optical properties (here absorption coefficients) from field measurements of remote sensing reflectance (Rrs). Validation match-ups between field measurements and satellite retrievals of absorption by particles (ap), phytoplankton (ap), CDOM (ag), non-pigmented particles (ad), and chlorophyll a, showed that the mean absolute percent differences (MAPD) were typically lower than 25%. Seasonal variability of absorption coefficients was also obvious and reasonable. Based on regionally specific bio-optical models, the satellite-derived absorption coefficients can be transformed to study the relevant biogeochemical parameters such as chlorophyll a concentration, primary production, dissolved organic carbon, particulate organic carbon, and total suspended particles.

HYPOGENESIS OF HIGH-TEMPERATURE CATALYTIC OXIDATION DOC ANALYZER TO IRMS: SIMULTANEOUS QUANTITATIVE AND ISOTOPE DETERMINATION OF DOC IN NATURAL SAMPLES

A commercially-available high-temperature catalytic oxidation dissolved organic carbon analyzer (HTC-DOC) with cryogenic trapping was coupled to an IRMS system to allow precise and accurate isotope determination in small volumes of natural aquatic and marine waters. Simple modifications to the HTC-DOC aimed at reducing blank signal contribution through permeation of ambient CO2 (replacing Teflon for stainless steel tubing) and CO2-catalyst interaction (changing Pt-impregnated silica for a cupric oxide/quartz rod mix) improved detection limits for isotope determination with a slight improvement to DOC instrument performance. Cryogenic trapping of CO2 following NDIR detection by the HTC-DOC serves both to increase the mass of analyze CO2 and focus the IRMS analyte peak, resulting in excellent IRMS peak shape. Additionally the need to amplify IRMS sensitivity at the cost of dynamic range is not necessary with this set-up.

NOT SO CONSERVATIVE? CHLORINE AND BROMINE IN CHEMICAL OCEANOGRAPHY

According to conventional wisdom, chlorine and bromine are present in the ocean as ions that are conservative with salinity, with the exception of some simple gases (i.e. CH, Br). However, numerous studies have shown that thousands of marine organohalogens are natural products. Furthermore, recent studies have identified organic bromine comprises a substantial (up to 70%) portion of the total bromine in sediment samples, and that Br in sediments can trap more than 98% of the organic bromine.

Patterns of dispersal in the deep-sea remain largely unknown, yet are key elements in the comprehension of biogeochemistry and biodiversity. We are interested in whether seawater samples of specific age, as a result of deep-sea dredging, are made of deep-sea samples that have not or that have only partially escaped from the water masses. Seismic migration produces a pseudo 3D image of the water structure, whereas VSP can map out the boundaries between water masses and map temperature have different acoustic velocity (and density). Seismic methods designed for imaging the subsurface can thus map out the boundaries between water masses and map temperature have different acoustic velocity (and density).

IS RESTORATION OF THE MISSISSIPPI DELTA FEASIBLE?

We review controls, including subsidence, sediment supply, sea-level rise, vegetation dynamics, and carbon storage, that influence the feasibility of restoring wetlands in the Mississippi Delta. We use data from physical experiments, modern deltaic systems, and different approaches to reconstruct the stratigraphic record to obtain broad constraints on delta response to these controls. We then combine this information with relatively simple mass-balance models to investigate how much wetland area could be sustained under different scenarios of sediment retention and subsidence. Even with the current total reduced sediment supply, and assuming historical rates of coastal relative sea-level rise (1-2 cm/yr), there is sufficient sediment to maintain a total wetland area of the order of several hundred square kilometers or more, if natural processes of wetland dynamics and sediment delivery can be restored.

VERTICAL SEISMIC PROFILING (VSP) IN SEISMIC OCEANOGRAPHY - A PROOF OF CONCEPT

As part of the European funded GO Project the concept of vertical seismic profiling was tested for being a tool to image water mass boundaries in 3D. Water bodies with different temperature have different acoustic velocity (and density). Seismic methods designed for imaging the subsurface can thus map out the boundaries between water masses and map mixing processes at meso-scale with unprecedented horizontal resolution. In addition to conventional surface streamer geometry, a new approach of vertical seismic profiling (VSP) has been developed. Following standard VSP techniques (walkaway- and offset- VSP), a first approach using 2 ships has been tested to collect 3D seismic data of different water masses. Seismic migration produces a pseudo 3D image of the water structure, which, when combined with 2D seismic profiles and oceanographic data, give detailed information on the lateral extent of boundaries involved in the mixing process.

VERIFICATION OF CH3D-SSMS FORECASTING SYSTEM FOR CHARLOTTE HARBOR, FL. WITH DATA DURING HURRICANE WILMA (2005)

Storm surge and inundation due to hurricanes represent the greatest threat to life and property in US coastal regions. Numerical surge and inundation models can provide forecast to enable timely emergency response. However, surge and wave data are usually limited with little information of the spatial extent and temporal dynamics of inundation. This paper verifies the CH3D-SSMS forecasting systems using a comprehensive dataset of wind, surge, and inundation in Florida during Hurricane Wilma (2005). CH3D-SSMS is a CH3D-based integrated storm surge modeling system which includes a coastal surge (CH3D) and wave (SWAN), plus large scale surge (ADICIRC/UnCoH3D) and wave (WW3) models. We compare the accuracy of forecast winds with FCMIP and COOPS data to determine the sensitivity of surge and inundation forecasted obtained by CH3D-SSMS to various forecast wind fields. We then conduct a thorough validation of CH3D-SSMS forecasts using high frequency storm surge and inundation data obtained at 30+ locations by USGS and COOPS in Charlotte Harbor, Florida; examine simulations sensitivity to hurricane track and intensity errors and river flows inclusion.

OCEANIC BIOGEOCHEMICAL MODELING OF TRACE METALS: PROGRESS, UNCERTAINTIES AND OUTLOOK

Observational studies have shown that trace metals, most notably iron, are essential micronutrients necessary for biological activity. This has in turn led to the inclusion of iron into oceanic biogeochemical models over the past decade. Here I will review the evolution of iron modeling in global scale biogeochemical models and the uncertainties in the models. I will also discuss process studies and measurements that could lessen these uncertainties, as well as the potential insights that the inclusion of modelling studies can bring to programs such as GEOTrACES and SOLAS.

SEA SURFACE HEIGHT VARIABILITY OBSERVED BY PRESSURE-RECORDING INVERTED ECHO SOUNDERS AND SATELLITE ALTIMETRY IN THE KUROSHIO EXTENSION

AVISO sea level anomaly (SLA) products are compared with in situ sea surface height (SSH) anomaly measurements from an array of 41 pressure-recording inverted echo sounders (PIES) in the Kuroshio Extension during 2004–2006. PIES measure bottom pressure and round-trip acoustic echo time from the sea floor to the sea surface, which are used to estimate, respectively, mass-loading and steric height variations in the SSH anomaly. Good correlations (r>0.9) are found between satellite and PIES measurements with the best agreement near the jet, where the largest SSH variations exist. The mass-loading component affects the correlation and regression coefficients slightly and improves them overall by ~5%. Comparisons agree best with the AVISO up-to-date product, merging all available satellite measurements. Satellite-derived absolute dynamic topography (ADT) maps are also compared with PIES-derived ADT maps. Several mean dynamic topography (MDT) maps, added to SLA products to obtain satellite-derived ADT maps, are tested. Comparisons reveal that R̂io06, the most recent AVISO MDT utilizing GRACE data, is the best MDT in this region. It is significantly improved over R̂io03, a previous AVISO MDT without GRACE contributions. We compare the accuracy of forecast winds with FCMIP and COOPS data to determine the sensitivity of surge and inundation forecasted obtained by CH3D-SSMS to various forecast wind fields. We then conduct a thorough validation of CH3D-SSMS forecasts using high frequency storm surge and inundation data obtained at 30+ locations by USGS and COOPS in Charlotte Harbor, Florida; examine simulations sensitivity to hurricane track and intensity errors and river flows inclusion.

310 ASLO/AOGU/TOS/ERF 2008 Ocean Sciences Meeting
The horizontal, two-dimensional Princeton Ocean Model was modified to include the salt and heat balance equation. It was applied to Prydz Bay (Korea) to reproduce mean conditions for one typical year. Extensive data were compiled and analyzed to evaluate input parameters representative of long-term mean conditions for the tide, salinity and temperature. The model, forced by four major tidal constituents (M2, S2, K1 and O1), daily freshwater discharges and daily net surface heat exchange, produced a reasonable reproduction of observed tidal elevations, tidal currents and long-term mean monthly distributions of salinity and temperature. The calculated residual circulation pattern is consistent with previously observed, though limited, data collected in the vicinity of Kangwja Island and Inchon Harbor. The model was used to study the following mass transport mechanisms: tidal nonlinearile, barotropic pressure gradient associated with freshwater discharge, and baroclinic pressure gradient due to density gradient. The residual circulation pattern, and its variations under different freshwater flow regimes, was examined.

APPLICATION OF HIGH FREQUENCY RADAR FOR SURFACE CURRENTS
ANALYSIS AND DATA ASSIMILATION

A new vector mapping method is developed. This method is based on a variational algorithm for the calculation of stream function and velocity potential from given velocity fields, and has the ability to interpolate vectors over any irregular domain with complex coastlines and multiple islands. The method was used to map surface current fields in the Florida Straits, while other surface events are induced by the passage of hurricanes and atmospheric fronts. During periods of observed eddy activity, the combination of WERA surface and ADCP subsurface current measurements provide insight into the kinematical and dynamical structure of the Florida Current. YOUR WEBSITE & U.S. DIVERSITY: WHAT THE RESEARCH LITERATURE SAYS ABOUT MULTICULTURAL DESIGN

U.S. demographics are changing rapidly. By 2050 minority populations combined are expected to be half of the U.S. resident population. Yet within science & engineering fields racial and ethnic minorities are underrepresented for the most part. To address this, COSEE and many other groups are reaching out to underrepresented audiences through education and outreach efforts, including websites. The question is: Are our web-based outreach efforts effective? Can a website be "culturally neutral," that is, for all racial, ethnic and cultural groups within the U.S.? If so, what are the design guidelines? If not, what makes websites attractive, useful and relevant to our society’s culturally diverse audiences? This paper summarizes an NSF-funded research literature review focused on what is currently known about website outreach to culturally diverse audiences. It concludes with a synthesis of the findings into guidelines for outreach that more effectively meets the expectations and the needs of these audiences within the U.S. The purpose is to assist those involved in education and outreach who are trying to engage diverse audiences via the web.

PHOTOPHYTONK DYNAMICS IN THE PLUME OF THE MISSISSIPPI RIVER:
RESPONSES TO NITROGEN ENRICHMENT, SILICA LIMITATION, AND PHOSPHORUS LIMITATION

The Mississippi River watershed is the largest in North America, terminating in the northern Gulf of Mexico. Nitrate concentrations in the river have tripled over the last century, resulting in higher phytoplankton productivity, contributing to the development of the second largest area of coastal hypoxia in the world. Silica concentrations in the river have dropped 50% during this time period, causing the N:Si ratio to drop from 4:1 to 1:1, resulting in episodes of silica limitation affecting phytoplankton dynamics since the 1980s. Recent studies suggest that phosphorus limitation is an even more recent development, further influencing the phytoplankton dynamics of this coastal
ecosystem. Phytoplankton samples have been collected on a routine basis in the plume of the Mississippi River since 1990. Examination of these samples, coupled with comparisons with historical data, has indicated that 1) harmful algal species (primarily Pseudo-nitzschia sp.) are now more prominent versus the past; 2) larger, more heavily siliciated diatom species (e.g., Paralia sulcata) have been replaced by smaller, more lightly siliciated ones (e.g., Cyclotella chocticawhatchenea); and 3) primary consumer (copepod) biomass decreases substantially during periods of silica limitation.

DISTRIBUTION OF MICROALGAL BIOMASS OFF EAST ANTARCTICA: MODEL RESULTS

Sea ice plays a key role in structuring the Antarctic ecosystems. It has been shown in different regions of the Southern Ocean that there is a strong relationship between sea ice extent and krill abundance and recruitment. Bottom algal communities thriving in the underside of ice floes provide food for krill during the critical winter and early spring period. In order to improve our understanding of the relationships between sea ice extent, sea ice properties and the biological productivity in the Southern Ocean, we present the first results of a sea ice ecosystem model applied in the seasonal ice zone off East Antarctica. The 1-dimensional coupled sea ice thermodynamical, bio-optical and biogeochemical model is applied using a backward lagrangian approach. The model allow us to explore the links between sea ice properties and the dynamics of sea ice algal communities, and give some insights into the temporal dynamics of this ecosystem with a particular emphasis on the spatial distribution of primary production and microalgal biomass in the pack ice during winter and early spring.

EARLY DIAGENETIC PROCESSES IN A ROMAR SYSTEM: THE RHÔNE DELTA

The biogeochemistry of coastal sediments is greatly influenced by terrestrial inputs and especially material from rivers. These inputs disrupt the normal sedimentation and diagenetic regimes and thus often create non steady state conditions for carbon and nutrients cycles in Riomar sediments. Detailed geochemical analyses of sediments (polarity, grain size, reactive Mn and Fe, Corg, C/N, pigments, amino-acids) and porewaters (Mg2+, Fe2+, NO3-, NO2-NH4+, Si, PO4, SO4) are reported in 10 sites along a depth gradient in the mouth and the plume of the Rhône River. These parameters were supplemented with microelectrode measurements of O2 and pH as well as benthic fluxes (O2, CO2, NH4+). 1-dimensional coupled models allowed for ecosystem simulations over the last several years. The detailed sedimentary measurements were combined with mineral provenance analysis and 3D numerical modeling to determine the dominant sediment transport pathways in the region. Powerful tidal currents that exceed 2.5 m/s generate bedforms of up to 317 m in wavelength and 10 m in height. Modeled tidal residuals determined by 2D flow modeling broadly agree with bedload transport directions inferred from the bedform measurements. This collective analysis suggests that the system is ebb dominated, with net seaward-directed sediment transport. Therefore, great caution must be exercised when artificially modifying San Francisco Bay sediment volumes and transport pathways as this could limit the coastal sediment supply. This multi-faceted research approach using state-of-the-art tools has greatly advanced our understanding of sediment, morphology, and sedimentary processes in the San Francisco Bay Coastal System and high energy estuaries in general.

MULTIPLE PROXY RECORDS OF DELTA EVOLUTION AND DISPERAL SYSTEM BEHAVIOR: DEEP BOREHOLE EVIDENCE FROM THE BENGAL BASIN, BANGLADESH

Evolution of the Ganges-Brahmaputra delta over the Late Quaternary has been dominated by climate, eustasy, tectonics, and immense sediment discharge. The complex history of river behavior, delta evolution, and catchment scale processes is not easily recognizable within the simple sand and mud stratigraphy developed to the Bengal margin. We present new stratigraphic, paleoenvironmental, and provenance data for two deep boreholes (150 meters) from the Ganges-Brahmaputra delta in order to resolve the sequence and timing of delta evolution through the Late Quaternary. Continuous natural gamma, conductivity, and magnetic susceptibility logging reveals distinct lithologic packages tied with monsoon strength as a major control on sediment provenance, weathering, and flux to the margin. In conjunction with existing Sr and Nd isotope data, detrital zircon geochronology is used to reveal erosional response to shifting climate in the Himalayan catchment. This multiple proxy approach has proven useful for unraveling complex fluviodeltaic response to external forcing.

VOLUNTEERS AND SCIENTISTS UNITE TO MONITOR MARINE PHYTOPLANKTON AND HARMFUL ALGAL BLOOMS

The volunteer Phytoplankton Monitoring Network (PMN) is a NOAA sponsored community outreach program developed to promote a better understanding of harmful algal by participating in phytoplankton sampling and identification. PMN currently has 135 sampling sites from Massachusetts to Texas with volunteer groups including teachers, students, parks, aquaria, citizen groups, and research facilities. Volunteers receive instruction on phytoplankton identification and collect samples on a weekly or biweekly basis, reporting data via a secure website to researchers at the Marine Biotoxins Program. Since the program began in 2001, over 50 blooms have been reported by volunteers. During November 2006, a multi-species bloom of Pseudo-nitzscha was observed by student monitors in North Carolina. Bloom samples were positively identified as Pseudo-nitzscha pungens, P. multiseries, and P. pseudodelicatissima. Analysis of seawater samples from the bloom detected domoic acid, making this the first report of domoic acid from the Carolina coast. Identification of this toxic bloom along North Carolina’s coast is an example of a volunteer monitoring program contributing to a greater awareness of harmful algal presence and distribution patterns.

DETERMINING SEDIMENT TRANSPORT PATHWAYS IN THE SAN FRANCISCO BAY COASTAL SYSTEM BY UTILIZING MULTIBEAM BATHYMETRY, NUMERICAL MODELING AND MINERAL PROVENANCE

The length, height, depth, and asymmetry of over 3000 individual bedforms were measured from high resolution grids derived from a series of multibeam surveys conducted in the San Francisco Bay Coastal System over the last several years. The detailed bedform measurements were compared as a function of satellite zenith angle to determine the optimum cut-off angle for effective applications requiring the most recent data available. However, in areas where there are few marine as well as sensor and environmental effects at high satellite viewing angles. Near-real-time daily mosaics and seven-day latest pixel composites of Sea-viewing Wide Field of View Sensor (SeaWiFS) derived products such as divers viability, chlorophyll concentration and the solar diffuse attenuation coefficient at 532 nanometers. Data quality is known to decrease at the edges of satellite image swaths due to significant increases in pixel sizes as well as sensor and environmental effects at high satellite viewing angles. Near-real-time applications require the most recent data available. However, in areas where there are multiple SeaWiFS passes available within a couple of hours, it may be advantageous to use better quality data values from a slightly older overpass in place of more recent data values observed by the very high satellite resolution in situ measurements. NOAA’s Aquarius satellite data collected from the Bloom of domoic acid, making this the first report of domoic acid from the Carolina coast. Identification of this toxic bloom along North Carolina’s coast is an example of a volunteer monitoring program contributing to a greater awareness of harmful algal presence and distribution patterns.

THE OPTIMUM SATELLITE ZENITH ANGLE FOR NEAR-REAL-TIME SEAWIFS COASTAL IMAGES

The Naval Oceanographic Office uses the Automated Optical Processing System developed by the Naval Research Laboratory at Sennix Space Center to create near-real-time daily mosaics and seven-day latest pixel composites of Sea-viewing Wide Field of View Sensor (SeaWiFS) derived products such as divers viability, chlorophyll concentration and the solar diffuse attenuation coefficient at 532 nanometers. Data quality is known to decrease at the edges of satellite image swaths due to significant increases in pixel sizes as well as sensor and environmental effects at high satellite viewing angles. Near-real-time applications require the most recent data available. However, in areas where there are multiple SeaWiFS passes available within a couple of hours, it may be advantageous to use better quality data values from a slightly older overpass in place of more recent data values observed by the very high satellite resolution in situ measurements. NOAA’s Aquarius satellite data collected from the Bloom of domoic acid, making this the first report of domoic acid from the Carolina coast. Identification of this toxic bloom along North Carolina’s coast is an example of a volunteer monitoring program contributing to a greater awareness of harmful algal presence and distribution patterns.
TEMPORAL VARIABILITY OF CARBON FLUXES IN THE SUBTROPICAL ATLANTIC AT 24.5°N

A transatlantic hydrographic section including carbon measurements has been occupied in 1992, 1998 and 2004, allowing us to examine decadal changes in the circulation and fluxes of heat, salt and carbon and the net budgets north of 24.5°N. The principal changes in the circulation have been a reduction in the overturning circulation, compensated by an increase in southward thermocline circulation shallower than 1000 m. The northward transport of inorganic carbon/anthropogenic carbon in the Gulf Stream is increasing with time and is compensated by an increasing southward flux in the interior. The net flux for inorganic carbon is southward and for anthropogenic carbon is northward. Here we examine the sensitivity of the net fluxes to and of inferences of their temporal changes to uncertainties in the circulation and for anthropogenic carbon in particular to its method of estimation.

ROUGH BED BOUNDARY LAYER PROCESSES AT THE KILO NALU OBSERVATORY

The turbulent motions generated along the seabed by surface waves and currents play a fundamental role in nearshore environments through their effects on energy dissipation and sediment transport. Near-bed turbulent shear stresses also directly affect benthic ecosystems via nutrient transport. These processes are especially important for coral reef environments that are characterized by very high roughness with significant spatial variability and inhomogeneity. Analysis of field observations of steady and wave-driven flow over roughness caused out by the Kilo Nalu Observatory (Oahu, Hawaii) is presented. Drag coefficients with corresponding apparent hydrodynamic roughnesses are estimated for mean currents using log fits to observed velocity profiles with wave friction factors estimated using wave-current boundary layer models. These are compared with direct measurements of roughness over the reef to examine the relevance of standard roughness parameterizations for the tropical reef environment. Observations indicate that the bed friction and apparent roughness are generally insensitive to variations in wave forcing, in contrast with existing wave-current interaction models of flow over homogeneous roughness. The observations are consistent, however, with highly inhomogeneous roughness with broadly varying length scales.

PHYSICAL FACTORS AFFECTING PRODUCTIVITY IN THE STRAIT OF GEORGIA

We have developed a circulation scheme for the Strait of Georgia, British Columbia, which shows a surprising insensitivity to variations in fresh-water inflow. The scheme can be used to identify the sources and sinks of nutrients. Sinks occur at the surface as more nutrients are upwelled than are removed by advection. These sinks can in turn be used to estimate primary productivity. By comparison with coincident observations of zooplankton and phytoplankton biomass and species composition we describe the evolution of a number of spring blooms and attempt to quantitatively synthesize a food web in this system.

TEMPORAL AND SPATIAL VARIATION OF NUTRIENTS AND PLANKTON PRODUCTIVITY IN THE CALIFORNIA CURRENT SYSTEM: A MODEL-DATA COMPARISON STUDY

As part of evaluating a Pacific physical-biogeochemical model performance, we compared simulation results with the existing times series observations from the California Cooperative Ocean and Fisheries Investigation (CalCOFI) and Monterey Bay Aquarium Research Institute (MBARI). The physical model is based on the Regional Ocean Model System (ROMS) with 50-km spatial resolution. The biogeochemical model is based on the Carbon, Silicate, Nitrogen Ecosystem (CoSINE) model. The coupled model is forced with air-sea fluxes from the NCEP reanalysis from 1990 to 2005. Although the model is not intended to reproduce near-shore dynamics, primary production and seasonal phytoplankton groups success success along the coast are well simulated with the Pacific basin-wide model. The model is also able of reproducing the seasonal cycle for temperature, mixed layer depth, nitrate, silicate, chlorophyll, and oxygen concentrations. High correlation...

USE OF WAX READS TO FACILITATE BIOCAPSULATION OF OXYTETRACYCLINE BY ARTEMIA SALINA NAUPLII

Artemia salina nauplii, a live feed commonly used to rear marine fish larvae, were evaluated for their ability to biocapsulate antibiotics by feeding them on wax spray beads (WSB) containing oxytetracycline (OTC). Feeding experiments using WSB containing riboflavin were initially conducted to determine gut filling and expected rates, followed by experiments with OTC-WSB to evaluate uptake of OTC into tissues of purged nauplii, estimated using an E. coli growth rate assay. Tissues of Artemia fed WSB produced with cores of aqueous solutions of OTC had significantly higher OTC concentrations than adult Artemia produced with particulate OTC. Our study found the average concentration of OTC in purged Artemia was 20.48 ng per individual - a concentration that was comparable to an estimated effective OTC concentration of 17.64 ng per day for zebrafish larvae. WSB appear to be an effective means of facilitating bioencapsulation of OTC by Artemia nauplii.

LABORATORY INVESTIGATIONS OF NONLINEAR INTERNAL WAVES

We present the results of laboratory experiments investigating the generation and dynamics of nonlinear internal waves in a variety of scenarios, including: barotropic tidal flow past steep ocean ridges; the interaction of a wave beam with the thermocline; and the scattering of internal tides by topography. We compare our results with the predictions of numerical simulations and ocean observations.

AUTOMATED LARGE-SCALE SHORELINE VARIABILITY ANALYSIS FROM VIDEO

Land-based video systems are a cost effective and versatile tool for coastal science, combining the ability to assess short- and long-term shoreline changes. We report on a video system deployed at Rehoboth Beach on the Atlantic coast of Delaware to monitor and quantify the evolution of a nourished beach. Hourly images from 7 cameras are geo-referenced to a horizontal plane at the tidal elevation in a local coordinate system. Shorelines are automatically identified using pixel intensity gradients from time exposure and variance imagery, achieving correlation scores with user-defined shorelines exceeding r2 values of 0.92. Variations in camera azimuth and tilt are automatically corrected through image correlation procedures. Shoreline data are tidally and seasonally-averaged to quantify seasonal morphodynamic variability. Comparison of mean summer and winter shoreline locations reveals a mean seasonal beach retreat of ~1.4 m, consistent with prior studies of this area. The spatial variation of yearly shoreline position change will also be discussed. [This work is being supported by Delaware’s Department of Natural Resources and Environmental Control]

UNDERGRADUATE AND PRE-COLLEGE EXERCISES UTILIZING RECENT AND HISTORICAL DATA FROM CORKS AT SEVERAL ODP AND IODP DRILL SITES ON THE JUAN DE FUCA PLATE

Interactive exercises were developed for undergraduate and pre-college audiences by scientists, educators, and graduate students working together during RV Atlantis Cruise 15-23 that serviced CORKS near the Juan de Fuca Ridge in September, 2007. The exercises introduce or reinforce plate tectonics through a study of formation water pressures, temperatures, and chemistry; and are built around data downloaded during the cruise and collected in the past from CORKS placed during ODP Legs 139 and 168 and IODP Expedition 301. Video clips and photos from DSV Alvin dives to the CORKS, and venting of the Middle Valley will immerse students in the technical challenges of long-term in situ measurements. Other exercises feature geomicrobiological sampling and water chemistry techniques as carried out by scientists in shipboard laboratories after recovering osmosamplers from the CORKS. These activities offer an educational link between scientific ocean drilling and the Ocean Observing Initiative and a foundation for a School of Rock Expedition to the Juan de Fuca aboard the JOIDES Resolution in 2008. These activities incorporate the principles of inquiry learning and the use of authentic data.

THE POTENTIAL OF AN AUTONOMOUS UNDERWATER VEHICLE (AUV) AS A MARINE SAMPLING PLATFORM.

In a collaborative effort with the Norwegian Defence Research Establishment and Kongsberg Maritime Ltd, an AUV (HUGIN), a 1.2m ADCP equipped with an Avviso Laser Plankton Counter (LOPC), a CTD and an ADCP. The platform can be pre-programmed as a fixed-grid surveyor or enabled for adaptive sampling strategies. In combination with the capability of deep-sea descent, this will provide unprecedented data, both with respect to physical parameters and biological communities. An example of an ongoing research effort along the Norwegian continental shelf is provided, addressing hibernating copepods.

AN ASSESSMENT OF SPATFALL ON RESTORED OYSTER BARS IN THE SEVERN RIVER ESTUARY (MARYLAND, USA).

Crassostrea virginica restoration bars have been placed in Chesapeake Bay tributaries to improve water quality and enhance the oyster fishery. While recent spat-on-shell plantings have shown high juvenile survival, the cost of regularly replacing laboratory-reared spat on restored beds may prohibit large-scale restoration efforts. Therefore it is critical to know whether spat are recruited to the restored bars. Nevertheless, monitoring restored bars is expensive and logistically challenging, so many restored reefs are not regularly assessed. To address this problem we determined oyster mortality and spatfall at 3 restored bars (College Creek (CC), Weems Creek (WC), Lake Ogleton (LO)) in the Severn River system. Of the 3 sites, only CC had been monitored previously. In the fall of 2007 oysters were sampled via SCUBA dives on each bar. Oysters collected in 0.25m2-diameter quadrats were measured, and inspected for mortality and spatfall. While no spatfall was observed at any site, mortality rates in CC and WC were low. In contrast, samples recovered from LO consisted primarily of the shell foundation provided for the site, rather than live oysters. This may be attributed to illegal harvesting of C. virginica at LO site in a previous year. Though the data illustrated no spatfall of oysters planted in the Severn River, conditions were favorable for survival and growth, suggesting that new bars placed in the system may provide some benefit to the local ecosystem.

CHANGES IN IRON SPECIATION CAUSED BY ZOOPLANKTON DURING THE IRON FERTILIZATION EXPERIMENT EIFEX

Zooplankton grazing of marine phytoplankton generates chlorophyll degradation products (Porphyrins) which complex iron. Porphyrin-chelated iron is bioavailable for marine eukaryotes and thus grazing may affect the bioavailability of iron in iron limited ocean regions. Grazing experiments with natural phytoplankton and different zooplankton grazers were conducted during the in situ iron fertilization experiment EIFE, to investigate the effect of grazing on iron ligand and phaeopigment production under light and dark conditions. We observed an increase in the relative amount of free ligands and a positive effect on phytoplankton biomass in the light treatments under copepod grazing. No such effects were observed in experiments using salps, which seem to have grazed beyond the maximum sustainable yield for phytoplankton growth. We conclude that after copepod grazing, more iron is complexed in a form that can be used by phytoplankton. This positive feedback mechanism increases the amount of bioavailable iron and may enable phytoplankton species to survive under unfavorable growth conditions such as iron limitation and moderate grazing pressure in the Southern Ocean.

ESTABLISHING A REFERENCE MATERIAL FOR 'ACCURATE' ANALYSIS OF DISSOLVED ORGANIC NITROGEN (DON) IN SEAWATER SAMPLES

To evaluate consistency of analytical measurements, daily use of certified reference materials (CRM) gives greater comparability (accuracy) among laboratories. The use of dissolved organic carbon (DOC) CRM is established; we are experimenting with a DON reference. Since dissolved organic nitrogen (DON) is determined by measuring TDN and subtracting DOC (DIN: NO2, NO3 and NH4), it is critical for analysts to measure DIN accurately, especially low concentrations. We recently collected surface and deep water off the Mid-Atlantic shelf to use as DON references. Initial results from over 20 participating labs around the world will be discussed. With a good
DON reference, it will be possible to check TDN prior to analysis with high temperature combustion (HTC), by analysis by pycvolat or UV, and DIN in nutrient analysis. Different laboratories will have varied uses of the references, but all should benefit from regular use of references.

MAPPING SEMI-REGULAR AUTONOMOUS UNDERWATER VEHICLE GLIDER OBSERVATIONS ONTO A CROSS-SHELF SECTION

Two Autonomous Underwater Vehicle Gliders have alternated continuous sampling of a 45-nautical mile transect line (the Newport Hydrographic Line) across the Oregon continental shelf since April, 2006. Strong currents (>25cm/s) push the gliders off their trac- tory and they slowly return to connect line, and the protocol will describe the methods developed to map the semi-regular glider data onto a cross-shelf line, a process which combines the binning of data along-isobaths and objective analysis. The mapping procedure is tested by comparison to moored observations on the Newport Line at 80m water depth varying the spatial and temporal averaging scales.

OCEANOGRAPHIC VARIABILITY ALONG THE ALASKAN COAST

There is a dearth of observations in Alaskan waters that can be used to help understand the linkages between the climate change and the response by coastal ecosystems. We present oceanographic data from an under-utilized source, the temperature measure- ments at coastal tide stations and buoy, and examine the linkage with fisheries informa- tion from the Alaska Department of Fish and Game tide station data. We attempt to examine changes in oceanographic conditions back to the 1920’s. Using historical tide gauge data for long time series analysis requires careful evaluation of how variations in instrument location and sampling frequency intersect with local environmental conditions, such as the thermocline depth. Using the spatial variability we tease out potential local sources of variability from larger scale oceanographic changes, though the specific causes of those patterns cannot always be determined. We then examine how the variability is related to shrimp biomass in Kachemak Bay.

Peierls, R. L., Univ. of North Carolina at Chapel Hill, Institute of Marine Sciences, Morehead City, USA, hans_peierls@unc.edu; Paerl, H. W., Univ. of North Carolina at Chapel Hill, Institute of Marine Sciences, Morehead City, USA, hans_paerl@unc.edu

USING SPATIAL PATTERNS TO INFERR ORGANIC CARBON UTILIZATION BY ESTUARINE BACTERIOPLANKTON

Microbial communities are thought to be important regulators of estuarine biogeochemical cycles through their processing of allochthonous and autochthonous organic matter. Since estuarine dissolved organic carbon is a complex mixture of different sources, it is difficult to determine which source drives microbial metabolism. We measured bacterioplankton pro- ductivity for four years along the salinity gradient in the Neuse River and Pamlico Sound, North Carolina. As has been shown in cross-system studies, mean annual bacterioplankton productivity showed a strong correlation with phytoplankton productivity, suggesting the importance of autochthonous organic matter as a substrate for microbial growth. Also, the mostly conservative mixing behavior of CDOM points to dilution rather than microbial utilization of allochthonous carbon. This is contrasted with discrete longitudinal transects of bacterioplankton productivity, which exhibited strong to no spatial coherence with phytoplankton productivity and biomass. The same range of coherence was apparent for bacterioplankton versus DOC, but not always in conjunction with phytoplankton, especial- ly after a major hurricane impacted the system. This variation in coherence indicates that alternating substrates fuel bacterial production, probably as a function of river discharge.

ON THE GRADIENT RICHARDSON NUMBER IN ISOPYCNIC COORDINATES

The gradient Richardson number Ri in vertical coordinates (x,y,z) is the square of the ratio between buoyancy frequency N and vertical-shear amplitude S, Ri=N²/S², so that a decrease/increase in stratification brings a decrease/increase in dynamic stability. In isopycnic coordinates (x,y,p), however, it becomes the square of the ratio between the inverse of the buoyancy frequency, or buoyancy period, and the diapycnal-shear ampli- tude S, Ri=1/(NS²), where S²=∫(∂u/∂z)²+∫(∂v/∂z)²+∫(∂w/∂z)², so that a decrease/increase in stratification leads to an increase/decrease in dynamic stability. The apparently different role of stratification is the consequence that S and S² are related through the stratification itself. Here we use simple arguments to endorse the usefulness of the isopycnic approach, and the advantages of thinking in terms of S, rather than S. We use field data from three different situations (island shelf-break, Gulf Stream and Gibraltor outflow) to test these idealizations. We conclude that in frontal systems, such as the Gulf Stream and specially the Gibraltor outflow, the isopycnic Ri perspective has more physical significance than the vertical classical view.

GLOBAL DISTRIBUTION OF PHYTOPLANKTON FUNCTIONAL GROUP ABUNDANCES USING PIGMENT MARKERS

The recognition of the importance of phytoplankton functional groups in controlling energy flow through marine ecosystems has led to the development of a new class of marine ecosystem models that explicitly consider such groups. The construction of a phytoplankton functional group climatology is not only critical for the verification of such models, but it also serves as an ecosystem-based tool for the management of phytoplankton class abundance, which are binned into functional groups. Since CHEMTAX output can be highly constrained by initial pigment ratios, we utilized this as a tool to evaluate the potential success of this approach. Furthermore, algal abundance was approximated iteratively to increase confidence in the program's output. The preliminary results will be discussed in the con- text of our current understanding of global phytoplankton distribution.

VARIABILITY IN THE SLOPE WATER AND ITS REALIZATION TO THE GULF STREAM PATH

Sea Surface Temperature (SST) and Sea Surface Height (SSH) data for 1993-2007 for the Western North Atlantic are combined with hydrographic and mooring data at 69W to investigate the relation between fluctuations in the position of the Gulf Stream and the flow in the Slope Water. SST anomalies north of the Gulf Stream are correlated with tem- poral changes in its mean spatial pattern. The spatial distribution of the correlation suggests that SST anomalies move westward along the slope with speeds several cm/s, consistent with the observed velocities in this area. Joint EOF analysis of the anomalies shows cooling (warming) and strengthening (weakening) of the anomalies in phase over the Slope Water. The vertical structure of these fields at 69W agrees reasonably well with the surface patterns, and suggests that larger transports in the Deep Western Boundary Current lead to southward shifts of the mean path of the Gulf Stream. This relation between the Slope Water properties and the Gulf Stream position provides some predictability for the latter.

RESPONSE OF NORTH ATLANTIC RIGHT WHALES TO REGIONAL-SCALE COPEPOD CONCENTRATIONS IN GULF OF MAINE: CLIMATOLOGICAL AND INTER-ANNUAL TRENDS

Each winter and spring a portion of the endangered North Atlantic right whale (Eubalaena glacialis) population enters Cape Cod Bay to feed and to nurse their young. Later in the spring, aggregations of right whales are found feeding and socializing in the Great South Channel. The right whale movements are thought to be driven in large part by their need to feed on ultra-dense patches of copepods, particularly Calanus finmarchi- cus. Using aerial sighting data of right whales and measurements of copepod concentra- tions from vessel-based oceanographic sampling in Cape Cod Bay and the Great South Channel, we tested the hypothesis that the regional-scale average copepod concentration is an indicator of right whale presence. In the Channel, right whales are most likely to be found when Calanus concentrations are anomalously high (r=0.62, p<0.05 during sum- mer). In the Bay, right whales are most likely to be found when Calanus concentrations are near seasonal mean values. We use these and other results to inform a conceptual model of right-whale habitat use in the Gulf of Maine.

COMPARATIVE ASSESSMENT OF THE DRAKKAR MULTI-RESOLUTION 1958-2004 GLOBAL SIMULATION ENSEMBLE

The DRAKKAR consortium has performed a hierarchy of 1958-2004 global ocean/sea-ice simulations at 2, 1, 2/2, and 1/4-degree resolution, driven by the same hybrid forcing func- tion (reanalyzed + observed fields + bulk formulae). These simulations were processed identically to yield collocated equivalents of altimetric (AVISO sea-level anomalies) and hydrographic (INACT/ENSEMBLES in-situ profiles) observational databases. The global
and regional impacts of successive grid refinements are then quantified against these two
synoptic observational references using original measured magnitude, phase, correlation,
spacetime structure of sea-level variability modes in various wavenumber/frequency
ranges (almitetry); space-time structure of thermal and haline model biases and monthly
variability of various mixed layer characteristics (ARGO), etc. Simulated mean states and
seasonal/interannual variabilities get globally more realistic all the way from 2 to 1/4-
degree resolution, with resolution thresholds. We document how resolution improves
the timescale and structure of the forced oceanic response, but also how it enhances nonlinear-
early driven intrinsically interannual variability.

MODELING LIGHT SCATTERING IN LAKE SUPERIOR THROUGH A TWO-
COMPONENT APPROACH

Particulate attenuation, scattering, and backscattering coefficients \( a_p \), \( b_p \), and \( b_{bp} \) were measured in situ in the littoral and pelagic sites of Lake Superior. Individual particle analyses
(IPA) of suspended material were performed for collected water samples. IPA provides information on light-scattering attributes (composition, size distribution) of minerogenic (inorganic) particle populations, thus allowing an analytical approach (Mie theory) to
model the minerogenic scattering component \( b_{bp} \). Adopting empirical equa-
tions for the organic scattering component \( bo \) and \( bbp \) based on measured chlorophyll a concentrations \( Chl(a) \), we represented the measured \( bp \) and \( b_{bp} \) by the summations of these two components. The estimated surmises approached equivalently both with measured \( bp(650) \) (range 0.2 – 1.35 m–1) and \( b_{bp}(650) \) (range 0.0015 – 0.0049 m–1). \( b_{bp} \) accounted for an average of 51% of \( bp \) in the pelagic, and 64% in the littoral sites. The backscattering ratio \( b_{bp} / bp \) was negatively correlated with log \( Chl(a) \) and the sum \( Chl(a) + cp \). Modeled backscattering ratio \( b_{bp} / bp \) was generally well with that based on in situ measurements [on average, 15% absolute relative error]. Size distributions
(a logarithmic-normal function), composition (clay minerals dominating), and
(backscattering efficiency factors of inorganic particles are presented.

VARIABILITY OF THE FLORIDA CURRENT TRANSPORT AT 27N

Several GODAE (the Global Ocean Data Assimilation Experiment) products using
HYCOM are applied to a 1/25-degree South Florida coastal region HYCOM (SoFLA-
HYCOM) as nesting boundary conditions. High-resolution HYCOM output is applied to
a 1/25-degree South Florida coastal region HYCOM (SoFLA-HYCOM) as nesting boundary
conditions. The impact of the boundary conditions on variability of the Florida Current transport at 27N is examined using year 2004 simulations, compared with observations based on the cable data and in-situ data from research cruises. Sensitivity of the Florida Current transport to the resolution of local atmospheric forcing and the model vertical resolution will be discussed as well. Seasonal and decadal
variability of the Florida Current transport will be examined using the cable data from
1982 to 2005 and model output from a 1/3-degree North Atlantic free-running HYCOM
simulation from 1948 to 2003. Distinct annual cycles of the Florida Current transport
based on the cable data are found and shown to be associated with strong positive and
strong negative NA0 (North Atlantic Oscillation) regimes. Relationship between decadal
variability of the Florida Current transport represented in the model and the variability of gyres in the North Atlantic and NA0 (North Atlantic Oscillation) will be discussed.

A NUMERICAL PROJECTION OF THE COASTAL FLOODING AND EROSION IN
CAROLINA COAST

Sea level rise due to global warming may alter coastal circulation, wave propagation, and
sediment transport processes. As a result, a tropical storm occurring at the end of
next century with a higher sea level as its initial condition may produce more severe coastal
flooding and erosion than the same storm occurring at present. In this paper, Carolina
coast is chosen as the test bed. A three dimensional coupled circulation (ROMS), wave
(SWAN), sediment transport and erosion model system is developed to evaluate the
flooding and erosion difference due to sea level change. In the modeling system, the sedi-
ment flux model is based on the approach of Sargsian and includes approximations for
both bed-load and suspended load. The bathymetry is then updated by computing the
divergence of the time averaged sediment fluxes. The process is then repeated using
the updated bathymetry in both SWAN and the circulation model. The modeling results indi-
cate that the ensemble maximum flooding area for a given category tropical storm along Carolin
coast is appeared larger at the end of the century than at present. The results also indicate that the sediment flux, bathymetry modification and erosion for a given
storm are also much different in this area.

DECADAL INCREASE OF ANTHROPOGENIC CO2 IN THE OCEAN

Results of re-evaluation of GEOSECS carbon data in the Atlantic Ocean by examining
depth properties at crossover stations between GEOSecs and WOCE cruises show that
DIC measurements made in GEOSECS program are systematically higher than
those made during recent WOCE/DOE global CO2 survey. In the N Atlantic, the overall
average offset is estimated to be 27 ± 4 μmol/kg north of 15ºN. In the oceanic region between
15ºS and 15ºN, the model output from a 1/3-degree North Atlantic flow estimated to be 0.57 mol/m2/yr for the equatorial region, and 0.28 for 15º South Atlantic south of 15ºS. The anthropogenic CO2 increase using par-
ison of salinity normalized DIC after correction for AOU along the isopycnal shows that
the CO2 uptake rates are consistent with those derived from MLR method. Works are
underway for analyzing A16 and P16 using isopycnal DIC comparison.

MODEL-DATA COMPARISON OF SEDIMENT TRANSPORT OVER EVOLVING
RIPPLED BEDS

The results of a three-dimensional, time dependent, live-bed, boundary layer flow and
sediment transport model are examined and compared with laboratory data. The model employs a mixture approach, with the fluid-particle system modeled as a continuum of two interacting mediums. It has been shown to predict bedform heights, lengths, and shapes similar to those found in the laboratory. Advancements to the model include the forcing from an arbitrary time series of random waves allowing for a close comparison with laboratory data of the modeled flow and concentration fields. A mean boundary current at oblique angles to the flow is added for the examination of ripple migration. We
investigate the transition of two- to three-dimensional ripple fields and the conditions under
which the-dimensional ripples form. The time scales of long term ripple development
are also compared with laboratory data. The results from the comparisons with
suspended sediment concentration and boundary layer flow data obtained at the CROSSTEX lab experiment indicate that the model can reasonably predict the sediment and flow dynam-
ics over an evolving ripple bed.

INFLUENCE OF A MESOSCALE ANTICYCLONIC EDDY ON THE DISTRIBUTION
OF UNICELLULAR CYANOBACTERIA IN THE SUBTROPICAL NORTH PACIFIC

Ocean mesoscale eddies affect oceanic biological communities at micro- and macroscopic scales through the redistribution of heat, nutrients and salinity. As part of the CMORE (Center for Microbial Oceanography: Research and Education) activities we conducted a cruise in the North Pacific subtropical gyre in which we sampled inside and around a mesoscale anticyclo-
nic eddy to assess the microbial diversity associated with nitrogen fixation. The distribu-
tion and abundance of Groupb Crocosphaera-like diatrizoic unicellular cyanobacteria were determined in situ by whole-cell quantitative PCR (wecQPCR) and flow cytometry. Flow cytometric analyses yielded a 6 fold increase in abundance of Groupb cells in surface water near the center of the eddy relative to the periphery. Groupb cells were also more abundant at deep inside the eddy when compared to sites outside. These results were similar to estimates by nh14 wecQPCR asays. Thus, the anticyclonic eddy appeared to influence significantly the abundance of Groupb cyanobacteria suggesting that mesoscale features may play a critical role in the distribution and activity of cyanobacteria, thereby contributing to our present uncer-
tainties of nitrogen fixation budgets in the marine pelagic environment.

THE IMPACT OF AN IOP-BASED UNDERWATER LIGHT PROPAGATION SCHEME
ON AN ECOLOGICAL MODEL OF THE CALIFORNIA CURRENT SYSTEM.
A coupled physical-ecological model of the California Current System (NCOM-CCS) includes a novel scheme for the attenuation of solar radiation in oceanic and coastal waters. This innovative approach is based upon the inherent optical properties (IOP), absorption, and backscattering of the water column. The circulation model component of NCOM-CCS receives boundary information from the global Navy Coastal Ocean Model (NCOM) and forcing from high-resolution surface fluxes determined by the regional Coupled Ocean-Atmosphere Mesoscale Prediction System (COAMPS). The NCOM-CCS temperature and salinity fields are relaxed to the daily fields derived from the Naval Research Laboratory’s Modular Ocean Data Assimilation System (MODAS). The location and timing of chlorophyll blooms along the US West Coast are well represented by NCOM-CCS. Using different statistical metrics to compare observed and predicted chlorophyll distributions, the impact of this new light scheme on the model (surface and sub-surface) chlorophyll dynamics is evaluated for the period 2001-2005.

SEASONAL VARIABILITY OF MASS IN THE ARCTIC OCEAN USING GRACE, THE PIOMAS MODEL AND IN SITU BOTTOM PRESSURE MEASUREMENTS

Ocean Bottom Pressure (OBP) measured by the Gravity Recovery and Climate Experiment (GRACE) shows excellent correlation with Arctic Bottom Pressure Recorder (ABPR) measurements near the North Pole. Both GRACE (2002-2007) and ABPR (2005-2007) OBP show a seasonal variability of about 6-10 cm of water equivalent peak to peak with a maximum occurring during the summer and a minimum during the winter. In situ OBP measurements from the Beaufort Gyre and from the Fram Strait are positively correlated with the North Pole OBP. The phase and amplitude of their seasonal variability suggest that the mass of the Arctic Ocean increases and decreases annually at basin scale. This is also supported by OBP simulated with the Pan Arctic Ice-Ocean Modeling and Assimilation System (PIOMAS). The PIOMAS model data is in general agreement with GRACE and is used to investigate the seasonal forcing in the Arctic Ocean.

CHEMICAL PROPERTIES OF MARINE DISSOLVED ORGANIC MATTER ISOLATED USING THE COUPLED RO/ED METHOD - INSIGHTS FROM 13C NMR SPECTROMETRY AND FTICR MASS SPECTROMETRY

The coupled reverse osmosis/electrodialysis (RO/ED) method has been used to isolate 16 samples of dissolved organic matter (DOM) from seawater with an average yield of 75% ± 12%. Samples are concentrated 40-fold at sea, and pulsed ED has been introduced in the final desalting step to reduce conductivity to 50 µS cm⁻¹. The 13C nuclear magnetic resonance spectra of five representative samples, including one coastal sample, are similar in appearance, except for a stronger signal for aromatic carbon in the coastal sample. The RO/ED samples are enriched in aliphatic carbon and deficient in carbohydrate carbon, relative to DOM that has been isolated from surface ocean water using ultrafiltration. Fourier transform ion cyclotron resonance (FTICR) mass spectra of the five samples contain thousands of peaks, and chemical formulae can be unambiguously assigned to many of those peaks. For the coastal sample, 25% of chemical formulae have atomic H:C ratios of less than one, which is indicative of rather highly unsaturated compounds. In contrast, the four open-ocean samples do not contain significant numbers of such unsaturated compounds.

SOUTHERN ANNUAL MODE RESPONSE AND ITS IMPACT ON THE WEDDELL SEA IN A EXPERIMENT FOR MINIMUM SEA ICE CONDITIONS AROUND ANTARCTICA

In this study the interaction between Antarctic sea-ice and the SAM on the Weddell Sea is investigated. To accomplish this satellite-observed sea-ice concentration (SIC) prescribed to the CCSM3 coupled model were employed. A 150-year simulation, with the minimum SEC repeat annual cycle was used to drive the CCSM3 run. The goal of the research is to evaluate the Weddell Sea response to positive SAM events with respect to observed minimum SEC. This study focuses on interannual timescales and uses EOF analyses to identify preferred perturbation pathways. The variability of sea surface temperature and sea surface salinity anomalies reveal a spatial pattern that characterizes the cold regime of the Weddell Gyre, associated with low Circumpolar Deep Water intrusion. The response of the oceanic circulation in Weddell Sea inflow and outflow regions, related to positive SAM events, show intensification with respect to the control (average SEC).

NITROGEN SPECIATION AND DYNAMICS IN THE SAN JOSÉS AND PÁIONES LAGOONS OF THE SAN JUAN BAY ESTUARY, PUERTO RICO

The San Juan Bay Estuary (SJE) is a tropical estuary located in the San Juan Metropolitan Area in Northern Puerto Rico. For decades, the SJE has been affected by point sources of pollution and currently several locations within the estuary remain heavily polluted. To assess the current eutrophication levels we analyzed: (i) spatial and temporal patterns of inorganic nitrogen (NH₄⁺, NO₂⁻, and NO₃⁻) concentrations and (ii) explore spatial differences in the distribution of nitrogen species in the San Jor (SJ) and Páiones (PL) lagoons. Since N studies in tropical estuarine ecosystems are limited, our goals is to summarize available nitrogen data (present and historical) to develop a N budget for the SJL and PL. Our goal is to assess how nitrogen dynamics are impacted by human activities in an urbanized tropical coastal estuarine ecosystem.

THE THREE-DIMENSIONAL STRUCTURE OF THE TROPICAL CIRCULATION CELL IN THE CENTRAL EQUATORIAL PACIFIC OCEAN

The surface limb of the mean tropical circulation cell in the central equatorial Pacific Ocean is characterized by strong upwelling near the equator, near-surface poleward divergence, and downwelling near 4 degrees latitude. Meridional and vertical velocity fluctuations associated with nonlinear tropical instability waves (TIWs) are much larger than those associated with the cell and may modify the background circulation through nonlinear oceanic mixing. The PIOMAS circulation is used to simulate the spin-up of the cell along 140°W in response to anomalous winds during various phases of the annual cycle. Equatorially-modified versions of geostrophy and Ekman theory are introduced to study the wind-driven response and zonal filtering separates the large-scale response of the cell from that of the TIWs. Weakening the Trades rapidly weakens the cell, decreases the shear of the zonal currents, and reduces the amplitude and propagation speed of the TIWs. Strengthening the Trades to first order produces the opposite response. However, the response of the tropical circulation cell is nonlinear and its meridional-vertical structure is sensitive to the strength of the background winds and TIWs.

COMPARISON OF DOPPLER RADAR AND VIDEO DERIVED MEASUREMENTS OF SURF ZONE CURRENTS AND MORPHOLOGY

During the Fall 2003 Nearshore Canyon Experiment (NCEx) the University of Massachusetts Amherst deployed two X-band Doppler radars to estimate wave fields and surf zone properties including longshore surface currents and surf zone extent. Video cameras deployed by the Ohio State University observed the same region. Radar estimates of surface velocity in the surf zone are inferred from the Doppler shift of backscattered radiation, while video velocity estimates are produced using the Particle Imaging Velocimetry (PIV) technique. Comparisons of velocity estimates in the nearshore show strong correlation (0.9 and higher) within the central surf zone. Differences are observed at the outer edge of the surf where strong breaking occurs, and near the inner edge where the beach is frequently exposed in the swash zone. Surf zone extent is estimated from video data using time-stacking technique and contrast of visible features. The same parameter is inferred from radar data using edge detection on time-averaged radar backscatter images. The radar’s ability to observe in low visibility conditions and at night are particularly advantageous.

Perrie, W., Bedford Institute of Oceanography, Dartmouth, Canada, perrie@fdl.mpo.gc.ca

A TWO-SCALE APPROXIMATION FOR EFFICIENT SIMULATION OF NONLINEAR INTERACTIONS IN HURRICANE-GENERATED WAVES

We recently derived and presented a new method for estimating the transfer rates in wind wave, based on a two-scale approximation (TSA) to the full Boltzman integral (FBI) for quadruplet wave-wave interactions. In that presentation, the TSA method was tested for idealized spectral data. In this paper, we focus on observed wave spectral from...
field measurements. Comparisons are given of TSA, the full Boltzman integral, FBI, and the Discrete Interaction Approximation (DIA) which is presently used in almost all operational wave forecast models, using data collected in Currituck Sound, and in open ocean conditions. The latter data include directional wave rider observations off the Field Research Facility at Duck North Carolina during hurricane Wilma in 2005. These comparisons show that TSA compares favorably with FBI, and that it is a notable improvement over the DIA.

COMBINING SATELLITE DATA SETS TO STUDY SOUTHERN CALIFORNIA COASTAL WATERS

In order to support the Southern California Coastal Ocean Observing System (SCCOOS), the Physical Oceanography Distributed Active Archive Center (PO.DAAC) at the NASA Jet Propulsion Laboratory has been providing Southern California researchers with regional near-surface and historical data from Jason-1, QuikSCAT and MODIS. However, data obtained from these instruments is problematic along the coast for a variety of reasons including inadequate spatial and temporal sampling and cloud contamination. By combining these NASA data sets with data available from NOAA and international agencies, improved data products can be produced for coastal research. The accuracy and effectiveness of these new products will be presented using observations of Los Angeles coastal waters during the Hyperion Treatment Plant's diversion of effluent from the 5-mile to the 1-mile outfall in November 2006.

MULTIYEAR SEAGLIDER OBSERVATIONS OF NORTHERN CALIFORNIA CURRENT ECOSYSTEM: VARIABILITY IN PHYTOPLANKTON ANNUAL CYCLE IN DEEP WATERS OFF THE WASHINGTON SLOPE

Since September 2003 Seaglider, an autonomous underwater glider has been making physical, chemical and bio-optical measurements in the Northern California Current Ecosystem, in waters off the Washington coast. One goal of the program is to provide a climatological understanding of the oceanography in this region, and also to establish the relationship between physical forcing and phytoplankton response. Seaglider occupies a repeat survey transect beginning approximately at the shelf/slope break and continuing seaward about 250 km offshore. Here we focus on the most seaward region of the repeat transect, a region revisted on a monthly schedule. Measurements include temperature, conductivity, and dissolved oxygen from the surface to 1,000 m and chlorophyll fluorescence and optical backscatter in the upper 150 m. The depth of the winter pycnocline varied among years, between about 80 and 120 m, with the deepest pycnocline followed by the largest spring bloom while the timing of the transition between the deep winter and shallow pycnocline controls the timing of the spring phytoplankton bloom. Glider observations are proving a valuable tool for studying physical forcing and biological responses.

COHERENT RESPONSE OF NORTHWEST ATLANTIC SHELF ECOSYSTEMS TO DECADECAL CLIMATE VARIABILITY

During the 1990s, a series of freshwater anomalies propagated down the Northwest Atlantic Shelf. Pelagic ecosystems on the shelf exhibited a complex response to the freshening. In general, the freshwater was associated with an increase in phytoplankton abundance, especially in autumn and winter, and an increase in many copepod species. However, both the seasonality of the response, as well as the species exhibiting the strongest responses, changed across the shelf. By examining the coherent signals in the plankton community, and those species that deviate from the signal, we develop a conceptual model for how the ecosystems of the Northwest Atlantic Shelf will respond to future climate variability and change.

DEMONSTRATION MISSIONS IN ESONET NOE

ESONET is a Multidisciplinary European Network of Excellence (NoE) associating 50 partners from 14 countries and more than 300 scientists and engineers. The goal of this NoE is to facilitate the blending of European research on deep sea multidisciplinary observatories. Over the ﬁrst 4 years, the approach is to merge the programs of members organisations by managing marine research activities, addressing the common scientiﬁc objectives and by networking activities specially designed for Excellence integration and spreading. Amongst other actions, it works by establishing sea ﬂoor infrastructure that will provide platforms for instrumentation deployed throughout the water column and the seafloor below. These platforms will provide power for instruments and real-time two-way data communications. Firstly, some “demonstration missions” have been selected in November 2007 and are presented here. Demonstration actions are bringing technology excellence at high level for different development phases, implementing the standardisation and interoperability of the different platforms from the consortium. By acquiring relevant time-series of multidisciplinary data, they will be an input for integrated studies, common workshops and a material support to implement a data management plan.

THE LANS-ALPHA TURBULENCE PARAMETRIZATION IN PRIMITIVE EQUATION MODELING

The Lagrangian-averaged Navier-Stokes-alpha (LANS-alpha) model is a turbulence parameterization that increases eddy activity near the grid-scale. We will review the implementation and results of LANS-alpha in the POP ocean model. Simulations with LANS-alpha in an idealized channel model domain produce turbulence statistics like a doubling of resolution, including kinetic energy, eddy kinetic energy, and temperature profiles. The cost of adding LANS-alpha is only 30%, versus a factor of ten for doubling the horizontal resolution. LANS-alpha, which is derived using Hamilton's principle, modifies the momentum equation with an extra nonlinear term and a smoothed advecting velocity. The alpha parameter controls the strength of smoothing in a Helmholtz inversion operator, and is equal to the strength of the turbulence model. We show that efficient filters can replace the Helmholtz inversion, with similar results. A linear dispersion analysis of LANS-alpha shows that it increases the effective Rossby Radius, thus allowing more eddy activity near the grid-scale in low-resolution ocean simulations. Preliminary simulations in a North Atlantic domain produce deeper and more realistic penetration of eddy kinetic energy in the North Atlantic Current.

THE CONTRIBUTION OF ATMOSPHERIC ACID DEPOSITION TO OCEAN ACIDIFICATION OF THE NORTH ATLANTIC OCEAN AND CORAL REEF DOMINATED MARINE ECOSYSTEMS

We evaluate the influence of atmospheric acid deposition on the acidification of oligotrophic waters of the North Atlantic Ocean and coastal waters of the Gulf of Maine. We conclude that acid deposition led to a significant decrease in surface water pH. This decrease is the result of an increased effectiveness of these new products will be presented using observations of Los Angeles coastal waters during the Hyperion Treatment Plant's diversion of effluent from the 5-mile to the 1-mile outfall in November 2006.

A TWO-EQUATION MODEL OF INTERNAL WAVE- AND SHEAR-DRIVEN TURBULENT MIXING

Turbulent mixing driven by internal waves and mixing driven by
a gas-exchange parameterization to estimate the new production along the transect. Continuing observations from 2002 to 2005 onboard of a ferry from Coos Bay (DE) to Harwich (GB) together with wind fields derived from a regional meteorological model were used to estimate the seasonal dynamic of oxygen production along the track. Together with the other variables continuously measured by the FerryBox (S, T, Chl-a, Turb) areas of high productivity, such as fronts, can be easily detected and quantified. The new production values obtained using the oxygen flux method will be compared with net production rates provided by traditional methods and models.

Peterson, I. K., Bedford Institute of Oceanography, Dartmouth, Canada, peterson@mar-dfo.mpo.gc.ca

BEAUFORT SEA WIND FORCING OF THE FLOW THROUGH THE NORTHWEST PASSAGE

Monthly mean volume transport estimated from current measurements at moorings across Barrow Strait and observations from 2001 to 2005, compared with Monthly mean volume transport at monthly to interannual time scales is significantly correlated with north-eastward winds 1000km from the west to the moorings in the Beaufort Sea, parallel to the western side of the Canadian Arctic Archipelago. The optimum wind direction and direction are consistent, suggesting a wind礼品赠送风-driven circulation. This study relies on the understanding of the Beaufort Current along the opposite ends of the Passage, and the difference being determined by setup caused by alongshore winds in the Beaufort Sea. Monthly alongshore wind anomalies account for 38% of the variance of the transport anomalies, and 50-60% of the variance in the annual cycle of transport is attributable to seasonal variations in wind.

INTEGRATING NAGL APPROACHES TO CLASSROOM STRUCTURE WITH LOCAL OCEAN-SCIENCE MODELS THROUGH GRADUATE STUDENT-TEACHER PARTNERSHIPS IN WASHINGTON STATE

Partnerships pairing science graduate students with middle school science teachers in coastal Washington produced adaptations to existing science curricula and novel mechanisms to enhance student learning in local middle schools. Each classroom pairing, supported by GK-12 NSF funding, emphasized different scientific content, ranging from "Popular Culture and Ecology," to "Properties of Matter." Novel approaches redirected attention from whole-class, teacher-driven activities to a structure challenging students to be curious and practice scientific processes by emphasizing observation and continued reflection. Flowcharts, which broke the class into several student-groups, were utilized in multiple classrooms to move students through a strand of thematically tied activities at their own pace, combining individual focus with small group discussion and activities. Ocean science came to the forefront as a powerful example in three classrooms: using the movement of ocean currents to demonstrate the power of density, applying GIS to map sightings of local orca pods in northern Puget Sound, and employing Bellingham Bay, a local coastal area, to focus on securing ecological model. Students successfully applied fundamental scientific processes and content, learned through ocean-science examples, to multiple scientific disciplines.

INFLUENCE OF A RECIRCULATING RIVER PLUME BULGE ON BIOGEOCHEMICAL PROCESSES ALONG THE OREGON/WASHINGTON SHELF

While most numerical and laboratory models of coastal river flows result in the generation of a large anticyclonic bulge near the month of the river, evidence of such a feature in field observations is remarkably scant. Recirculation features act to concentrate plankton, and therefore they hold significant implications for ecosystem function and trophic transfer. We report direct observations of bulge circulation resulting from a period of low wind stress near the month of the Columbia River as tracked by drifters and corresponding physical, biological, and chemical properties. The bulge had a core approximately 5 m deep and 22 km wide with a total diameter of 30-40 km and was characterized by elevated rates of primary production, chlorophyll, zooplankton, and river-derived nutrients. We suggest that such ephemeral features may have a disproportionately large impact on shelf ecosystems and may thus contribute significantly to enhanced production over river-influenced continental shelves.

A SUBMERSIBLE HOLOGRAPHIC IMAGING SYSTEM

an in-situ digital holographic recording system, capable of recording movies of marine organisms (resolution down to 4.11 μm), has been deployed as a drifter, moving with the ambient current and as a fixed system sitting on the ocean floor: Deployments have been conducted in Spain, France, and New Jersey. Biological samples were collected using plankton net tows and niskin bottle samples in conjunction with deployments. At times, a second holographic recording system was used on the vessel to image organisms in water samples at higher frame rates and magnifications than was obtained with in-situ recording. From the drifting deployments we observe zooplankton in-situ, studying swimming behavior, nearest neighbor distances and predator-prey relationships. The preserved biological samples are used to provide species-level identification and concentration measurements. In addition, the high-speed holograms of collected water samples allow us to directly compare confined and in-situ behavior. From the fixed deployments we correlate organism concentrations and behavior to flow properties (i.e. wave phase) measured with an Acoustic Doppler Velocimeter, using this information to understand how organisms are transported by and react to benthic boundary layer flow.

The NEPTUNE Canada Network The NEPTUNE Canada Regional Cabled Observatory is conceived as a "utility" for ocean science. Power and communications will be delivered over standard interfaces and the network design and operation will be largely transparent to end users. Providing this capability requires a network architecture that gives equal consideration to power, communications and ocean engineering. The NEPTUNE Canada network design consists of a resilient loop with six nodes at locations of primary science interest. Extensions and junction boxes allow instruments and sensors to be placed in close proximity to items of interest. Branching units and repeaters based on proven, commercial telecommunications designs provide expansion as required. A parallel powering arrangement working at up to 10V and 8Amps provides 10 kW to each node. The communications network utilized IEEE 802.3 Ethernet standards to provide up to 4 Gbps at each node. Ocean engineering considerations include burial to secure the cable and repeaters from external aggression, trawl resistant node frames, and the use of wet-mate connectors to permit recovery of nodes, junction boxes, and instruments.

A TEN-YEAR RECORD OF PHYTOPLANKTON COMPOSITION AND BIOMASS IN THE INDIAN RIVER LAGOON, FLORIDA
Philips, E. J.
University Florida, Gainesville, USA, philips@ufl.edu

The Indian River Lagoon stretches across 350 km of the eastern shore of Florida. Historically, the watershed of the lagoon has been the site of extensive agricultural activity, but more recently has become one of the fastest growing population centers in the United States. Since the mid-1990s the lagoon has been extensively monitored for water quality, including phytoplankton populations, because of concerns about the potential conse-
quences of eutrophication for recreational activities and fisheries in the lagoon. In this study phytoplankton composition and biomass were determined on a monthly basis for 8 sites in the lagoon, along with associated water column conditions: including salinity, tem-
perature, dissolved oxygen, turbidity, light extinction coefficients, total nitrogen and total phosphorus. Over the course of the study there was a dramatic upsurge in the intensity and frequency of harmful algal blooms, particularly the saxitoxin-producing dinoflagel-
late Pyrodinium bahamense. The relationships between spatial and temporal patterns in phytoplankton populations and water quality parameters are explored to provide insights into the driving forces behind these bloom events.

WEST ANTARCTIC PENINSULA CIRCULATION AND IMPLICATIONS FOR BIOLOGICAL PRODUCTION
Pickart, S. R., Naval Research Laboratory, Senns Space Center, USA, pickart@nrlssc.navy.mil

Observations of the distribution and abundance of marine mammals and other predators, obtained as part of the Southern Ocean Global Ocean Ecosystems Program, showed that these animals concentrate in specific areas of the western Antarctic Peninsula (WAP) continental shelf. The relative contribution of circulation in producing these regions of enhanced predator abundance was investigated with Lagrangian particle tracking stud-
ies that used simulated circulation fields obtained from the Regional Ocean Modeling System (ROMS). Flows were derived from simulations performed at different seasons and depths. The simulated particle trajectories showed preferred sites for cross-shelf exchange and onshelf intrusions which related to areas where higher predator abundance was observed, such as inside and around Margarite Bay, and north of Adelaide Island. Also, trajectories of floats released along the southwestern portion of the WAP show inputs from the Bellingshausen Sea, particularly for the southern limb of Margarite Bay. The float trajectories suggest that the circulation is potentially important in develop-
ing localized areas of high predator abundance perhaps through facilitating aggregation of prey and/or providing areas of enhanced nutrient availability and biological production.

FLOW OF DENSE PACIFIC WATER INTO THE WESTERN ARCTIC OCEAN THROUGH HERALD CANYON
Pickart, S. R., Woods Hole Oceanographic Institution, Woods Hole, USA, pickart@whoi.edu

Dense water of Pacific origin drains into the western Arctic Ocean from the Chukchi Sea via two routes: Barrow Canyon and the Herald Canyon in the west. The dynamics of the flow through the canyons and the associated mixing play important roles in determining the ultimate fate of the water in the Arctic Basin, including the flow of the upper halocline. In August 2004, as part of the Russia-US Long-term Census of the Arctic (ROSLI) program released along the outer shelf and mid-shelf regions were car-
ried out in Herald Canyon (the first such high-resolution survey of the region). Both dense and buoyant Pacific-origin water were flowing northward through the canyon, and both flows changed significantly from the the head of the canyon to its mouth. The evolution of the water masses and currents is described, including the possible role of hydraulic
control in influencing the character of the dense flow. A comparison is made between the canyon outflow and the resulting downstream boundary current.

EFFECTS OF CONTINUOUS IRON, COPPER AND DOMOIC ACID SUPPLY ON SHAPING THE TRAJECTORY OF PHYTOPLANKTON ASSEMBLAGES IN NEAR AND OFFSHORE SUBARCTIC PACIFIC WATERS

The effect of iron addition on phytoplankton production in subarctic Pacific HNLC waters has long been studied using large, pulsed iron amendments in bottle and mesoscale experiments. Analogous natural events are rare, and the effects of low but continuous metal enrichment on subarctic phytoplankton assemblages is largely unknown. We used shipboard continuous cultures to measure the effects of iron, copper and domoic acid amendments in nearshore waters, young Haida Eddy transition waters, and oceanic waters at Ocean Station PAPA. Population responses differed sharply among these environments but in each case domoic acid, a comparatively weak iron and copper chelator, enhanced diatom growth more than iron additions alone. Domoic acid, a neurotoxin produced by Pseudo-nitzschia, has been measured in these coastal and offshore waters and its production and release can be attributed to both Fe and Cu limitation. Our findings indicate that dissolved DA may help alleviate metal stress in Pseudo-nitzschia and other phytoplankton, as might other weaker metal chelators. These findings demonstrate how continuous cultures can provide novel insights to the bottom-up control of phytoplankton community trajectories in these iron-limited systems.

WARMING OF THE WEST SPITSBERGEN CURRENT AND SEA ICE EXTENTION NORTH OF SVALBARD

Extensive warming of the Atlantic Water (AW) layer in the Fram Strait has been observed since 2003. During summers 2004-2006 isotherm 5°C at 100 m has moved meridionally 4.5° northward. In summer 2006 temperature of AW core reached record-high values. Observations revealed large positive heat anomalies carrying northward heat surplus enough to melt 130,000 square km of 1 m thick ice sheet. It coincided with extensive northward shifting of the Barents Ice Edge. For long time the area was warmer and it was the main source of the Arctic Ocean ice-shrinking. Only recently influence of the ocean and its heat transport is more and more recognized as very important factor influencing changing of sea ice coverage. The IOPAS data on the West Spitsbergen Current temperature, heat content and transport are confronted with the sea ice extension north of Svalbard. Good agreement between the AW layer heat anomaly in July and sea ice extent north of Svalbard in next winter is presented. In summer 2007 the AW layer temperature has decreased, probably it could be the beginning of reversing trend in the AW temperature.

AN OBSERVATIONAL STUDY OF THE RELATIVE IMPORTANCE OF WIND AND TOPOGRAPHIC FORCING ON OCEANIC EDDY SHEDDING BY TALL DEEP WATER ISLANDS (GRAN CANARIA).

In a recent numerical study (Jiménez et al., Ocean Modelling, accepted, September 2007) we have investigated the relative importance of wind and topographic forcing on oceanic eddy shedding by tall deep water islands. The main conclusion is that the wind shear at the island wake (topographic forcing) enhances eddy production by lowering the threshold of ocean incident flow speed (topographic forcing) required to shed eddies. Presently we are analyzing observational data to get evidences of this conclusion for Gran Canaria Island eddies. Eddies generation and shedding frequency was obtained from SST images and temperature anomalies of a two year mooring placed on the track of cyclonic eddies. Topographic forcing was inferred from the incident oceanic geostrophic flow calculated from altimeter and tide gauge data. Wind forcing (shear), was inferred form two meteorological stations, one located in the wind accelerating part of the island, and other at the island wake. Although we are still analyzing these data, preliminary results suggest that the main mechanism for eddies generation is the topographic forcing.

QUANTITATIVE RELATIONSHIPS BETWEEN ZOOPLANKTON VERTICAL DISTRIBUTION AND OXYCLINE DEPTH: COMPARISONS BETWEEN REGIONS, SIZE CLASSES, AND TIME OF DAY

We developed metrics to quantitatively assess the effect of hypoxic (<2 mg ml⁻¹) bottom water on pelagic zooplankton vertical distributions. Data were collected in the northern Gulf of Mexico and the Chesapeake Bay on four summer cruises in each location. We used an Optical Plankton Counter mounted on a Scanfish to collect zooplankton and phytoplankton simultaneously along transects in each region that were subdivided into eight size classes ranging from 250 μm – 5 mm equivalent spherical diameter. The slope of the relationship between zooplankton median depth and the oxycline depth was positive for nearly all cases, and increased with increasing zooplankton size. In addition, die changes in vertical zooplankton distribution varied between size classes and regions, and not die vertical migration was observed for larger size classes at certain times. Increasing hypoxia decreases the available habitat for pelagic mesozooplankton, which can alter trophic dynamics in systems experiencing hypoxia.

A COMPREHENSIVE COASTAL SURGE, INUNDATION AND FLOOD MODEL WARNING SYSTEM ARCHITECTURE

The Coastal and Inland Flood Warning System is presented. The model architecture is designed for the development and transition to operations of new river, estuary and coastal flood-forecast capabilities and products coupled with improved prediction of water quality and eutrophication. The Coastal and Inland Flood Warning System (CIFWS) model architecture captures and combines the most recent advances in modeling coastal, estuarine, and watershed zones utilizing state-of-the-art modeling systems and simulation infrastructure for real-time flood-forecast capabilities and products coupled with improved prediction of water quality. CIFWS is designed for the development and transition to operations of new river, estuary and coastal flood-forecast capabilities and products coupled with improved prediction of water quality and eutrophication.

DEVELOPING TERRESTRIAL-LIDAR-BASED DIGITAL ELEVATION MODELS FOR MONITORING BEACH NOURISHMENT PERFORMANCE

Since the completion of a 398,000 m³ nourishment project along 2 km of Rehoboth Beach, Delaware in August of 2005, the subaerial volume and area of the northern 25% of the beach has been monitored through the use of terrestrial light detection and ranging (LIDAR) surveys. Traditionally, analyses of beach width from aerial imagery and volumes estimated from widely spaced profiles have been used to measure nourishment performance and determine renourishment quantities. However, these survey methods lack the spatial and temporal resolution often required for management decisions. This study investigates a method of monitoring beach nourishment performance using terrestrial LIDAR, which allows for high-temporal and spatial resolution models of subaerial beach topography on a monthly basis. Analyses of the digital elevation models created: 1) allow for a better understanding of the range in variation in beach area and volume, especially that due to storm events; 2) provide more accurate volume estimates than traditional profile surveys by as much as 8%, and 3) indicate that the area and volume do not covary, limiting the usefulness of aerial imagery in estimating volume.

PARTICLE DYNAMICS AND BIOGEOCHEMISTRY OF THE GULF OF MAINE BENTHIC NEPHELOID LAYER

Considerable evidence indicates that the benthic nepheloid layer (BNL) is a distinctive and critical component of the coastal ocean, with major role in influencing the character of the dense flow. A comparison is made between the canyon outflow and the resulting downstream boundary current.

Piper, J. D., University of Maine/Darling Marine Center, Walpole, USA, babyskill@ hotmail.com;
extends 30-10 m above the bottom and is a pervasive feature throughout the region. Tidal mixing and the water inflow are at their highest levels and can be used to estimate the salinity and lateral movement. Elevated concentrations of total particulates, enhanced oxygen consumption levels, extracellular enzyme activity, and greater biota abundance are associated with the BNL as compared to overlying, relatively particle-free waters. Geochemical data from time-series sediment trap studies and optical measurements indicate that more organic- rich BNL particulate material, as well as previously associated, and as well as a temporal relationship between suspended particle composition and dissolved oxygen conditions. Trap results document enhanced labile particle delivery to the BNL during seasonal phytoplankton blooms, a diverse community of BNL zooplankton consumers, and the importance of time-varying BNL resuspension fluxes to the transport and fate of toxic dinoflagellate cysts throughout the Gulf.

DISTRIBUTION, EGG PRODUCTION AND GROWTH OF EUPHASIAWDS IN THE VICINITY OF THE PРИБОЛ ISLANDS AND ON THE MIDDLE SHELF, SOUTHEASTERN BERING SEA

Distribution, egg production and growth of euphausiids near the Pribilof Islands and on the middle shelf of the Bering Sea were studied during August 2004. Thysanoessa longipes was abundant in the oceanic water, aggregations of T. inermis were observed both in the oceanic shelf water and shelf water, while T. raschii was found near the islands. Euphausiabundance es on the middle shelf were several orders of magnitude lower than in the cold summer of 1999. Juvenile T. inermis showed intensive growth (~8 % of dry body weight/day). In contrast, the somatic growth of T. inermis and T. raschii was slow (<1.5% of body weight/day) suggesting the investment of resources into lipid deposition and reproduction. Egg release corresponded to ~11% of female dry body weight/day for T. raschii indicating that enough resources were available for the animals to maintain reproductive activity. Our data suggest that the region near the Pribilof Islands, known for its high biological productivity, may provide a refuge for the shelf euphausiid population during warmer summers, when conditions on the shelf are unfavorable for their growth and reproduction.

RESILIENCE AND RECOVERY OF LAKE PONCHTRAIN AFTER HURRICANE KATRINA

Floodwaters pumped into Lake Pontchartrain following Hurricane Katrina contained toxic chemicals, carcinogens, pathogens, and human waste as well as high nutrient concentrations. The rate of loading of these contaminants presented a unique opportunity to describe ecosystem responses to this catastrophic event. Changes in phytoplankton community composition was used as a sensitive bioindicator for quantifying shifts in ecosyst em structure. Water samples were collected weekly from 15 September to 15 December 2006 at several stations in Lake Pontchartrain. Photopigment concentrations and algal standing stocks were determined by HPLC and ChemTAX. Phytoplankton community structure. their periplasm and feeding on degraded macromolecules. The Nudix hydrodrolases catalyze the hydrolysis of a nucleoside diphosphate linked to different moieties, X (NUDIX). They have in common the signature sequence GXSEX/REUXEXXGU. The phenotypes associated are diverse, e.g. GdPTases are involved in preventing mutations by removing damaged nucleotides (MutT). The BALOs are mainly represented by two groups which genome were recently sequenced, Bdeilovibrio bacteriovorus HD100 (freshwater) and Bacteriovorax marinus SJ (salwater). Sequence analysis shows that the HD100 genome has five ORF with the nudix consensus sequence and HDS contains three. The objective of this work is to identify which of the nudix hydrodrolases in the BALOs present the MutT phenotype. To test the MutT activity, a complementation assay was performed using a hydrolytic enzyme gene cloned in the plasmid pT3909A. Escherichia coli MutT was transformed and plated in media supplemented with streptomycin and nalidixic acid, to check for mutations. Further enzymatic analysis will be performed to complete the characterization.

EVALUATION OF QUIKSCAT ULTRA-HIGH RESOLUTION WIND RETRIEVAL IN THE GULF OF MAINE

The QuikSCAT scatterometer is widely used to retrieve ocean winds at 25 km and now 12.5 km resolution. Currently, a 2.5 km resolution product is also being created. These higher resolution wind field estimates offer the potential to resolve physical processes that the lower resolution fields do not. This study investigates this ultra high resolution (UHR) QuikSCAT product in the Gulf of Maine for the month of October 2006, using in situ measurements from the large network of buoys in the gulf. The comparison of UHR and collocated buoy winds indicates interesting trends regarding near-shore wind retrieval, spatial cross-swath differences, and the UHR winds are evaluated both with and without a land contamination compensation routine. Comparison with mesoscale meteorological model winds and other types of satellite data, including the lower resolution QuikSCAT products, Envisat ASAR imagery, and MODIS data allow further insights into physical processes that may be resolved within the UHR wind fields. This research has potential industrial, commercial and climate-related applications.

MOLECULAR APPROACHES FOR CATEGORIZING MARINE BIODIVERSITY OF CORAL REEFS

Although they represent less than 0.2% of the ocean area, coral reefs may be the most diverse of all marine ecosystems. However, we don’t know to even the nearest order of magnitude how many species are associated with coral reef ecosystems. The only two published estimates are based on extrapolations from rainforest and aquarium diversity measurements. Coral reefs are also among the most threatened of all ecosystems. Unfortunately we lack the taxonomic expertise and the time needed to characterize this diversity, as well as the extent of biodiversity loss related to human impacts, using traditional methods. However, the revolution in molecular genetics dramatically changes the potential for reef scientists to make progress in this area. Molecular techniques appear particularly useful for groups less well-characterized for which taxonomic expertise is very shallow (especially small organisms). In this study, we employed a DNA barcode approach to standardized samples of marine invertebrates in Moorea (French Polynesia) and the Line Islands to assess biodiversity associated with coral reefs. Our results provide meaningful comparisons between different regions.

REANALYSIS OF OCEANIC REMINERALIZATION STOICHIOMETRY BY SIMULATED ANNEALING APPLIED IN A WATER MASS ANALYSIS FRAMEWORK

We use the tool of water mass analysis together with a global non-linear optimization algorithm to investigate the spatial distribution and variability of remineralization ratios in the ocean. We apply the simulated annealing scheme to the GLODAP data set and compute the remineralization stoichiometry and the mixing fractions of the water masses contributing to each sample for each sample individually. Our results support previous claims that the C:N:P stoichiometry is constant below 2000m, with proposed values of 106:7:14 ± 11. We observe positive deviation from the Redfield values in the Mode and Intermediate waters, however. Although some of this variability may be associated with preformed definition issues, we curtail rule out the influence DOM remineralization or unresolved mixing processes. We propose a deep S:N:P of 9 below 4000m and 5 in the upper 2000m and a C:O:P that increases with depth from 140 at 2000m to 180 below 3000m. Although our results represent path-integrated remineralization signals, they may be useful for model diagnostics as they are sensitive to the circulation and the remineralization history of water parcels.

DISTRIBUTION OF BIOACTIVE TRACE METALS IN LARGE PARTICLES (>53μM) AROUND THE CROZET ISLANDS, SOUTHERN OCEAN

CROZEX is a large multidisciplinary study performed during the austral summers 2004-2005 and 2005-2006 in order to examine the effect of natural iron fertilization on carbon sequestration. Large particles (>53μm) that were sinking out of the mixed layer were collected at 20 stations around the islands using in situ pumps (Challenger Oceans). The particles were categorized into several discrete biomass metal traces (AlMn, FeCu, and Zn) in a variety of biogeochemical environments. Systems were deployed around the Crozet Islands. A two step sequential leaching technique has been applied on each particulate sample to distinguish the labile fraction from the more refractory fraction. The distribution of bioactive metals in both phases will be presented. There is a very strong correlation between POC concentrations for some of these bioactive metals. The differences between the sites under the influence of the islands, and the true HNLC sites will be as well investigated revealing a greater concentration of all elements at close proximity of the islands, consistent with the

NEW TECHNIQUES FOR LOW LEVEL AMMONIUM MEASUREMENTS IN THE OLIGOTROPHIC OCEAN

Much of the productivity in the oligotrophic ocean is fueled by ammonium. Despite this fact analysis is difficult at nanomolar concentrations. Using a gas diffusion technique coupled with conductometric detection we were able to measure ammonium down to 5 nM during a transect from Monterey Bay, California to an oligotrophic site 800 km to the west in July of 2007. Discrete samples from CTD casts were measured using a bench top system with a detection limit of 5 nM. In addition a drifter was released with an in situ autonomous ammonium analyzer which measured surface ammonium concentrations every 30 minutes for four days with a detection limit of 10 nM. Surface concentrations were at or near detection limits while profiles exhibited a distinct subsurface peak coincident with the chlorophyll maximum.

BAYESIAN-PREDICTION APPROACH APPLIED TO COASTAL MORPHODYNAMICS

The processes that drive coastal evolution (i.e., morphodynamics) are extremely sensitive to small changes in bathymetry and topography. This is particularly true for barrier island response to large storms. In this case, key morphodynamic variables include dune height, dune width, beach slope, inlet widths and inlet depths. Even if we had perfect models for predicting flows due to waves and winds and correspondingly perfect models for predicting response to large storms. In this case, key morphodynamic variables include dune height, dune width, beach slope, inlet widths and inlet depths. tends to lead to CO₂ outgassing nearshore and biologically-driven CO₂ uptake offshore. Yet, the net air-sea CO₂ balance of EBCs remains unresolved. High nearshore productivity coupled with filamentous and other meso- and submesoscale phenomena cause a substantial lateral export of organic carbon. We investigate these coastal processes in the California Current (CalCCS) and the Canary Current Systems (CanCCS), on the basis of the eddy-resolving, physical-biogeochemical model ROMS. First results confirm the onshore-offshore trends in the air-sea fluxes, with substantial spatial and temporal differences due to topography, upwelling strength, and eddy activity. The CalCCS is modeled to be a very small source of CO₂ to the atmosphere, consistent with a recent data-based estimate by Chavez and Takahashi, while for the CanCCS this is not clear yet. Regarding offshore transport, the CalCCS appears to be stronger than the CanCCS. Further analyses of the processes that determine the carbon fluxes and the differences between the two systems will be presented.

The Coastal and Global Scale Nodes of the Ocean Observatories Initiative

The National Science Foundation is presently implementing the Ocean Observatories Initiative (OOI), an outgrowth of several years of community-wide scientific planning efforts. The OOI will use advanced technology and integrated cyberinfrastructure (CI) to provide, the research and education communities with a new, interactive view of the oceans and offer innovative approaches to the examination and discovery of oceanic processes. The Coastal and Global Scale Nodes (CGSN) of the OOI Network include a coastal Pioneer Array in the Middle Atlantic Bight, a coastal Endurance Array in the Pacific Northwest, open-ocean sites at high latitude in the Atlantic and Pacific Oceans, and a mid-latitude Atlantic site. The CGSN will be integrated with the Regional Scale Node and CI component of the OOI. The science drivers for the CGSN have been evaluated by a variety of community panels and committees, and the CGSN design has been under continuous review and refinement since the publicly vetted Conceptual Network Design of March 2007. This presentation will describe the CGSN science priorities and summarize the current status of the CGSN network design.

LIGHT AND PHOTOSYNTHESIS OF PHYTOPLANKTON IN KUWAIT WATERS

The annual variability of the photosynthetic parameters by phytoplankton studied in the waters of Kuwait, northwestern Arabian Gulf. Waters in that part of the Arabian Gulf strongly vary in underwater light climate and seasonal changes in light availability also considerable. Turbidity changes from the highly turbid and productive northern waters off Bubiyan Island to the clearer southern offshore waters. Therefore, primary productivity is highly variable in space and time, due to the complex physical and chemical conditions, which vary seasonally in this arid climate. Estimations of the main physiological parameters were evaluated in a two-year study, using a PI incubators and C-14 technique, to identify periodic patterns and their causes. Correlation of physiological parameters of the phytoplankton with temperature, solar irradiance, and underwater light indicate significant differences along turbidity gradient. The results of the measurements and the quantitative regularities obtained rather correctly represent the spatial distribution of the photosynthetic and bio-optical characteristics in the waters of Kuwait.

GLOBAL TEMPORAL TRENDS IN THE QUIKSCAT WIND VECTOR AND IN THE AMPLITUDE OF ITS VARIABILITY

In situ observations, numerical models, and satellite altimeter data agree that the global sea level has increased in the past 14 years. This increase can be of eustatic or steric origin, and the latter can be separated into halosteric and thermosteric components. Thermosteric changes in sea level imply that the heat content of the ocean has changed and thus there may be significant changes in the amount of heat exchanged with the atmosphere. Momentum transfer depends on the stability of the planetary boundary layer. The heat exchange that takes place at the sea surface creates convective turbulence, and therefore has a potential impact on the momentum transfer between air and water. Scatterometer measurements are based on Bragg scattering by capillary--gravity waves which is empirically associated with the wind through its stress. This makes the satellite scatterometer particularly well suited to detect changes in the global rate of momentum transfer through the air-sea interface. The rates of change are estimated for the wind magnitude and direction and for its derivatives: divergence and curl. In addition, if more energy enters the ocean--atmosphere system, an increase in wind variance is expected. This study aims to quantify the changes in the amplitude of this variability associated to large and meso--scale dynamics.
ANAEORIC DEGRADATION OF ORGANIC MATTER IN AN INTERTIDAL SEDIMENT HARNESSING NATURAL C ISOTOPES TO UNDERSTAND ORGANIC MATTER TRANSFORMATIONS

Coastal and continental margin sediments supply dissolved organic carbon (DOC) to the overlying water at rates similar to riverine DOC fluxes. The biogeochemical role of benthic DOC flux in the marine C-cycle is nonetheless unclear, because porewater DOC remains one of the least chemically resolved pools of organic carbon. To better understand the nature of DOC that accumulates in marine sediments, an intertidal sediment was incubated in sealed vessels for three months during which the concentrations of porewater dissolved inorganic carbon (DIC) and DOC were monitored. By further determining the Δ13C and δ18O signatures of these pools, the goal is to determine the isotopic signature of the fraction of particulate OC (POC) that extends earlier steady solutions. After non-dimensionalisation and assuming the forcing to be time periodic, the solution depends on the topography, the horizontal distribution of the wind stress, the ratio of the oscillating viscous boundary layer thickness to the characteristic times for eddies that are shed are long compared to tidal timescales.

UNDERSTANDING ACOUSTIC WAVE SAMPLING IN THE NEARSHORE: ADVANTAGES AND LIMITATIONS

Recent addition of acoustic surface detection techniques to Doppler current profilers makes it an attractive option for measuring wave field in the near shore. Acoustic surface detection (ASD) works in a similar way to a common echo sounder and was in use since mid 1980 for measuring surface and internal waves. ASD requires that there is a sharp contrast between reflectors, which can be from the water and the surface in order to reliably detect surface. Hence, AWS method does not fare well in the presence of acoustic reflectors such as seaweed and bubbles, due to breaking waves that are commonly found in the nearshore environment. We describe field test results conducted off of the Scripps Pier, under varying wave conditions. Our data show that acoustic wave detection works fairly well (97.5% detection success rate) in the absence of breaking waves and moderate wave conditions (Hs<2m). However, its performance rapidly deteriorates as waves grow in strength and breaking starts to dominate wave dynamics. Potential augmentation techniques are discussed aimed at improving reliability of acoustic wave measurements in the near shore.

riRNA-derived. Taxonomic binning of the sequences showed a dominance of genes expressed by Proteobacteria and Cyanobacteria. Expressed gene bins representing several taxa of heterotrophic bacteria including the Roseobacter and SAR11 groups indicated a significant representation of predicted highly expressed genes, as identified by genomic analysis of cultured relatives, in the metatranscriptomic libraries. Statistical comparisons of the day vs. night libraries revealed differences in relative representation of COGs and KEGG pathways, reflecting the conditions at the time of sampling. Our results demonstrate the application of environmental metatranscriptomics to the examination of dominant and differential gene expression in marine microbial communities.

CAN FISH FARMING CHANGE MICROPLANKTON COMMUNITY COMPOSITION?

Eutrophication involves increased growth of aquatic primary producers leading to an undesirable disturbance to the balance of organisms. Eutrophication can be induced by sewage discharge of fish, which is increasing in fjords in northern and southern hemispheres. We have made a physical-biological model to simulate the impact of fish farmers on microalgae plankton plus pelagic microphytoplankton and sealochs, aiming to find a safe limit to the lochs’ capacities to assimilate farm waste. The model simulated seasonal cycles during 1975 and 2003 in loch Cりaran (western Scotland). In 1975, prior to fish-farming, Loch Cりaran had low nutrient levels but a long growth season with high chlorophyll and a diatom-dominated phytoplankton. In 2003 a salmon farm was added significant N and P to the loch, but maximum chlorophyll was lower than in 1975 and the growth season was shorter. The explanation seems to be a shift from diatoms to flagellate dominance greater than expected from the shift in the N:Si ratio. We used our model to test hypotheses about the possible causes of this change.

PROCESSING HIGH FREQUENCY RADAR SPECTRA IN THE PRESENCE OF SEA ICE

During the open water seasons of 2005 and 2006, the University of Alaska Fairbanks deployed two High Frequency (HF) Radar systems manufactured by CODAR Ocean Sensors on the Prudhoe Bay Oil Fields in Alaska. These systems monitored the nearshore Beaufort Sea and were able to have their frequency switched remotely. During the spring breakup season, while the ice was nearshore, the system ran at 25 MHz, and as the ice moved further offshore the frequency was switched to 13 MHz. One of the goals of this deployment was to see how well the HF Radar worked in varying ice conditions. This was challenging because the presence of ice causes the normally single first-order peak to be split into multiple first-order peaks. Having multiple valid peaks means that the first-order line settings need to be optimized depending on environmental conditions (i.e. whether there is enough fetch and/or wind for second order echo to be present). Results and examples of this optimization as well as surface current data from the field seasons will be presented.

ANALYSIS OF DIURNAL VARIATION WITH THE GHRST HIGH RESOLUTION DIAGNOSTIC DATA SET

The GODAE High Resolution Sea Surface Temperature Pilot Project (GHRST-P) has commissioned the construction of a High Resolution Diagnostic Data Set (HR-DDS) in order to better understand the variability in SST data sets from satellite, model and in situ observations and analyses. The HR-DDS system is an interactive web based framework intended for user-defined real time analysis of multiple data sets, in the form of high resolution regional subsets and analyses. The HR-DDS system is an interactive web based framework intended for user-defined real time analysis of multiple data sets, in the form of high resolution regional subsets and analyses. The HR-DDS system is an interactive web based framework intended for user-defined real time analysis of multiple data sets, in the form of high resolution regional subsets and analyses.

AN EVALUATION OF VIABILITY ASSAYS USING A CONTINUOUS IMAGING PARTICLE ANALYZER (FLOWCAM®) FOR BALLAST WATER ANALYSIS AND REGULATORY COMPLIANCE.

A major source of invasive species in aquatic environments is ballast water discharge from vessels as they travel from port to port. A Ballast Water Convention has been adopted by the International Maritime Organization that will require vessels to treat discharged ballast water limiting the number of viable organisms from entering the environment. The FlowCAM is an instrument used for rapid plankton detection and analysis, with the ability to detect auto-fluorescence (chlorophyll) or stain-induced fluorescence in organisms. The fluorescence is used as a “trigger” for a camera to capture images of target organisms within a sample. The FlowCAM adds a unique capability to the ballast water monitoring process by using different stains to determine the viability of organisms in ballast water. Compared to traditional microscopic methods which are laborious and plagued by operator error, the value of FlowCAM lies in the feedback the user receives with regard to viability. We present results of different viability assays using the FlowCAM, using both fluorescent and visual stains, in order to determine how effective these assays are at detecting viable organisms in ballast water.

MODELING THE TRANSPORT PATHWAYS OF TROPICAL TEL EEL LARVAE IN INDIAN OCEAN

The potential migratory routes of tropical eel larvae in the Indian Ocean are assessed through the use of a quarter-degree global ocean model ORCA025 implemented by the DRAKAR modelling Group. The eddy-permitting model reproduces mesoscale activity and seasonal to interannual variability of main dynamic features consistently with observations. A Lagrangian model, ARIALE, recalculates off-line the pathways of anguillid leptocephalus larvae represented as passive particles. Qualitative analysis of backward and forward calculations allows us to identify a possible common spawning area for eels recruited in Islands of Mayotte, Mauritius and Reunion, which is consistent with biological information on leptocephalus migration behaviour issued from otolith microstructural analysis. However the depth of the particles strongly influences the migration pathways of eel larvae in the Mascarene region. The choice of the spawning date is also crucial, as strong variability exists in the intra-seasonal and interannual time-scales. Statistical analysis of several simulations will be presented in addition to these qualitative results to propose most robust hypothesis on spawning areas and migration depths in anguillid leptocephalus larvae.

DATA ASSIMILATION AND REAL-TIME ENSEMBLE OCEAN FORECASTING IN THE INTRA AMERICAS SEA

Using the Regional Ocean Modeling System (ROMS), we have developed a real-time 4DVAR data assimilation system for the IntrAmericas Sea combining in situ velocity measurements from the Explorer of the Seas along with satellite surface observations (temperature and dynamic height) to generate best estimates of the ocean state for the current day. Utilizing the numerous tangent-linear solutions from the data assimilation system, we generate a set of orthonormal perturbations applied to the initial conditions to generate two-week ensemble predictions. This automated assimilation/prediction system is now running in an experimentally operational mode aboard the Explorer of the Seas. We will discuss the use of the Explorer of the Seas as a platform for real-time modeling experiments.

AQUARIUS REEF BASE: ADVANCED UNDERSEA TECHNOLOGY NOW AND FOR THE FUTURE

The Aquarius undersea research station has evolved from the programs of the past into a state-of-the-art saturation diving facility for science along with a synchronous ocean observing test bed for technology development, and advanced communications that now allows for telepresence education and outreach events. The habitat program has expanded into Aquarius Reef Base, which is composed of the undersea lab, an ocean observing station with real-time access via the Internet, and a shorebase. Our partners, such as NASA and the Navy, have helped make advanced technologies at Aquarius Reef Base available for research, training, and education, and new collaborations with the media are providing exciting avenues for outreach. We plan to enhance and encourage the use of Aquarius Reef Base for underwater technology development, coral reef research, training, and education, and to direct our programs to support research and research needs along with management issues in the Florida Keys National Marine Sanctuary and topics of national importance, such as outlined in the nation’s Ocean Research Priorities Plan.

The study of the ocean on scales of less than a meter is intrinsically important to understanding plankton ecology, since these are the scales at which individual organisms live, move, and perceive their environment. We have developed a bi-spectral planar laser imaging fluorometer (PLIF) system to acquire two-dimensional images of planktonic particles that scatter light or contain chlorophyll a. The 9.8 x 13 cm images have 100 µm spatial resolution, allowing us to localize individual particles. The PLIF system is mounted on an autonomous free-falling vehicle, generating profiles of images as it descends through the euphotic zone. Connecting these overlapping images, we will describe the distribution of phytoplankton on a continuous range of scales from millimeters to tens of meters. We show that the particles are randomly distributed at the smallest scales, but show persistent gradients at larger scales. The scale at which this transition occurs has important implications for the biological and physical mechanisms that drive phytoplankton distributions in the euphotic zone.

ON THE MECHANISMS OF EPISTODIC SALINITY OUTFLOW EVENTS IN THE STRAIT OF HORMUZ

Observations in the Strait of Hormuz (56.08°E, 26.26°N) during 1997-1998 showed substantial velocity fluctuations, accompanied by episodic changes in the salinity outflow events with amplitude varying between 1 and 2 psu on time-scales of several days to a few weeks. These events are characterized by a rapid increase in salinity following by an abrupt decline. Mechanisms behind these strong pulses of salinity events are investigated in a high-resolution (~1 km) Hybrid Coordinate Ocean Model (HYCOM) with special reference to the year 2005. In accordance with the observations the simulated salinity events are characterized by strong coherence between the enhanced flows in zonal and meridional directions. We infer that most of the simulated and observed outflow variability is associated with the continuous formation of strong mesoscale cyclonic eddies; their origin can be traced upstream to around 55.5°E, 26°N. These cyclonic eddies have a diameter of about 63 km and have a remnant of Persian Gulf water (PGW) in their core, which is eroded by lateral mixing as the eddies propagate downstream at a translation speed of 4.1 cm s⁻¹. The primary process that acts to generate mesoscale cyclones results from the baroclinic instability of the exchange circulation through the Strait of Hormuz induced by fluctuations in the wind-stress forcing.

LAGRANGIAN STUDIES OF WARMWATER PATHWAYS IN THE NORDIC SEAS

Past studies suggest that Atlantic water reaches far into the Nordic Seas along two distinct pathways: the Shetland Current (SC) which feeds the Norwegian Coastal Current (NCC) that flows north towards the Barents Sea and Svalbard, and the Norwegian Atlantic Current (which connects the Iceland-Faroe Front) which feeds the Norwegian Basin to its west and the Fram Strait in the north. Examination of 2100 depth RAPOS floats deployed in Atlantic waters south of the Icelan and the Faroes reveals comparable exchange between these two branches, specifically from the NAC to the NCC. Significantly, this exchange manifests itself all along the currents, starting already south of the Iceland-Svalbard Ridge. Five floats drift southeast of the Faroes to join the NCC via the Shetland Current. In the Norwegian Sea many floats leaked out of the NAC to join the IIF, even over the imposing topographic relief of the Voring Plateau. A total of eight of the 2100 floats entering the Nordic Seas drifted north along the expected NAC path towards Jan Mayen and the Mohn Ridge.

Spall, M. A., WHOI, Woods Hole, USA, mspall@WHOI.edu

CIRCULATION AND EXCHANGE IN CHOKED MARGINAL SEAS

A simple theory for circulation and exchange in a buoyancy-forced marginal sea with a narrow connection to the ocean is developed and tested numerically. Consistent with the overall heat and volume balances for the marginal sea there exists a continuous family of hydrodynamically confined states with critical flow at the most constriction section of the strait. Included in this family is a limiting ‘maximal-exchange’ solution that has the minimum temperature difference and maximum volume exchange of all possible solutions. In principle, forcing the flow beyond the limit of maximal exchange results in an ‘overmixed’ state in which no further changes in the properties of the exchange occur. The exact state of exchange for a given forcing, whether maximal or submaximal, can be predicted using a theory that assumes energy conservation over a certain path connecting the strait to the marginal sea or, in some cases, the ocean. Numerical tests of the prediction for the temperature difference and the state of exchange are described. The analytical model is an alternative to the Price and Yang (1998) model of marginal sea outflow.

CORAL REEFS IN OAHU, HAWAII: RELATIONSHIPS AMONG WATERSHEDS, CHEMICAL POLLUTANTS, AND CORAL DISEASE

To date, only a few of the stressors and pathogens responsible for coral diseases have been identified or showed possible causes of coral diseases may be linked to freshwater input from runoff contaminated with pharmaceuticals, pesticides, metals, introduced microorganisms, and antibiotics. From surveys of 27 sites around the island of Oahu, we provide preliminary results that suggest the prevalence of coral disease is higher in enclosed bays where chemical contamination appears to be elevated. Previous studies recorded high levels of Dieldrin and Chlorodane in some bays as well. The recent preliminary studies of sediments from enclosed bays and harbors found polynuclear aromatic hydrocarbons (PAH) in concentrations ranging from 0.01-0.05 µg/g, Chlorodane (0.03 µg/g), and Irgarol (40 ng/L). Diseases were observed in Porties sp. more commonly than in Montipora sp. or Pocillopora sp. (p < 0.002). These preliminary studies will assist in understanding which pollutants are currently present at coral disease study sites, which pollutants may lead to higher levels of disease in Hawaiian corals, and if these pollutants alter biofilms and coral associated microbial communities, possibly decreasing coral settlement and recruitment.

HYDRODYNAMICS AND THE DISPERAL OF SUBMARINE GROUNDWATER DISCHARGE IN KALOKO-HONOKOHAU NATIONAL HISTORICAL PARK, HAWAII

The impending development for the west Hawaii coastline adjacent to Kaloko-Honokohau National Historical Park (KAHO) may potentially alter coastal hydrology and water quality in the marine portion of the park and its associated 590 acres of land. SGD is a major contribution to local surface water discharge on the Hualalai mountains and can be traced upstream to around 55.5°E, 26°N. These cyclonic eddies have a diameter of about 63 km and have a remnant of Persian Gulf water (PGW) in their core, which is eroded by lateral mixing as the eddies propagate downstream at a translation speed of 4.1 cm s⁻¹. The primary process that acts to generate mesoscale cyclones results from the baroclinic instability of the exchange circulation through the Strait of Hormuz induced by fluctuations in the wind-stress forcing.

ZOOPLANKTON GRAZING ON TWO ECOLOGICALLY IMPORTANT HARMFUL ALGAL SPECIES IN THE CHESAPEAKE BAY

Dinoflagellates Prorocentrum minimum and Karlodinium venicicum are two harmful algal bloom species (HABs) of increasing importance in the Chesapeake Bay, yet little is known about the grazers that can control their recurring blooms. We investigated the grazing rates on two non-bloom and bloom concentrations of these two HABs by various zooplankton including the copepod Acartia tonsa, and two heterotrophic dinoflagellates - Oxyrrhis marina and Gymnodinium dominans. All zooplankton had 5-33 times higher ingestion rates when fed bloom concentrations of the HABs compared to non-bloom concentrations. Heterotrophic dinoflagellates had the highest weight-specific ingestion rates on P. minimum, averaging 0.4 (non-bloom) and 8.9 (bloom) µgC prey/µgC predator/day compared to copepods (0.4 and 2.3, respectively). While K. venicicum was ingested by A. tonsa (0.3 and 1.2 µgC prey/µgC predator/day), this species was not ingested by the heterotrophic dinoflagellates, and grazer mortality occurred. These results suggest that copepods can easily ingest these two harmful algal species and are likely important in controlling these blooms. However, protozoan grazer-HAB dynamics are more complex, suggesting heterotrophic microzooplankton may be differently affected by various harmful species.

GROUNDWATER INPUTS OF NUTRIENTS TO COASTAL ZONES OF SOUTH FLORIDA

Coastal areas are often regions of fresh and brackish groundwater discharge. This groundwater discharge may be important for not only the delivery of water but also nutrients to coastal areas. Along the coastlines of Everglades National Park, seawater intrudes into the underlying unconfined aquifer as far inland as 6 to 28 km of the coastline. This results in brackish groundwater to discharge to the overlying freshwater of the Everglades. Elevated concentrations of phosphorus in the brackish groundwater represent a previously
The Rhône River is the major source of freshwater and terrigenous material to the PRODELTA (GULF OF LYONS, FRANCE). Origin and quality of sedimentary organic matter in the Rhone River were collected in the river mouth and the distal region. The origin and quality of sedimentary organic matter (OM) were assessed using biochemical properties (pigments, fatty acids, total amino acids and bioavailable amino acids...). These biomarkers indicate a strong terrestrial signature in the surface sediments from the river mouth. Despite a marked offshore decrease of the river inputs, biochemical signatures of terrigenous OM were also present in surface sediments of the distal sites. The downcore profiles confirmed the rapid mixing and/or burial of terrestrial OM inputs in the sediment. The quality of the OM river inputs for the benthic fauna will be discussed.

GENETIC SIGNATURE OF THE SPATIAL SCALE OF DISPERSAL MEDIATED BY CORAL REEF FISH LARVAE.

The assessment of marine dispersal is a notoriously challenging task, owing notably to the difficulty to track dispersing larvae directly. Genetic isolation by distance (IBD) is the indirect signature of localized dispersal by excellence, yet population genetics theory shows that IBD provides limited information on the scale of dispersal with an additional estimate of density over the area where IBD is detected. Here, we use the barred hamlet (Hypoplectrus pella, Serraniidae) as a model species to assess the scale of dispersal in coral reef fishes. Ten hypervariable DNA markers analysed on 854 fish from 15 locations show that IBD emerges at a scale of 200 km and is maintained until the regional scale despite lower levels of genetic structure overall. Furthermore, we provide population density estimates from both genetic data and SCUBA surveys, allowing an estimation of mean squared parent-offspring axial dispersal distance. Our results, complemented with individual-based simulations, indicate that coral reef fish larvae tend to disperse within tens of kilometres or less, and that this pattern is compatible with low levels of genetic structure over thousands of kilometres.

INTRASEASONAL FLOW IN MAKASSAR STRAIT.

Makassar Strait is the primary path for Pacific water to enter the Indian Ocean as part of the Indonesian Throughflow. Intraseasonal variability (<90 days) are energetic features within the Makassar throughflow. Here we investigate the nature of the intraseasonal variability by analysis of along-channel currents observed near 3°S within Makassar Strait and at its northern boundary with the Sulawesi Sea. We find that the dominant 50-day variability within Makassar Strait is ampliﬁed at all depths relative to the upstream location at the southern entrance to the Strait. The first two EOFs indicate transition of the thermal structure at the southern entrance to the Strait, with a depth-dependent structure that is due to contour-following mixing and/or intrusions from the Sulawesi Sea. The second EOF indicates transition of the thermocline followed by the more complex flow regime in downstream marked by a depth dependent phase shift. Baroclinic events of the Sulawesi Sea are thought to be the forcing of 50-day oscillation within thermocline layer while the deep layer variability is related to the topographically controlled subflow flow.

AIR-SEA DYNAMICS DURING THE PHILIPPINES MONSOON.

During the summer and winter of 2007 a comprehensive suite of ONR-sponsored observations focused on the dynamics of straits was deployed in the Philippines region. Measurement platforms included moorings, gliders and drifters. Our companion high resolution coupled ocean-atmosphere simulations focus on concentrating the summer and winter monsoon conditions and the associated circulations in the ocean. In particular, intense wind jets during the winter monsoon drive a field of coastal eddies that migrate offshore and reform in the lee of islands. The signature of these eddies is evident in the intraseasonal variability by analysis of along-channel currents observed near 3°S within Makassar Strait and at its northern boundary with the Sulawesi Sea. We find that the dominant 50-day variability within Makassar Strait is amplified at all depths relative to the upstream location at the southern entrance to the Strait. The first two EOFs indicate transition of the thermal profile from the thermocline intensified flow toward the more complex flow regime in downstream marked by a depth dependent phase shift. Baroclinic events of the Sulawesi Sea are thought to be the forcing of 50-day oscillation within thermocline layer while the deep layer variability is related to the topographically controlled subflow flow.

ADAPTIVE WATER SAMPLING FROM AN AUTONOMOUS UNDERWATER VEHICLE BASED ON UNSUPERVISED CLUSTERING.

Autonomous Underwater Vehicles are widely used for oceanographic surveys, during which data is collected from a multiple sensors. At MBARI we have developed a water sampler for our AUVs, called the Gulper, that can acquire and return samples for laboratory analysis triggered based on sensors detecting features of interest. For example, scientists interested in studying the mobilization and transport of shelf sediments would like to detect intercalibrating nepheloid layers. To do so we must extract a model that can identify the feature in-situ since we are generally dealing with multiple sensor data. We propose to use unsupervised clustering techniques from Machine Learning to extract features from past missions that will then be used for onboard classification to automatically trigger the
RATES OF PRIMARY PRODUCTION IN THE OCEAN: A COMPARISON OF TRADITIONAL IN-VITRO AND NEW IN-SITU METHODS

The rate of primary production (PP) at the ALOHA time-series station in the subtropical North Pacific has been estimated using three methods: triple isolopes of oxygen and bottle incubations using both 18O-labeled water and 14C-labeled CO2. Monthly measurements for more than a year by each method provide the opportunity to evaluate an in-situ PP method with more traditional in vitro PP methods. Monthly measurements of the dissolved oxygen as a gas ratio at ALOHA yield direct estimates of the rate of net community production to gross primary production rates and the export rate of organic carbon. We examine the monthly variability and annual means in PP at ALOHA estimated by the three methods in order to evaluate bottle versus in-situ PP estimates and compare these results to satellite-based PP estimates.

PRIMARY PRODUCTIVITY ESTIMATES IN GULF OF MEXICO WATERS: COMPARING IN SITU METHODS (FRR, FIRE, FIRE) WITH TRADITIONAL TECHNIQUES.

In situ active fluorescence techniques provide rapid estimates of phytoplankton physiology and photosynthetic activity, and the ability to make measurements across comprehensive spatial (horizontal and vertical) and temporal scales. Fast Repetition Rate Fluorometers (FRRFs) have both light and dark chambers, a PAR sensor and are deployable. The Fluorescence Induction and Relaxation (FIRE) system can only be used as a bench-top instrument, has no PAR sensor, and may be used in continuous underway mode (dark chamber only). On two cruises in the Gulf of Mexico (May and August 2007), parallel FIRE, FRRF and traditional 14C primary productivity measurements were made across the Louisiana-Texas coastal shelf. Fv/Fm, the ratio of variable to maximum fluorescence, sigma PSI, the functional cross section of PSI and other derived photosynthesis and production parameters were compared. Most FRRF-derived values for Fv/Fm were less than 10% different from the corresponding FIRE derived Fv/Fm values. Theoretical and empirical calculations were used to characterize phytoplankton community properties in situ. These provide useful estimates of primary production that are comparable to measurements made using 14C traditional techniques.

ECOSYSTEM KNOWLEDGE LEADS TO SOUND POLICY, OR DOES IT?

Coastal hypoxia research programs provide an ideal opportunity to explore how ecosystem research informs management decisions. Long-running studies have been conducted in the Chesapeake Bay and Long Island Sound. The studies in the Gulf of Mexico were initiated by the scientific curiosity of a few, then efforts by NOAA in a concerted peer-reviewed external research effort under NECOP (Nutrient-Enhanced Coastal Ocean Productivity). Subsequent legislation to study hypoxia and HABs (HABHRC, or Harmful Algal Blooms and Hypoxia Research and Control Act, 1998) asked for assessments of hypoxia in the Gulf of Mexico and nationwide. Competitive ecosystem research programs led us from early hypotheses concerning increased nitrogen loads in the Mississippi River (circa 1973), nutrient enrichment and Gulf of Mexico productivity, followed by nutrient over-enrichment and the potential negative effects, including hypoxia. Ecosystem research helped inform management of nutrient inputs and their mitigation, forecasting capabilities and considerations under climate change. The links among science, policy and management decisions are tempered, as always, by stakeholder interests.

RECYCLING OF ORGANIC MATTER IN ARCTIC MARINE SEDIMENTS: INVESTIGATIONS AT THE DEEP-SEA LONG-TERM OBSERVATORY HAU/GARTEN

The past decades have seen remarkable changes in the Arctic, a key region for the global climate. Due to the lack of observations, impacts of these changes on biogeochemical cycles and Arctic marine ecosystems are largely unknown. During an expedition to the deep-sea long-term observatory HAU/GARTEN in July 2007, we investigated the biogeochemical cycling of organic matter by performing in-situ and shipboard measurements of oxygen profiles, bacterial activities, and the total sediment oxygen demand. Shipboard measurements across the continental margin showed a classical bathymetric pattern in biogeochemical recycling with overall low fluxes except for the deepest station.
(Molyo Hole, 5000 m), which concentrates deposited organic matter produced in the
HAUGAARDEN area. In-situ oxygen microprofiles were taken by a ROV-operated micro-
profile at two experimental sites at 2500 m water depth; inside/outside an in-situ flume
increasing near-bottom current and around a whale carcass deposited to study the effect
of large food-fall in the deep sea. Perturbation experiments showed interesting and partly
unexpected pattern, e.g. with the persistence of high organic matter turnover near the
whale carcass even two years after deposition.

TRANSPORT AND DEPOSITION OF PARTICULATE MATTER AND
PARTICULATE METAL ON THE GULF OF LION SHARK SHELF: NEW FINDINGS FROM
LARGE MULTIDISCIPLINARY EXPERIMENTS

New findings were obtained during the last five years on particulate matter and particulate
heavy metal transport, deposition and export on the Gulf of Lion's continental margin
(France, Mediterranean Sea). This talk will summarize these results from several French
(PNCE, ORME) and European (REMOTRANS, EUROSTRATAFORM) programs
combining in-situ and multidisciplinary observations (sedimentology, hydrodynamic,
geochemistry) and numerical modeling. The presentation deals with: suspended particulate matter and metal
inputs by the Rhone (one of the two largest river of the Mediterranean sea) and smaller mountainous rivers, accumulation rates on the shelf, resuspension processes and fluxes
induced by trawling or natural events, export of particulate matter and metal to the contin-
ental slope. The role of eddies as primary sinks of fluvial material, and that of extreme events
-such as floods, storms and deep water cascading - on the particulate matter exchanges
between the different interfaces of this coastal system will be emphasized.

OCEANIC SEASONAL VARIABILITY NORTH OF PAPUA NEW GUINEA: AN
INTEGRATED APPROACH

SeaWiFS chlorophyll imagery suggests that advection of nutrient- and phytoplankton-rich
waters from the west may explain the chlorophyll increase in the warm pool during the
2002 El Niño event. A potential source is from the upwelling north of Papua New Guinea.
In order to determine its structure and variability, we used multiple satellite data to infer
the response of surface chlorophyll, sea surface temperature, and sea level anomaly to sea-
sonal wind reversal. The RUMS (Regional Oceanic Modeling System) has been coupled to the
biogeochemical model PISCES (Pelagic Interaction Scheme for Carbon and Ecosystem
Studies) to assess biological processes at work and to evaluate the relative contributions
of horizontal and vertical processes. Results highlight two seasons. The surface current is
north-westward when south-east trade winds prevail and advection of nutrient-rich water
 toward the equator may enhance phytoplankton growth downstream. It reverses during the
north-east monsoon (December-March) which favors upwelling along the PNG coast and
may also result in enhanced phytoplankton in the warm pool. Additional interannual experiments are performed during the QuickSCAT period to understand such chlorophyll
variations during El Niño.

ORIGIN AND DYNAMICS OF THERMOHALINE STAIRCASES

This study explores the dynamics of thermohaline staircases, frequently formed in the
regions of active double-diffusive convection. We separately consider two distinct, double-diffusive regimes: (i) diffusive layering, which is generally observed in high-lati-
itude regions, particularly in the Arctic and (ii) salt finger staircases, more common in the
mid-latitude oceans. In both cases, we discuss the mechanism for the formation and
maintenance of thermohaline staircases in terms of a combination of the direct numeri-
cal simulations, analytical considerations, and data analysis. It is argued that steps in the
vertical temperature and salinity profiles are caused by the parametric variation of the
heat/salt flux ratio, which leads to an instability of the equilibrium with strong stratifica-
tion. We explain the evolutionary patterns of the numerically simulated staircases by
considering the secondary instabilities of a series of identical interfaces. A simple theoreti-
cal model is developed which predicts the average step height in fully developed staircases and its dependencies on the large-scale environmental parameters. We find that the key
aspects of the theoretical model are consistent with the observations of diffusive staircases
in Beaufort Gyre and salt finger staircases in tropical Atlantic.

ESTIMATING REAERATION RATES IN TROPICAL SALT-WEDGE ESTUARIES: A
COMPARISON OF METHODS

Estuarine metabolism studies are extremely scarce in tropical developing islands. Some
estuaries in densely populated tropical islands such as Puerto Rico are affected by sewage
discharges, most with some level of treatment. The effects of these sewage discharges on
the fluxes of oxygen and particulate organic matter are largely unknown, particularly in
the tropics. Precise measurements of reaeration rates in salt-wedge estuaries are ex-
tremely important in order to develop acceptable estimates of the estuarine metabolism.
The size of the estuary, depth, wind velocity and tidal amplitude are important factors
that control gas exchange across the air-water interface. In this work we report reaeration
rates of three salt-wedge tropical estuaries measured with the chamber method described
by Kremer (2003) and the estimation method of Caiffery (2003); an initial step in meta-
bolism studies being conducted in tropical estuaries in Puerto Rico.

POSSIBLE HYDROCARBON-DEGRADING ENDOSYMBIONT IN
BATHYMODIOLUS HECKERAE, A MUSSEL FROM CHAPOPOTE, AN ASPHALTIC
SEEP IN THE GULF OF MEXICO

Chemosynthetic life was recently discovered at Chiaopote, in the southern Gulf of
Mexico at 3000 m water depth. At this site, lava-like flows of solidified asphalt cover a
large area that also includes oil seeps and gas hydrate deposits. In this study, molecular
methods were used to characterize the symbioses of the mussels and tubeworms col-
lected from this site. We identified one of the two mussel species found at Chiaopote as
Bathymodiolus beckeriae based on its cytochrome oxidase sequence. Using comparative
16S rDNA sequence analysis and fluorescence in situ hybridization, we found that this
host harbors the well known sulfur- and methane-oxidizing symbionts commonly found in
many other Bathymodiolus species. Unexpectedly, we discovered a novel third symbi-
ont phytoyte that is closely related to hydrocarbon degrading Cycloclastius bacterium.
The discovery of a novel symbiont that may be able to use hydrocarbons as an energy
source is particularly intriguing because until now only methane and reduced sulfur compounds
have been identified as energy sources in chemosynthetic symbioses. The large amounts of
hydrocarbons available at Chiaopote would provide these mussel symbioses with a rich
source of nutrition.

SI-BASED RECONSTRUCTION OF THE CARBON BIOLOGICAL PUMP

Our ability to understand and predict the role of the ocean in the global carbon cycle and
its response to climate change strongly depends upon our capacity to model the function-
ing of the biological pump at the global scale. The complexity of the processes that take
place in the mesopelagic zone and the difficulties in flux measurement at these depths
complicate this capacity. Here, we combine in vitro diatoms-silica dissolution experiments
with regional budgets of Si and C fluxes to reconstruct at global scale, the efficiency of the
biological pump. We show that this efficiency increases with seasonality rather than pri-
mary production and is strongly modulated by the depth of the winter wind mixed layer.
An algorithm is applied to Longhurst's biogeochemical provinces to derive a global esti-
mate of the biological pump, therefore based on a semi-mechanistic approach. The general
applicability of such a semi-mechanistic algorithm is discussed, emphasizing the need
to understand better Si and C interactions in sinking particles, and the role of the meso-
epycic food web in modifying these interactions and the associated Si and C fluxes.
TURBULENT MIXING IN THE MIXED LAYER/THERMOCLINE TRANSITION LAYER

The oceanic mixed layer is the dynamically active boundary layer linking atmospheric forcing to the circulation of the ocean interior. By its very definition, the mixed layer is a region of intense mixing, where turbulence supplied by wind and wave energy homogenizes the vertical distributions of temperature and salinity down to depths of O(100) m. Below the mixed layer, in the upper layers of the stratified thermocline, turbulent energy levels are greatly reduced. The transition between these regions is usually marked by a take-place abruptly at the mixed-layer base. However, observations suggest that enhanced turbulence penetrates significantly into the stratified water just below the mixed layer. Here, we present an examination of turbulence data collected during 30-days of steady wind-forcing in the sub-tropical North Atlantic. These data will allow for direct estimates of diffusivity and diapycnal flux occurring in the mixed layer/thermocline transition layer. This analysis establishes statistics for turbulence dissipation levels occurring just below the mixed layer, which have not been previously documented. A preliminary analysis suggests that the transition layer often extends 30 m below the mixed layer base, and that diabatic fluxes in this region are 3 times greater than in the thermocline under normal surface forcing conditions. Exceptional forcing events, such as the passage of storms, likely lead to an even stronger enhancement of fluxes.

BENTHIC-PELAGIC COUPLING IN THE BAY OF BREST (FRANCE): NEW INSIGHTS FROM A COUPLED PHYSICAL-BIOLOGICAL MODEL.

Functioning of the ecosystem of the Bay of Brest (France) is controlled both, by hydrodynamical processes as the bay is a macrotidal system, and by biological processes which are dominated by the activity of an invasive benthic filter feeder, a slipper limpet (Crepidula fornicata). A coupled physical-biological model is used to represent the influence of these interactions on the phytoplankton dynamics, with a focus on benthic-pelagic coupling. The selected spatial resolution allows resolving the heterogeneous density distribution of the slipper limpet in the Bay and its implication for spatial variations of benthic fluxes. This heterogeneity is not reflected in the pelagic dynamics because transport and mixing homogenize the distributions of nutrients and biomasses. Validation of the model is done on stocks and in, in an original way, on rates (benthic recycling, carbon and silicon uptake). In a prognostic scenario which forecasts the impact of removing the invasive benthic filter feeders, the silicic acid efflux at the sediment-water interface is reduced by 63% and a pronounced algal bloom of dinoflagellates, potentially harmful, develops in late summer.

EFFECTS OF BULKHEADS ON ESTUARINE BEACH SWASH ZONE CHARACTERISTICS

Bulkheads are common structures on estuarine shorelines. These structures fragment and truncate the shoreline causing wave and swash reflection that alters swash zone dynamics and beach morphology. Topographic profiles, sediment cores, and sediment activation depth measurements were taken at two bulkhead sites and a control site 9-22 June 2007 at Fortescue, New Jersey to characterize beach changes. Video records of swash-bulkhead interactions are used to provide process explanations. Results reveal the topographic variability in front of bulkheads that occur when the wave and swash energy becomes concentrated in a narrower zone than on unobstructed beaches.

EVOLUTION OF THE NORTH PACIFIC SUBTROPICAL MODE WATER DURING KESS

The mooring and float observations collected during the Kuroshio Extension System Study (KESS) show that the formation of Subtropical Mode Water (STMW) is a highly variable process in both space and time. Global high-resolution numerical simulations confirm that the strength of atmospheric air-sea heat fluxes are the dominant factor controlling the volume of STMW formed for a given year, but the formation is dominated by episodic events with time scales of days that can be directly related to wind storms frequently coming from the northwest. One-dimensional mixed-layer models also suggest that enhanced vertical diffusivity values in the upper ocean are necessary during the summer to fall to accurately simulate the evolution of the mixed layer depth and top of the STMW layer. Our observations elucidate the causes of this enhanced mixing and the impacts it has on the evolution of the STMW.

SALT FLUX AND TURBULENT MIXING IN AN ESTUARY WITH STRONG TIDAL FRET AND HYPSELM BATHYMETRY AND FORCING.

Strong tidal and river forcing in the Merrimack River (MA) estuary makes conditions highly unstable at tidal timescales, and along- and across-channel bathymetric variability presents significant spatial complexity: constriction at the mouth, bedrock constraints upstream, and broad, intertidal shoals surrounding a narrow, deep channel in between. A sharp salinity front advects tidally from the coastal ocean through a series of silts and constructions, and strong stratification inhibits vertical mixing. Because of the complex bathymetry and strong salinity gradients, the Merrimack offers significant challenges for numerical modeling. We have applied the Finite Volume Coastal Ocean Model (FVCOM) to simulate conditions in the estuary, and compare model results against extensive field observations that include salinity and velocity time series and intensive hydrography. We evaluate observed and modeled estuarine salt flux mechanisms, and find that results compare favorably. We also evaluate turbulence and buoyancy fluxes in regions of intense mixing, and compare with observations from an instrument array that measures turbulence at multiple elevations above the bed. With the model, we relate local mixing measurements to integrated changes in potential energy in the estuary.

MODELLING UNDERWATER LIGHT FIELDS IN SHELF SEAS: IMPLICATIONS FOR PRIMARY PRODUCTION MODELLING.

Absorption and scattering by dissolved and particulate materials in shelf seas influence the attenuation of light in the water column. These effects are most pronounced in coastal regions where the light available for phytoplankton absorption may be limited by the presence of sediment and coloured dissolved organic matter. Quantification of the underwater light field is therefore a key element in primary production modelling. Most existing models were devised for oceanic conditions and make simplifying assumptions about the underwater light field leading to inaccuracies in primary production calculations. Consequently a forward model has been devised for optically complex shelf seas which allows prediction of the underwater light field from constituent concentrations and specific inherent optical properties. This model was applied to the Irish Sea where an extensive data set and a regionally tuned ocean colour algorithm were available. Chlorophyll concentrations and diffuse attenuation coefficients for downward irradiance were determined from satellite measurements of water leaving radiance and an empirical relationship was established between Kd490 and euphotic depth which allowed euphotic depths to be estimated from space.

A COMPARISON OF TAXONOMIC AND ALGAL ACTIVITY FROM THE BBE FluOROPROBE WITH DIRECT TAXONOMIC AND GAS FLUX MEASUREMENTS IN THE CANADIAN COASTAL BEAUFORT SEA

In July and August of 2007, as part of our ongoing work on the ecosystem of the Mackenzie Shelf we conducted surveys near Cape Bathurst and Herschel Island on board the CCGS Nahidik. As part of the program, continuous measurements were made at the 2 m depth using: (1) a bbe Algal Online Analyzer (ACOA) fluoroprobe; and (2) a “gas box” designed and built in our laboratory. The ACOA was used to determine total chlorophyll concentration, concentration of five algal groups, activity of these algal groups and the detection of “yellow substance” or dissolved organic matter. In the “gas box,” water was pumped through a permeable, water impermeable exchange that allows a gas-filled loop to come to equilibrium with the gases in the water. The partial pressure of these gases circulated past the various detectors: a non-dispersive IRGA for CO2, an O2 sensor, and a CH4 sensor. These data can be used for subsequent flux estimates. Material was collected for taxonomic algal identification. The results, strengths and weaknesses of using these instruments in the Beaufort Sea will be discussed.

DETERMINATION OF INTERNAL WAVE PROPERTIES FROM X-BAND RADAR OBSERVATIONS

As part of the Nonlinear Internal Wave Initiative (NILW) a variety of instrumentation were deployed on the continental shelf offshore New Jersey in summer of 2006. The
experimental effort was aimed to understand the impact of nonlinear internal waves on acoustic propagation and scattering in shallow water. Two surface sampling V-Band radar (WaMoS) systems were installed on board the research vessels R/V Knorr and the R/V Oceania that were tracking internal waves in the area during the experiment. The R/V Knorr sampled in short-pulse mode, while the R/V Oceania sampled in medium-pulse mode. Both ships measured several internal wave events. The estimated properties from these measurements are compared to theoretical values and evidence of changes in these properties as the solitons propagate into shallower water is explored.

SEASONAL VARIABILITY OF THE NONLINEAR INTERNAL WAVE (NLW) FIELD IN THE NORTHEASTERN SOUTH CHINA SEA

The Windsy Islands Soliton Experiment (WISE) was conducted from April 2005 - May 2006 in the northeastern South China Sea. The cross-basin transect included one mooring in the Luzon Strait, two in the deep basin, one on the continental shelf, and two on the continental shelf. CTD transects were collected on five deployment and recovery cruises to map the seasonal variability of the stratification. Sampling was conducted at 3 minute intervals or less to resolve the large-amplitude, high-frequency motions. The most striking feature of the annual time series was the complete absence of NLW motions during December - February. Individual wave packets could be traced rigorously back to specific beats of the Luzon Strait tide. Since the winter tide was as strong or stronger than the rest of the year, the lack of propagating waves is attributed to seasonal changes in the stratification at the generation sites and/or along the propagation path. There were no other obvious seasonal signals, the monthly wave amplitude variability being dominated instead by large-scale north/south advection of the northwestward-propagating wave packets imbedded in the mesoscale currents.

ASSESSING THE INTENSITY OF A STRATIGRAPHIC SEQUENCE USING PAIRED AMS RADIACON Dates on PLANKTONIC FORAMINIFERA: DEVELOPMENT OF A HIGH-RESOLUTION CHRONOLOGY

Downslope transport is a risk in areas with high sedimentation rates such as Orca Basin. One hypothesis suggests robust tests would preferentially survive resedimentation processes and dissolution compared to more fragile species, leading to anomalous age dates [Broecker et al., 2006]. Core MD02-2550 is a 9.09n gravity core from Orca Basin, ideally suited to test this hypothesis and to record decadal meltwater pulses into the Gulf of Mexico. Anomalous bottom water prevents bioturbation, resulting in laminated sediments. AMS radiocarbon ages on relatively fragile and dissolution susceptible Globorinoides rubber samples were compared with the more robust species Neogloboquadrina dutertrei, using the same reservoir age correction. Except for one interval, the paired ages showed no significant differences, indicating analytical error is a small correction to AMS radiocarbon dates taken every 10cm; the sedimentation rate is ~50cm/ky which demonstrates a continuous record. Using paired AMS radiocarbon dates and generating a high-resolution chronology verifies the integrity of the stratigraphic sequence from 290-616cm.

TEMPERATURE EFFECTS ON EARLY LIFE HISTORY TRAITS AND POPULATION REPLENISHMENT OF A REEF FISH

Temperature is a primary factor influencing growth during the early life of fishes, and growth-related processes can affect the magnitude and composition of recruitment events and early juvenile survival. To elucidate the effects of temperature and growth-related processes on recruitment and post-settlement survival, 16 monthly cohorts of newly settled bicoral damselfish Stegastes partitus were sampled in the upper Florida Keys, USA over multiple years. The domain is characterized by highly variable wind fields with significant influence on the upwelled front appears to relax back towards the shore on a time scale of ~2 days after the wind relaxes. We argue that the observed relaxation of the upwelled front south of Chesapeake Bay is in part governed by the buoyant estuarine plume from the bay using a simple numerical model and observations from the CoOP Duck Project. Observations show the Chesapeake plume has an alongshore propagation speed of 0.55 m s⁻¹ and the plume front reaches the study area in ~2 days. We examine this using 3 arrays of cross-shore CTDs and numerical analysis to show the relaxation time scales for each array is dependent on the plume propagation speed and alongshore distance from Chesapeake Bay. A simplified numerical model will define the mechanism by which the plume leads to apparent frontal relaxation.

LARVAL CONNECTIVITY IN A DYNAMIC DOMAIN: LIMITATIONS AND ADVANTAGES OF A COMBINED MODELING-FINGERPRINTING APPROACH

To assess population connectivity of many coastal species, models must extend into dy- namic inner shelf regions and simulate processes forced by small-scale variations in topo- graphy, wind fields, and source inputs. This zone typically falls between the domains of most nearshore and coastal studies, despite its importance for biological connectivity and sustainability. We present an interdisciplinary study employing a small-scale circulation model developed to test mussel larvae transport hypotheses and conduct sensitivity analy- sis of physical parameters that may affect connectivity on scales of order 10-100 kilome- ters. The domain is characterized by highly variable wind fields with significant influence from remote winds, and we explore effects and limitations of available forcing products on circulation and connectivity results. Model experiments are also combined with local demographics and elemental analysis of juvenile mussels which show distinct spatial pat- terns. Combining modeling and elemental fingerprinting enables more detailed analysis of connectivity in a dynamic area and better identification of modeling and data gaps.

THE PERFORMANCE OF A REGIONAL COUPLED OCEAN/SEA ICE MODEL IN THE NARES STRAIT
A simulation of the climate around Greenland has been made with HIRHAM (The Danish Meteorological Institute’s atmospheric climate model) for a period of 100 years. The result from this simulation has been used to force a regional coupled ocean and sea ice model (HYCOM+CICE) at the surface. The region considered is Nares Strait, Lincoln Sea and the Baffin Bay. The lateral boundaries of HYCOM and CICE have been relaxed towards a global model. The purpose of this study is to investigate the coupled systems ability to model the hydrography and the sea ice distribution and to investigate the freshwater flux through the Nares Strait. The Nares Strait is expected to be a demanding test case for both the ocean and sea ice model with mixing of different water masses, building up an ice bridge, and formation of polynias. This talk will focus on the flux of water and sea ice through the Nares strait. The sea ice fluxes will mainly be compared to satellite images. The implementation of boundary conditions in CICE will also be discussed.

ELECTROCHEMICAL PRODUCTION OF OCEAN ALKALINITY FOR CARBON DIOXIDE AND ACID MITIGATION, AND HYDROGEN GENERATION

Absorption of CO$_2$ by the ocean can be increased by the addition of alkalinity, e.g., Ca(OH)$_2$, derived from the thermal calcination of limestone (Kheshgi, 1995). Diluted in the ocean (to pH~9) this alkalinity will react with excess CO$_2$ to form primarily calcium bicarbonate: Ca(OH)$_2$ + 2 CO$_2$ -> Ca(HCO$_3$)$_2$. However, thermal calcination is very energy and carbon intensive. A potentially more efficient alternative is to generate CO$_2$ directly in seawater via electrolytic splitting of limestone. Using DC current, the acidity generated by an anode submerged in seawater can be used to decompose limestone, forming Ca(OH)$_2$, that will enhance CO$_2$ absorption by the ocean and restored its pH. If produced, H, gas generated at the cathode can be used to recover/storing energy, helping defray process costs. Chlorine generation may be avoided via the use of certain current densities, or the use of O$_2$, selective anodes. Thus wind-, wave-, tidal-, or solar-powered, fixed/floating platforms could be actively increased ocean alkalinity. Such platforms could then help: 1) absorb and reduce atmospheric CO$_2$, 2) neutralize ongoing ocean acidification, and 3) generate hydrogen.

ADJOINT BASED ERROR ESTIMATION AND CORRECTION – A SHALLOW WATER CASE STUDY

We propose to apply adjoint methodology to derive both error estimates and error correction for geophysical flow problems. In each case an appropriately defined adjoint problem is solved to obtain an error estimate for the flow field itself and a reduction of the error in the computation of quantities derived from the flow field. Our adjoint error estimation and correction approach is evaluated in the framework of the standard SWE Williamson test suite for the ICON model, a newly developed semi-implicit shallow-water model on a cospherical grid. The adjoint ICON shallow water model is part of the dynamical kernel of a future general circulation model. This will lead to adjoint error correction in more realistic scenarios.

ENERGY EXCHANGE AT THE AIR-WATER INTERFACE

A direct numerical simulation (DNS) is performed to study velocity distribution and energy exchange at air-water interface in the intermediate depth and deep water waves. In the present investigation, average air velocity is kept as 1) $U_{air} < 0.5 \text{ c}$, 2) $U_{air} = 0.5 \text{ c}$ and 3) $U_{air} = c$. Here, $c$ is the wave speed. The shape of wave water and associated orbital velocities evolve dynamically under the action of the airflow. Numerical simulation results show the presence of recirculation just above the trough of the wave water. Momentum exchange between air and water increases the kinetic energy in the water. A region of closed streamlines is observed above the trough of the wave which is dynamically important and significantly affecting velocity and pressure in the air above the water surface. Energy density variation along the length shows the energy exchange between air and water in the viscous, nonlinear wave waves.

ANTARCTIC OCEAN TIDES FROM GRACE INTERSATellite TRACKING DATA AND HYDRODYNAMIC ASSIMILATION

Long-wavelength components of the oceanic tides surrounding Antarctica are estimated from over four years of GRACE satellite-to-satellite ranging measurements. An inversion is performed for the major constituents M2, O1, and S2, parameterized as localized average mass anomalies relative to a prior tidal model. Satellite state adjoint is made simultaneously. These long-wavelength anomalies are then assimilated into a high-resolution regional hydrodynamic tidal model. Comparisons to independent in-situ tide measurements show that the resulting assimilation solutions result in improved agreement, for all three constituents.

DISTRIBUTIONS OF CHROMOPHORIC DISSOLVED ORGANIC MATTER DURING THE GULF OF MEXICO EAST COAST BARRIER (GOMEC) CRUISE SUMMER 2007

Chromophoric Dissolved Organic Matter (CDOM) is responsible for light attenuation in the ocean, provides the basis for oceanic photochemical processes and is important for remote sensing applications. Understanding CDOM variability in the ocean is important for quantifying UV-dependent processes such as photochemistry. CDOM is characterized by its absorption spectrum with the “amount” of CDOM present defined by absorption at certain wavelengths. The absorbance spectrum shape, commonly reported as a total slope coefficient (S), relates to the aromaticity and chromophoric diversity of CDOM. CDOM samples were taken within and below the mixed layer in coastal waters from Texas to Maine as part of the GOMEC cruise (July 10 to August 4, 2007). Samples were 0.2 μm filtered and refrigerated until spectrophotometric measurement of absorbance spectra. S values ranged from 12-28 (avg = 20). Concurrent samples were taken for studies of CO and CO$_2$ photochemical production efficiency. These data represent a unique “snapshot” of CDOM spatial variability along the Gulf of Mexico and US East Coast that will prove useful for verification of remote sensing CDOM estimates and as a driver for regional-scale photochemical models.

HISTORICAL RECORD AND DECADAL-SCALE TRENDS OF NUTRIENT CONCENTRATIONS OF SLOPE WATERS IN THE GULF OF MEXICO

Nutrient supply to the Gulf of Maine (GoM) is from offshore, as nutrient rich slope waters enter the bottom. The slope waters that enter the GoM are a mixture of two types: warmer, saltier warm slope water (WSW) of Gulf Stream and Central Atlantic origin, and cooler, fresher Labrador Sea slope water (LSSW) from the north. Our analysis of over 100,000 nutrient samples from 1932–2007 in the GoM region shows that the GoM has undergone fluctuations in slope water types leading to varying nutrient concentrations in the deep basins. The 1960s were characterized by LSSW and had lower temperatures and nutrient concentrations, followed by the warmer, higher nutrient WSW through the 1970s. Recently, the years of 1995–present have shown decreasing temperature, salinity, and nutrient concentrations at depth. While the slope water shifts of the 1960s and 1970s have been attributed to shifts in the North Atlantic Oscillation (NAO), the more recent trend seems unrelated to the NAO Index and instead is affected by a larger volume of water from the Labrador Sea traveling southward along the continental slope.

SELF-ASSEMBLY OF DISSOLVED ORGANIC CARBON: INSIGHTS FROM LAKE WATERS

The spontaneous assembly of dissolved organic carbon (DOC) leads to particulate organic carbon (POC) formation with significant consequences for carbon export to sediments and/or transfer to food webs. Assembly occurs when inter-polymer distances allow chemical or physical bonds and, consequently, depends on pH, ionic composition, and dielectric properties of the solvent. Lake waters exemplify a diverse array of DOC and chemical environments that could be helpful to untangle the mechanisms and self-assembly contribution to DOC-POC dynamics in natural waters. We performed extensive lake samplings in Northern temperate and Mediterranean biomes covering wide DOC (12-3750 μM) and chemical (conductivity 9.6-61,500 S) gradients to determine polymer size and the fraction of total organic carbon assembled using homodyne dynamic laser scattering and a fluorescence quenching assay. In addition, we performed several experiments to corroborate the role of calcium and iron as promoters of DOC assembly.

OPERATIONAL FORECASTS OF RIGHT WHALE DISTRIBUTIONS FROM SATELLITE AND OCEANOGRAPHIC DATA USING DYNAMICAL MODELS

Recovery of the North Atlantic right whale is limited by high mortality due to ship strikes and entanglements in fishing gear. All management options depend on knowing where whales are likely to be. We have developed a system that can produce useful forecasts of right whale distributions on their feeding grounds in the Gulf of Maine. Our system uses satellite-based measurements of sea surface temperature and chlorophyll to determine the developmental and reproductive rates of Calanus finmarchicus, the preferred prey of right whales. The rate information then drives a population dynamics model of Calanus.
though for the oligotrophic oceans both iron and phosphate are often present in limiting quantities and consequently their relative availability may determine nitrogen fixation rates. The variance in nitrogen fixation rate was examined along a meridional transect in the Atlantic. In addition large scale (~25 km2) in situ enrichment experiments were performed to investigate the impact of phosphate and iron availability in surface waters in the eastern Mediterranean (CycloSIPS) in 2002 and the north-eastern sub-tropical Atlantic (FeEP) in 2004. During each study 15N natural abundance of the particulate nitrogen and nitrogen fixation rate measurements were made over periods of up to 10 days following addition. Iron availability had minimal impact on nitrogen fixation in both addition experiments, whereas phosphate addition appeared to stimulate diazotrophy in both. Unprecedented high rates of nitrogen fixation were found in the Mediterranean Cyprus Eddy, which appeared to be supported by dissolved organic phosphorous.

WAVE MODELING AROUND SUBMERGED BREAKWATERS/ARTIFICIAL REEFS

Submerged breakwaters have been developed as a successful alternative or assistance to beach nourishment projects. By dissipating wave energy in the nearshore, a submerged breakwater can be designed to minimize beach erosion and maximize accretion. Also, submerged breakwaters that double as artificial reefs are designed to include structural aspects to meet marine life requirements (e.g., Reef Balls). Considering the complexity of coral reefs, fabricated reefs that attempt to mimic aspects of natural habitats can further complicate the hydrodynamics. Due to the changes in wave dynamics, submerged breakwaters/artificial reefs could also have an effect on the adjacent shorelines and bathymetry in surrounding areas. Using the fluid modeling program, SWAN, this study will explore erosional "hot-spots" due to the wave dynamics around a submerged breakwater/artificial reef composed of Reef Balls.

ACOUSTIC INTENSITY FLUCTUATIONS RESULTING FROM PULSE PROPAGATION THROUGH TIDAL AND SUPER-TIDAL INTERNAL WAVES ON THE SOUTH CHINA SEA SHELF

Conducted in the northeast South China Sea from April 13-15, 2005, the shallow-water component of Windy Island Soliton Experiment (WISE) was designed by Taiwan and U.S. scientists to study the physics of low-frequency sound propagation through nonlinear, internal waves in shallow water, and to quantify the associated sound intensity fluctuations. Previous studies in this region revealed a highly dynamic environment where internal waves of varying temporal and spatial scales dominate the sound-speed field. The acoustic receiver was an eight element, vertical-line hydrophone array that recorded signals transmitted from a moored source. This paper discusses and contrasts the sound intensity fluctuations resulting from a transmitted signal through a complex, nonlinear internal wave field at two different times, one where the internal tide has rapidly repositioned the thermocline vertically, and one where the thermocline was slowly reeling up. Using temperature time-series collected along the transmission path, a space-time continuous wave field at two different times, one where the internal tide has rapidly repositioned the thermocline vertically, and one where the thermocline was slowly reeling up. Using temperature time-series collected along the transmission path, a space-time continuous empirical sound-speed model is combined with a coupled-mode acoustic model to explain the observed phenomenology and statistics of the sound intensity fluctuations. The research is sponsored by the Office of Naval Research.

IMPACTS OF CLIMATE WARMING ON ARCTIC PELAGIC METABOLISM: AN EMPIRICAL ASSESSMENT

The rapid current loss of the ice cover of the Arctic Ocean implies that it is now becoming active in gas exchange with the atmosphere. The role of the Arctic Ocean on gas exchange depends, partly, on the net metabolism of the planktonic communities. We will provide evidence, derived from comparative analysis across gradients of water temperature and ice melting, that gross primary production is suppressed by ice-melt waters and that community respiration increases with temperature, suggesting a shift towards a heterotrophic metabolism.

INTERACTION ON A BROAD AND SHALLOW SHELF

With a few exceptions, little effort has been made to understand the mechanisms of storm surge interaction with the tide over a broad and shallow shelf, which is also dependent on the trajectory of the hurricane. Recent numerical studies on storm surge have mainly focused on representation of hurricane winds, inundation schemes, hurricane track and its effect on specific estuaries or ports. We conduct an investigation of storm surge on the Louisiana coast by using the state-of-the-art UnStructured-grid Finite Volume Coastal Ocean Model (US-FVCOM) introduced by Chen et al. (2003). Field observations and data from existing platforms along the coast are used in the validation of the model for some of the 2005 hurricanes. In addition to this application, we also conduct experiments with idealized model setup within different parameter space. These experiments provide some insight about the effect of the hurricane parameters and the broad and shallow shelf on the interaction between storm surge and tides as well as the development of storm surges on the coast of comparable slope of topography and width of the shelf.
THE HUMAN HEALTH EFFECTS OF MARINE TOXINS: CURRENT AEROSOLIZED FLUX AND RED TIDE RESEARCH

Karenia brevis, the Florida red tide organism, produces the potent neurotoxin, brevetoxin. In addition to the health effects associated with the ingestion of contaminated shellfish, there have been widespread anecdotal reports of respiratory irritation and possibly immunologic effects associated with the inhalation of aerosolized Florida Red Tides. An interdisciplinary team of scientists is investigating the human health effects from environmental exposures to Florida red tide toxins. When a red tide moves onshore, the team rapidly assembles to collect environmental conditions and samples (air, water, particulates) and epidemiologic data (pre/post-exposure questionnaires, pulmonary function tests, and personal monitoring) in normal workers and asthmatic (>12 yrs) residents in endemic areas. Acute and chronic respiratory effects of red tides and brevetoxin are also evaluated in rodent and asthmatic sheep models, as well as toxin exploration (including natural antagonists). These models are being used to refine and validate biomarkers of brevetoxin exposure and effect, as well as explore the pathophysiology of health effects from aerosolized brevetoxins. This research has demonstrated acute and possibly sub-chronic effects in animals and humans with asthma, as well as providing an environmental model for public health interventions and the discovery of new medications based on the natural antagonists.

X-BAND RADAR MEASUREMENTS OF DIRECTIONAL SURFACE WAVES

The Wave Monitoring System WaMoS II is based on a standard marine X-Band radar which is generally used for navigational and ship traffic control. Each X-Band radar produces 'sea clutter' which is suppressed for its standard application. By analysing the sea clutter the directional wave spectra from the sea surface are obtained in real time. From there all spectral sea state parameters such as significant wave height, peak period, and peak direction both for wind sea and swell are derived. Remote sensing for waves on board vessels and harbor entrances is gaining a bigger interest with ships becoming larger and some port entrances allowing only smaller time windows for them to enter. Accurate knowledge of the actual waves and currents in the area of interest some times is difficult to get, as moored devices might be in the way of operation. In this paper the focus is on spatial inhomogeneities in both, the topography and the wave field. Effects of strong tidal currents on the wave data and how they are reflected in the radar data will be shown. Examples from determined sea surface elevations from radar data will be given. Data containing high individual waves will be analyzed and discussed. Those maps of remotely measured sea surface elevations, showing individual waves have a huge potential in all applications that need to include the individual wave profile. An overview of related ongoing activities will be given.

EFFECTS OF SEQUENTIAL INCREASES IN SEA TEMPERATURE IN THE NORTH ATLANTIC AND BERING SEA ON PLANKTON AND BENTHIC BIOAVAILABILITY, THE BIOLOGICAL PUMP AND THE ARCTIC

Results from the Continuous Plankton Recorder (CPR) and other surveys have shown that rapid changes have occurred in chlorophyll and the composition of plankton and benthos in the North Atlantic and Bering sea in recent decades. These changes have been linked to rising temperatures. For European shelf seas the increases have been correlated with Northern hemisphere temperature and thus linked to global warming. In the eastern North Atlantic the changes have been related to variability in the subpolar and subtropical gyres and in the western Bering Sea to changes in the subarctic gyre. An interesting observation is the increase in red tide blooms in both regions. It has been found that this increase is the result of changes in both, the topography and the wave field. Effects of strong tidal currents and peak direction both for wind sea and swell are derived. Remote sensing for waves on board vessels and harbor entrances is gaining a bigger interest with ships becoming larger and some port entrances allowing only smaller time windows for them to enter. Accurate knowledge of the actual waves and currents in the area of interest some times is difficult to get, as moored devices might be in the way of operation. In this paper the focus is on spatial inhomogeneities in both, the topography and the wave field. Effects of strong tidal currents on the wave data and how they are reflected in the radar data will be shown. Examples from determined sea surface elevations from radar data will be given. Data containing high individual waves will be analyzed and discussed. Those maps of remotely measured sea surface elevations, showing individual waves have a huge potential in all applications that need to include the individual wave profile. FEEDING DETERMINANTS IN THE CRUISING HYDROMEDUSE Aequorea VICTORIA

Medusae have been found to be capable of significantly impacting and restructuring the pelagic ecosystem in regions where they are found. It is primarily median species which forage as cruising predators that have the greatest impact. However, little work has been done to identify and quantify the mechanisms that determine feeding rates in cruising medusae. We examined the predator-prey interactions of Aequorea victoria, a hydromedusae which swims via rowing propulsion and forages as a cruising predator. We quantified the flow around swimming A. victoria using particle image velocimetry (PIV) and compared these results to the actual tracks of prey in the fluid around the swimming medusae. In addition, we quantified the encounter, capture and retention efficiencies of these prey as they interacted with the medusae. The regions around the swimming medusae where captured prey originated, based on prey tracks, were consistent predictions based on PIV data. Encounter, capture and retention efficiencies varied depending upon prey type and size. Predicted rates of feeding will be discussed in light of these findings.

INVERTING LIGHT WITH CONSTRAINTS

Long-term deployments of autonomous platforms present challenges for the direct measurement of the inherent optical properties (IOPs) of seawater due to weight and power considerations. However, measurement of hyperspectral radiometric quantities as well as a few select IOPs fits within the weight and power budgets of some autonomous platforms. Here we investigate the use of easily measured IOPs, such as beam attenuation c and backscattering b, at a small number of wavelengths to constrain the inversion of easily measured radiometric data E(λ) and L(λ) to order to obtain estimates of IOPs (a(λ), b(λ) and c(λ)). We use Ecological, the azimuthally-averaged version of the Hydrolight radiative transfer model, as our forward model. First, we consider optimal methods for the constrained non-linear inverse problem. Next, assuming we can measure radiometric data throughout a homogeneous, well-mixed Case I water column (e.g., such as a Lagrangian float in a N. Atlantic spring mixed layer), we investigated the quality of the inverted IOPs without IOP constraints. Finally, we investigated the quality of inverted IOPs when a small number of constraints, e.g., b(470), b(700) and c(660), are applied. We examine both the final goodness of fit as well as the rate of convergence. Results for various chlorophyll and CDOM concentrations are considered.

SIMULTANEOUS ESTIMATES OF LONGITUDINAL DISPERSION WITH TRACER STUDIES AND ACOUSTIC DOPPLER CURRENT PROFILER MEASUREMENTS

To compare methods for estimating the longitudinal dispersion coefficient, simultaneous tracer and acoustic Doppler current profiler (ADCP) measurements were conducted during four field experiments in the Kissimmee and Ocklawatchee Rivers in southern Florida. When mixing is controlled by shear dispersion, the dispersion coefficient can be estimated with a theoretical formula that uses measurements of velocity and bathymetry. In comparisons using previous tracer studies and ADCP measurements, the ADCP method was at least as accurate as empirical formulas at matching the tracer result (Carr and Rehmann 2007). However, since the previous tracer studies and ADCP measurements were usually separated by several years, we conducted simultaneous measurements to evaluate the ADCP method. The ADCP method performed better at higher flows and in cases with less area in dead zones. Reach averaged ADCP estimates of the dispersion coefficient matched tracer values more closely than local estimates, and the ADCP method outperformed the empirical formulas in many cases.

THE INFLUENCE OF BOTTOM TOPOGRAPHY ON BOUNDARY LAYER MIXING AND THE SEDIMENT-WATER INTERFACE

In many stream ecosystems, nutrient cycling is predominantly controlled by microbial and algal activity occurring along streambed sediments. How nutrients are transported and exchanged depends upon the combined dynamics of turbulent transport through the water column and diffusive transport across the sediment-water interface. We conducted fine-scale measurements of boundary layer flow and nutrient transport within a 25m by 0.60-m laboratory flume. Three flow rates were studied along with three different bed topographies, composed of sand, gravel, or gravel with large cobbles. Fluorescein dye, containing dissolved nitrate and phosphate, was injected at the bed surface and concentration was measured 1m from the source using planar laser induced fluorescence (PLIF). Particle image velocimetry (PIV) was used to simultaneously calculate velocities. PLIF/PIV images were obtained at 50 Hz, enabling nutrient flux calculations throughout the water column, by using an eddy-correlation technique. Pore-water concentrations were measured using a flow-through fluorometer and ion-exchange membranes. Our results suggest the larger
bedroughness elements increase turbulent mixing and nutrient exchange across the sedi-
ment-water interface. However, depending upon the size of the roughness elements, this
exchange became spatially more heterogenous.

THE EFFECTS OF A WASTEWATER PLUME ON PHYTOPLANKTON IN THE COASTAL OCEAN

Major cities discharge treated wastewater to coastal oceans contributing significant
amounts of dissolved nutrients. The Hyperion Wastewater Treatment Plant in Los
Angeles, for example, pumps 300-350 million gallons of secondary-treated wastewater per
day into Santa Monica Bay. From November 28-30, 2006, wastewater was diverted from
the primary outfall (57 m depth, 5 miles offshore) to a nearshore outfall (15 m depth, 1
mile offshore). We tracked the evolution of the surfacing plume using optical and physical
measurements (spectral optical absorption and scatter, temperature, salinity) and moni-
tored its effects on local phytoplankton populations. Plume waters were characterized
by low salinity, high CDOM, and measurable nutrient concentrations relative to ambient
waters. Elevated concentrations of several dinoflagellate species occurred after the event.
Localized blooms of a Cochlodinium-like dinoflagellate and Akashiwo sanguinea (chloro-
phyll a up to 100 mg/m² and densities between 100-200 cells/ml) occurred several days
after the diversion in low-salinity, high CDOM waters characteristic of the wastewater
plume. These species do not typically form blooms in southern California and may repre-
sent new nuisance species and/or an unusual response to the surfacing effluent plume.

SCALES OR OTOLITHS: AN AGE-OLD QUESTION

Fisheries management has long relied on age-assessed structures. Knowing fish ages
allows for use of population dynamics of a fishery. Fish ages are mainly determined from
otoliths (ear bones) and scales. Studies have shown that scales systematically underd
their ages compared to otoliths, particularly older fish. Reasons for these problems include loss and regeneration of scales as well as scale deterioration, causing a loss of annual bands. Since the early 1980's, we understood that otoliths provide more accurate ages compared to scales. Nonetheless, important fisheries, such as striped bass (Morone saxatilis) are still managed by otoliths based on scale ages. Otoliths, like scales, have annual layers that are counted to age.
The Center for Quantitative Fisheries Ecology at Old Dominion University currently
compares scales versus otoliths in striped bass, an important commercial and recreational
fishery. The implications of this work may improve stock assessment of the species, allow-
ing for more accurate estimations of growth, life history traits, mortality and year class
strength. Our results show Chesapeake Bay striped bass stock is rebuilding faster than
recognized by stock assessments which rely upon scale ages.

A BENTHIC MICROBIAL FUEL CELL FOR SANDY SEDIMENTS

A benthic microbial fuel cell (BMFC) has been designed for harvesting energy from sandy
sediments in the littoral zone. This BMFC utilizes a pair of domed chambers placed
over carbon-brush anodes at the sediment-water interface, and a common carbon-brush
cathode in the surrounding seawater. The combined footprint of the two chambers is one
square meter. The shape of the fuel cell and its interaction with flow create local pres-
sure gradients that are intended to cause the passive upwelling of anoxic reducing-rich porewaters into the chambers. Check valves limit flow to one direction (from sediment into chamber), and a timer circuit switches energy harvesting between the two chambers on a 24-h cycle. We will present the results of tests of this design at field locations on the Oregon Shelf and within San Diego Bay. In both experiments harvested energy is being passed to a DC-DC converter that operates as a potentiostatic power transformer. The converter steps up the output to 3.5V to recharge a lithium-ion battery for the long-term powering of sensors such as a commercial ultrasonic receiver.

OPTICAL CLASSIFICATION OF LAKES FOR REMOTE SENSING APPLICATIONS

Operational classification of waters in countries with high number of lakes which varies
greatly by their properties is often based on physical and chemical parameters. By re-
 mote sensing techniques some of the variables used in the classification can be measured
(Chlorophyll, Secchi depth, turbidity). Remote sensing offers advantages such as good spa-
tial and temporal coverage for estimation changes in certain parameters. In order to study
the usability of satellite sensors for lake water classification, we have compared optical
classification of lakes with their measured remote sensing reflectance spectra and limno-
logical classification of lakes. Optical classification is based on the concentrations of three
VARIABILITY OF NEAR-SURFACE CURRENTS NEAR THE TIP OF THE ANTARCTIC PENINSULA AND IMPLICATIONS FOR THE TRANSPORT OF NUTRIENTS AND ANTARCTIC KRILL

The highest concentrations of Antarctic krill (Euphausia superba) in the Southern Ocean are found in the Scotia Sea. It is assumed that to maintain these populations krill larvae are advected from spawning grounds along both sides of the Antarctic Peninsula. The pathways of the surface currents and the frontal system in that region are not yet fully understood. In February 2000, 40 surface drifters were deployed in the northwest Weddell Sea as part of the ADELIE project and provided the first Lagrangian observations east of the Peninsula. They revealed new information about the velocity field by resolving narrow frontal currents and standing eddies both controlled by topography. To analyse seasonal and interannual variability of the currents, we deployed virtual drifters in the velocity output of ORCA05, a global coupled sea-ice-ocean model with a resolution of 1/4°. First results indicate a high variability. Depending on deployment location and time, drifters can reach South Georgia within six months, while others need two years. On average, 10 to 15% of the drifters get advected westward around the Peninsula.

ANALYSIS OF HIGH-SPEED STEREO-PHOTOGRAMMETRY OF OCEAN SURFACE WAVES

The stability of a ship can be disrupted by large amplitude motions resulting from interactions with wave groups larger than the nominal sea state. A novel technique using high-resolution stereo-optic photogrammetry was deployed with the cameras mounted near the bow of the USS SeaFighter during an ONR sponsored field test. This system provided a detailed 3D characterization of the incoming wave field over 24 hour periods and ship moving at constant speed. The ocean surface height field over an area covering 20 to 120 m forward of the ship and 30 to 70 m cross-track was captured at 15 Hz. These unique 3D timeseries allowed an analysis of the incoming wave field propagation and evolution over a range of both spatial and temporal scales. The stereo-optic waves were obtained simultaneously with 6-DOF measurements of ship motion as well as accelerometer data indicating the structural response of the hull to wave slamming events. The characteristics of wave patterns that excite large ship motion in moderate sea state are examined. In addition, the use of stereo wave measurements to validate computational phase-resolved wave models is discussed.

IMPLICATIONS OF RECENT OBSERVATIONS ON THE ROLE OF WAVE BREAKING IN WIND WAVE SPECTRA

Recent observations show a transition in wave spectra from a form in frequencies for 1.8 - 3.5 times the spectral peak. The transition location is consistent with the existence of a dynamic equilibrium between nonlinear fluxes into this region and wave breaking within the region. This interpretation suggests that energy loss due to wave breaking predominately occurs at high frequencies. The physical mechanism for the breaking in this region of the spectrum appears related to the orbital velocities due to longer waves; thus, this new hypothesis is quite consistent with observations showing that wave breaking is concentrated at the higher frequencies. We discuss two aspects of this new formulation. First, the new hypothesis substantially reduces the number of “tuning” coefficients in wave model source terms, since the integrated losses are fixed to be equal to the total nonlinear flux rate through the equilibrium range. Second, because energy is lost from the wave field at higher frequencies than presumed in current wave models has a dramatic effect on nearshore radiation stresses, yielding substantially increased wave set-ups at the coast.

SUBMESOSCALE VARIABILITY OF PCO2 IN THE NORTHEAST ATLANTIC

A high resolution 3D bio-physical model is combined with high resolution observations to study the submesoscale variability of sea surface partial pressure of CO2 (pCO2) and its impact on air-sea CO2 fluxes in the northeast Atlantic Ocean during winter and spring. The model was validated against the extended data set of network stations and 5 Caricau floats collected during POMME (Programme Océanographique Multidisciplinaire Moyenne Echelle). The model shows that the large scale pCO2 distribution is highly modulated by submesoscale filaments where pCO2 gradients are more than 20 times larger than the large scale meridional gradient. The mean CO2 air-sea flux estimated by the model is much larger than the flux estimated from the Caricau measurements. The discrepancy is attributed to undersampling by the floats. Moreover, comparison of simulations with and without submesoscale resolution shows a limited impact of submesoscale stirring on the regional CO2 flux budget derived from the model.

MULTIPLE EFFECTS OF COLORED DISSOLVED ORGANIC MATTER ON UNDERWATER PHOTOSYNTHESIS IN A WARMING CLIMATE

Permafrost thawing and vegetation shifts caused by global warming will release increasing concentrations of allochthonous CDOM into northern aquatic systems. This highly light absorbing component will alter the biogeochemical cycling and photosynthesis of high latitude estuarine species. We partitioned the optically active components affecting PAR in the Great Whale River and its associated estuary and coastal Hudson Bay, subarctic Canada, and found that CDOM currently exerts the dominant control on the underwater light field throughout the system. We evaluated the optical effects of increased CDOM loading on phytoplankton by way of experiments using a CDOM filter incubation system to measure photosynthesis, in combination with modelling analyses. The results showed effects on the depth of the euphotic zone, spectral matching between phytoplankton absorption and in situ irradiance and a substantial decrease in maximum photosynthetic rate. This combination of multiple effects reduced the integrated primary production throughout the estuarine ecosystem, by more than 60% at the highest CDOM concentrations. These results imply that future climate change could result in greatly reduced primary productivity that in turn may impact on higher trophic levels.

HABITAT CHARACTERISTICS OF HARBOR SEAL (PHOCA VITULINA) FORAGING LOCATIONS IN THE GEORGIA BASIN

The marine resource distribution throughout the San Juan Islands, Washington, is expected to increase rockfish abundance, with a consequent increase from predators. To predict the impact of predators on marine resources one must understand their current foraging behavior. We used satellite telemetry and TDRs to characterize the foraging locations of harbor seals in the Georgia Basin. We tagged 20 seals at three haul-out sites: Padilla Bay Estuary (n = 6) and Bird Rocks (n = 6) in Puget Sound and the Belle Chain Islets in the Strait of Georgia (n = 8). Harmonic mean analyzes were used to identify core foraging areas for the study animals. The average water depth of these areas was between 10-60 m, and the average dive depth of seals was 30.1 ± 32.24 m; suggesting that seals foraged at intermediate water depths. Characterizing seal foraging habitat is important when considering the location of marine reserves, as the placement of a reserve in or near core foraging areas may inhibit rockfish recovery and the realization of reserve goals.

POMME A SUBDUCTION PROCESS EXPERIMENT IN THE NORTH-EAST ATLANTIC

POMME investigated the formation of mode waters in the north-east Atlantic. The processes studied were both dynamical and bio-geochemical. The field experiment took place in 2000-2001 between 38°N and 45°N in the eastern Atlantic. The experimental strategy relied on a mix of meso-scale sampling during four cruises, and in situ instrumentation. Dedicated air-sea flux fields were produced consistent with the observed in situ T and S variability. The analysis involved both combining the data in order to provide major components of the budgets, and trying to realistically model dynamics at the meso-scales or analyse satellite imagery, in order to derive information on the unresolved scales of variability of the system. This revealed a large range of dynamical scales playing a role in the formation or the subsequent evolution of mode water in this supposedly relatively quiescent region. One mode water eddy was well observed, indicating the presence of new Atlantic mode water not formed locally. Sub-meso scale processes clearly also play a role in modulating subduction during spring, but might not have a major contribution once integrated spatially. The data also clearly reveal primary production and export before the subduction starts (in 2001, this did not happen before March 6), and that phytoplankton involved in the primary or regenerated production presents a large seasonal evolution. The area was also found to be a net sink of atmospheric CO2.

A PARADOX IN THE GLOBAL SI CYCLE MASS BALANCE

There are problems with our understanding of the oceanic Si cycle that may be related to the importance of the Southern Ocean on the global budget of re-mineralized nutrients in the deep-sea. Basic geochemical box-models of the oceans are poor at capturing marine C and Si cycles together. One potential solution is to investigate the Si geochemical cycle via the use of stable Si isotopes, but initial results led to a paradox in our conceptual model of the Si cycles.
model results suggest that there should be no measurable Si isotope difference between the deep-water composition of the Atlantic and Pacific Oceans, but results demonstrate a relatively large isotopic gradient between the ocean basins. Reasons of the stable-isotope paradox will be explored and potential mechanisms discussed, with particular stress on the biogeochemical divide separating the Antarctic from the Subantarctic.

SOURCES OF TERRIGENOUS SEDIMENT IN HANALEI BAY, KAUA‘I, HAWAI‘I: COMPARISON OF MAGNETIC AND CS-137 PROPERTIES IN MARINE SEDIMENT AND UPLAND SURFICIAL DEPOSITS

Magnetic and cesium-137 properties of sediments in the reef-watershed system of Hanalei Bay and River, Kaua‘i, Hawai‘i, provide information about sources of terrigenous sediment and land-surface stability of these sources. Magnetic iron-oxide minerals in the Bay sediments originate in upland basaltic rocks and soils; thus, magnetic properties of these sediments characterize detrital input from the watershed. Magnetic property variations in Bay sediments indicate many sources of upland sediment. In contrast, recent flood deposits (2006) collected from a bathymetric depression offshore of the Hanalei River contain magnetic and cesium-137 properties that imply flood deposit-source(s) from one or a few landscape settings and sufficient land-surface stability to provide sediment containing the 40-60-years old cesium-137 tracer. The results suggest that a significant component of recent flood deposits in the Bay was derived from tilled floodplain in the lower watershed where sediment from many upland sources is mixed and widely exposed. Fine-grained fluvial sediment of similar origin may that be stored between floods in the deep parts of the lower river might be another source of flood sediment.

A DAILY BLENDED ANALYSIS FOR SEA SURFACE TEMPERATURE - VERSION 2

Sea surface temperature (SST) analyses have been produced daily on a 1/4-degree spatial grid using in situ and satellite data. The analyses are done by optimum interpolation (OI) with a separate step to correct any large scale satellite biases relative to the in situ data. Because microwave data can be retrieved under cloudy conditions as long as there is no precipitation, the coverage of microwave SST data is greater than infrared data. Thus, one analysis uses both infrared and microwave satellite SST data, while the other uses only infrared data. The latest version (version 2) uses 3 days of satellite and in situ data instead of 1 to reduce the day-to-day noise. This version also smooths the 7-day satellite bias correction to reduce a strong 7-day period in the correction. In addition, version 2 includes a step to reduce ship SST biases with respect to buoy SSTs. Daily error fields show larger errors in bias, sampling and random errors. These daily OI analyses are evaluated by intercomparison with other SST analysis products. Version 2 will be available before January 2008 at http://www.ncdc.noaa.gov/oa/climate/research/st/oi/daily.php.

AUTONOMOUS MOORED PROFILING SYSTEMS FOR COASTAL OBSERVATIONS

High resolution, 4-D environmental characterizations of the physical and biogeochemical structure of the near shore and coastal oceans are needed to assess the state of the coastal ecosystem and for monitoring changes due to natural and anthropogenic forcing. To address these needs, we have been developing a series of Autonomous Moored Profilers (AMP) to support a variety of long-term coastal applications, where real-time, high vertical resolution physical and biogeochemical data are required. The AMP includes a self-contained, winch-driven profiling platform with integrated control and power systems, a suite of environmental sensors, and a telemetry system. To provide a complete top-to-bottom ocean/atmosphere observing system, we have also been developing the Coastal Autonomous Profiling and Boundary Layer System (CAPABLE). CAPABLE consists of the extended endurance AMP, the Shallow Coastal Upward Looking Profiler Integration Mode (SC-137) to sample the ocean boundary layer and facilitate docking/recharging of the AMP, and the Surface Boundary Buoy (SBB) for making detailed meteorological and upper ocean observations. We present an overview of the AMP and CAPABLE systems as well as data collected from recent field deployments.

PROSPECTS FOR IMPROVING STANDARDS USED FOR CALIBRATION AND VALIDATION OF INFRARED SENSING SYSTEMS

We review a few key developments that have emerged at NIST and other national measurement institutes that enable ever-improved radiometric calibration and validation standards. We first discuss how radiant power scales are established at NIST and other standards laboratories through cryogenic electrical substitution radiometers, and how NIST propagates this scale to the other radiometric scales at the Spectral Irradiance and Radiance Calibrations with Uniform Sources (SIRCUS) facility. We then discuss the filter radiometers and interferometers that NIST has developed for radiometrically checking the blackbody standards in use by the sea-surface temperature and atmospheric temperature validation communities. The importance of independently arriving at radiometric scales through completely different physical means will be highlighted by discussing the comparison of electrical substitution-based scales to blackbody-based scales. We conclude with preliminary results of a project focused on verifying current absolute uncertainty claims of 0.1 K, 3 sigma, in the spectrally-resolved thermal-infrared radiance. Finally, we discuss the recent development at NIST of a Hyperspectral Image Processor (HIP), which propagates electrical-substitution-based scales to complex, realistic spectra and even to realistic hyperspectral spatial scenes, and its proposed application to infrared sensor system calibration and validation.

USING 2,4,6-TRIMETHYLPHENOL AS A SCAVENGER TO EVALUATE THE CONTRIBUTION OF HUMIC TRIPLET EXCITED STATES IN THE NOM-MEDIATED PHOTODEGRADATION OF POLLUTANTS

Natural organic matter is known to promote organic pollutants photodegradation in illuminated surface waters. Humic triplet excited states have been recently shown to be the main species involved in the phototransformation of phenolic compounds. For this purpose, we studied the competetive humic substances-mediated oxidation of two molecular probes: fururfural alcohol and 2,4,6-trimethylphenol. The former reacts with singlet oxygen while the latter is supposed to react with humic triplet excited states. The strong inhibiting effect of 2,4,6-trimethylphenol on the photooxygenation of fururfural alcohol confirmed this hypothesis. This scavenging technique using 2,4,6-trimethylphenol as a scavenger was extended to other systems. We present here examples of pollutants photodegradation in which using this phenol can help to delineate the role of humic triplet excited states in the reaction.

NASA DEVELOP PROGRAM: STUDENTS UTILIZING EARTH SCIENCE RESEARCH RESULTS TO ADDRESS COMMUNITY NEEDS

DEVELOP is a NASA Science Mission Directorate Applied Sciences Program that fosters human capital development to extend NASA science research to local communities. With advisers and mentors from NASA and partner organizations, graduate, undergraduate and high school students incorporate NASA science measurements and predictions into prototype projects that address local policy and environmental concerns. Students demonstrate the benefits of NASA’s Applied Sciences Program by presenting project results at scientific and public policy forums such as the American Geophysical Union (AGU), the American Meteorological Society (AMS), and the Southern Growth Policies Board (SGPB). Overall, students strengthen leadership and research skills, experiment with novel technology, and engage in cooperative interactions with colleagues and mentors. DEVELOP fosters students human capital development focus affords students real world experien- ence, enabling them to become a valuable asset to the scientific and global workforce. NASA’s DEVELOP Program is more than scientific exploration and valuable results; DEVELOP fosters human capital development by bridging the gap between NASA science research and federal, state, local and tribal policy decision makers.

Richards, D., Dalhousie University, Halifax, Canada, clark.richards@dal.ca; deYoung, B., Memorial University, St. John’s, Canada, bdeyoung@physics.mun.ca; Sub-TIDAL EXCHANGE IN BONNE BAY, NEWFOUNDLAND

We present and discuss current data from the sill of Bonne Bay, a fixed in western Newfoundland, Canada. ADCP data collected between 2002 and 2004 are used to examine the transport over the sill, in an effort to determine the response of the fjord to local and remote forcing. EOF analysis indicates a primarily two layer structure to the exchange. The dominant mode is strongly correlated with the local wind stress. Discrepancies are accounted for by topographic steering of the wind in different parts of the bay using a simple two layer numerical model.

Richards, K. I., University of Hawaii, Honolulu, USA, rkelvin@hawaii.edu

VERTICAL MIXING IN THE EASTERN TROPICAL PACIFIC

Vertical mixing is known to have a large impact on the dynamics of the tropical ocean. Because of the strong coupling between the ocean and atmosphere, particularly in the eastern tropical Pacific, we need to consider the coupled system in studies of the sensitivity of the ocean to changes in the forcing. There is a need to have consistency across the ocean/atmosphere interface. Here we investigate the role of vertical mixing in the ocean and its impact on both the ocean and...
atmosphere in the eastern tropical Pacific in the context of a regional coupled model. A useful diagnostic is the distribution of the diapycnic velocity (the diapycnic component of the overturning circulation) which allows the pathways of transport to be thoroughly examined and which gives a very different picture to that implied by the Eulerian vertical velocity. Changes to the level of the ocean vertical mixing affect the atmosphere through changes in SST which in turn can feedback to the ocean through the surface wind, precipitation and cloudiness. To illustrate the issue, increasing the vertical mixing in the coupled system produces a much larger change to SST than an ocean-only model, an increase in the strength of the EUC (as opposed to a decrease in an ocean-only model), and significant reductions in the NECC and height of the Costa Rica Dome. We need to go beyond stand alone ocean models in testing ocean mixing parameterization schemes.

SAILFISH (ISTIOPHORUS PLATYPTerus) SPAWNING AND LARVAL ENVIRONMENT IN A FLORIDA CURRENT FRONTAL EDY: RESULTS FROM A LAGRANGIAN STUDY

Fronts and eddies are widely hypothesized to be critical spawning habitat for large pelagic species, and to increased spawning success and/or adult feeding opportunities at these features. An ichthyoplankton study examined sailfish spawning around a cyclonic sub-mesoscale (126 km) Florida Current frontal eddy. The temporal progression of eddy dynamics over a 65 h period was determined from satellite imagery, continuous surface measurements along the cruise track, and non-linear least-squares fitting of the positions of three drifters deployed within the eddy. Early stage (1-4 d old) larval sailfish (n=4245, stations=49) were most abundant at the eddy frontal zone, relative to the eddy interior and exterior. Their first-feeding prey items (Farranula and Corycaeus copepods) were most abundant in the interior and frontal zone of the eddy. Ongoing work is using egg densities to indirectly assess the distribution of adult prey items (small carnagids and scounarchs) relative to the eddy. Ultimately, the consistency of occurrence of these small-scale features within a region may be equally if not more important than larger regional-scale processes in structuring the broader spawning patterns of sailfish and other large pelagic species.

ACOUSTIC CHARACTERIZATION OF TIME-DEPENDENT MIXING AT THE SEAFLOOR

Biological (bioturbation) and physical (wave and currents) processes dominate the time-dependent evolution of small-scale (mm to m) roughness at the seafloor. Recent experiments (SAX99 and SAX04) have used high-frequency (40 kHz and 300 kHz) acoustic backscattering and stereo-photography to quantify the changes in natural and artificially-created seafloor roughness in sandy substrates. A time-evolution equation with a random forcing term that creates roughness and a diffusion term that degrades roughness will be described. When compared to acoustic data this model yields values of horizontal diffusivity in the range of 10 to 80 cm yr⁻¹. (Supported by ONR)

TAXON-SPECIFIC DISSOLVED ORGANIC PHOSPHORUS UTILIZATION BY ESTUARINE PHYTOPLANKTON DETERMINED USING AN ENZYME-LABELLED FLUORESCENCE APPROACH

River-transported dissolved organic phosphorus (DOP) may comprise a substantial fraction of total dissolved phosphorus in coastal ecosystems. The chemical composition of this DOP pool and its utilization by estuarine phytoplankton communities are largely unknown. We investigated the taxon-specific utilization of DOP in phytoplankton collected from upstream (river) and downstream (ocean) sites in Winyah Bay, SC, using combined nutrient addition bioassays and an enzyme-labelled fluorescence assay for expression of alkaline phosphatase (AP). AP expression was highest in phytoplankton collected from the ocean location (up to 33% of total cells were labeled). Labeling was detected only in some dinoflagellates and diatoms. AP expression was significantly lower in bioassay containers with added inorganic P. Overall AP expression was species-specific, site-specific and varied with month of collection. Chemoac characterization of the bulk DOP pool may provide insight into the observed variability. Characterization of DOP using liquid 31P NMR is currently underway. (Supported by ONR)

ESTUARINE CIRCULATION AND NEW PRIMARY PRODUCTION IN THE STRAIT OF GEORGIA USING AN INVERSE METHOD

The circulation of the Strait of Georgia estuary is obtained from an inverse box model based on 48 surveys carried out over the years 2002-2005. We discuss seasonal and interannual variability in the circulation, and show that the effect of storage terms in the budgets is due to the superposition of the strait circulation from variations in freshwater inflows. By combining the circulation model with observations of nutrient concentrations we find that a nutrient sink exists in the surface water. We use this to estimate new primary production, which is different in winter, summer, and during the spring bloom. In addition we speculate on the strength of recycled production by examining the Si:N ratio of this sink.

INTERPRETING DYNAMIC SIGNATURES OF LAND-WATER COUPLING AND IN STREAM PROCESSES IN THE AMAZON FROM SMALL STREAMS TO THE WESTERN TROPICAL ATLANTIC

The spatial and temporal distributions of dissolved CO2 in surface waters of tropical river systems is the product of a long sequence of complex biological, hydrological, and geochemical processes. A key gap in our knowledge is how these distributions vary with the hydrograph across a broad range of landscapes and river size. Recent data from the Rede Beira Rio work are extensive, with roughly 20 sites characterizing a wide range of Amazon environments and river orders, from small streams to the Amazon mainstem, with a broad suite of measurements over the period 2004-2006. Systematic variations in pCO2 relative to other chemical parameters were observed, including O2, DOC, and FPOC, suggesting an environmental “coherence” across scales, which ultimately governs the export of the Amazon end member to the WNTA, with subsequent marine implications.

IMPACT OF MODEL REPRESENTATION ERROR ON OCEAN CLIMATE FORECASTS

Knowledge of the structure and magnitude of errors in both observations and models is critical for successful data assimilation. We have developed a reduced state space scheme to estimate model representation error using long term model forecasts and time series of remotely sensed sea surface temperature and sea surface height obtained from satellites. The long term forecasts are used to create the reduced state space; the complement of the reduced state space is shown to be indistinguishable from noise. The model representation error can be estimated from the null space of the projection of the model and observation linearizations into the reduced state space, using the techniques described by Richman, Miller and Spitz (Geophys. Res. Letters, 2005). The technique is applied to the ocean forecasts from the NCEP Climate Forecast System (CFS) at present the CFS uses data assimilation to provide an improved initial condition of the ocean for the coupled forecast. The resulting representation error does not dominate the model-observation misfits. The climate model has significant errors in the equatorial cold tongue and the western Pacific warm pool. A simple reduced state space optimal interpolation can not assimilate these errors. We include realizations of the representation error as an ensemble of annual forecasts of the ocean to characterize its impact on the probability distribution for temperature and sea surface height, and thus derive an enhanced data assimilation system.

WATERSHEDS AND CORAL REEFS: CONSERVATION SCIENCE, POLICY AND IMPLEMENTATION

Coral reefs worldwide are being degraded by human-induced disturbances, resulting in ecological, economic and cultural losses. Runoff and sedimentation are among the greatest threats to coastal reefs surrounding high islands and adjacent to continental landmasses. Scientific data exist that identify key stressors, synergisms, and outcomes at the coral reef ecosystem, community and population levels. These data demonstrate that marine protected areas alone may be insufficient for coral reef protection, and that integrated watershed management practices are also needed. Gaps in the effectiveness of environmental policy, legislation and regulatory enforcement have resulted in the continued degradation of U.S. reefs. Several Pacific Islands, with intact resource stewardship and traditional leadership systems, have been able to apply research findings to coral reef management policies relatively quickly. These case histories in Micronesia provide insight into how biophysical data can be applied to manage human behaviors responsible for coral reef destruction, through the social sciences.

INVESTIGATING EXCHANGE BETWEEN THE KUROSHIO AND MARGINAL SEAS OF CHINA USING MODEL SIMULATIONS OF FLOATS AND DRIFTERS

Simulated drifters and floats are seeded in the East Asian Seas Navy Coastal Ocean Model (EAS NCOM) to investigate exchange between the Kuroshio and marginal seas of China. Drifters follow surface currents, while floats remain at selected depths. Fidelity of short-term model prediction is assessed by comparing paired simulated and observed drifter trajectories, while accuracy over longer time scales is evaluated using model and historical transports in various straits. Distributions of trajectories over multiple years reveal long-term exchange patterns with interannual and seasonal variability. The EAS NCOM, driven with real-time atmospheric forcing and tides, has been running daily at the Naval Oceanographic Office for several years. Modeled annual transports in the Luzon strait are 7.2 Sv, 4.9 Sv and 5.4 Sv for 2004, 2005 and 2006 respectively. East of Luzon, the transport is 15 Sv in 2004 and about 30 Sv for 2005 and 2006. EAS gives reasonable transports for other straits in the region as well. Thus realistic flow exchange between the Kuroshio and adjacent marginal seas is expected.

THE FAROE BANK CHANNEL OVERFLOW: COMPARISON BETWEEN SIMULATIONS, SIMPLIFIED OVERFLOW REPRESENTATIONS, AND HYDRAULIC JUMP THEORY.

High-resolution regional simulations of the Faroe Bank Channel overflow, carried out using the MITgcm, are used to evaluate a simplified representation of the transport and mixing within the overflow, the Marginal Sea Boundary Condition (MSBC). This representation has recently been implemented in a global climate model as part of the Gravity Current Entrainment Climate Process Team. A key discrepancy between the simulations and the MSBC is shown to be the rapid widening of the overflow plume in the simulations which is not captured by the MSBC approximations. A possible cause of this widening, also indicated by observations, is a lateral hydraulic jump. Comparison between model results and hydraulic jump theory supports this hypothesis.

EFFECTS OF CO2-DRIVEN REDUCTIONS IN SEAWATER CACO3 SATURATION STATE ON ARAGONITE AND LOW-TO-HIGH Mg CALCITIC MARINE INVERTEBRATES AND ALGAE

Elevated atmospheric pCO2 decreases seawater pH and [CO3=], reducing seawater saturation with respect to aragonite and calcite, the primary shell-building minerals of marine calcifiers. We are conducting long-term laboratory experiments to determine the effect of reduced seawater CaCO3 saturation state on biocalcification by 21 aragonitic and calcitic (low-high Mg) taxa representing eight of the major marine calcifying groups: Chlorophyta; Rhodophyta; Crustacea; Bivalvia; Gastropoda; Annelida; Cnidaria; and Echinodermata. The CaCO3 saturation states of the experimental seawaters, constrained by intercalibrated determinations of pH, alkalinity, and DIC, are achieved via air-CO2 mixtures of 380 (ambient), 560, 840, 2240 ppm CO2, yielding Ω-arag of 3.2 (ambient), 2.4, 1.8, 0.8, respectively. Isotope spikes (137Ba) and buoyant weighing are employed to constrain rates of calcification/dissolution. Using a newly developed CT scan we are able to assess changes in bimineral morphology, trace element geochemistry, and shell density. Initial results indicate significant and taxonomically-varied responses to reduced seawater saturation states. At lowest Ω-arag (0.8), new CaCO3 continues to be accreted within the calcifying zones of many of the organisms. Significantly, these same organisms are simultaneously undergoing net CaCO3 dissolution.

INFLUENCE OF FIELD TEMPERATURE VARIATIONS ON PELAGIC LARVAL DURATION IN THE INVASIVE GASTROPOD CREPIDULA FORNICATA: IMPLICATIONS ON POPULATION CONNECTIVITY

Pelagic larval duration (PLD) is a key characteristic of marine benthic species with pelagic larvae, especially for invasive species as it strongly influences their potential for sustainable settlement and spread. Understanding how climate affects an invader's PLD is thus crucial. By combining field studies (bay of Morlaix, English Channel), experimental data and mathematical computations, we investigated the effect of temperature variations on the PLD of the larva of the slipper limpet Crepidula fornicata, invasive along the European coasts. In the range of field temperatures faced by larvae during a three-year survey (9-18°C) our results suggest a great range of PLDs, suggesting that larvae released during early spring, if they can overcome mortality, might contribute more to spread than to local settlement, the opposite occurring for larvae released at warmer temperature. Analysing similar patterns along the European distribution of C. fornicata allowed us to suggest that in some cases the potential ocean temperature increase might increase population connectivity.

AUTONOMOUS IMAGE SELECTION FOR BENTHIC CLASSIFICATION

Modern technology now allows vast numbers of images of the seabed to be captured and stored. Before this data can provide any meaningful information the images need to be classified by benthic ecologists. This can be a time consuming process, and often only a subset of the original data can be considered. We provide a computerised method to automatically select this subset. Using a Gaussian process approach, we consider the spatial variation of the benthos and autonomously select the subset which provides the maximum information about the underlying distribution.

THIN LAYERS AND HARMFUL ALGAL BLOOMS IN MONTEREY BAY, CA

As part of ONR’s interdisciplinary Layered Organization in the Coastal Ocean program, we studied the species-specific distribution of phytoplankton inside and outside of thin
layers in Monterey Bay, California during the summers of 2005 and 2006. Monterey Bay is home to an extraordinarily diverse community of phytoplankton, including many taxa implicated in Harmful Algal Blooms. A remarkable feature in 2006 was the prevalence of HAB species, including Alexandrium catenella, Dinophysis fortii, Pseudo-nitzschia spp. and Chaetoceros concavicornia. Harmful Algal Blooms are frequently dominated by a single taxon. However, during our experiment multiple HAB taxa co-occurred. In some cases they were concentrated in thin layers, while in others they were more broadly distributed throughout the water column. Dinophysis fortii co-occurred with its putative prey, Myrionecta rubra. Species-specific vertical distribution patterns have implications for both the impacts of HABs, and for their ecology. Thin layers contain enhanced concentrations of cells, so their waters may be more inimical than other regions of the water column. They may also contribute to the ecological success of specific taxa, by concentrating in close proximity interdependent organisms.

AEROBIC MICROBIAL FUEL CELLS FOR OPERATION IN THE OCEAN COLUMN
Microbial fuel cells (MFCs) harvest energy from a wide variety of carbon sources to produce electricity at neutral pH and ambient temperatures. Because most environments on Earth are exposed to significant levels of oxygen, we believe the transition from sediment based MFCs to oxygen-tolerant MFCs is necessary. Our specific focus is on the powering of ocean water column sensors by an oxygen-tolerant mini-MFC. We isolate the desired electron-producing microbes in the anode chamber with membranes that contain pores sizes smaller than the microbes of interest (< 1 μm). Selected nanoporous polymer filters can be used effectively in place of standard PEMs in the mini-MFC (device cross-section: 2 cm²). Exposing the anode to air also creates unique growing conditions for the microbes themselves compared to the standard anerobic anode conditions used in MFCs. We found that significant power was generated from glucose using Shewanella species in the mini-MFC design under aerobic conditions. In addition to glucose, other carbon fuels including fructose, sucrose, acetate and ascorbic acid were tested. The power produced from glucose decreased considerably if strictly anaerobic conditions were maintained. The design of the mini-MFC has expanded the breadth of potential electron donors for Shewanella MFCs and demonstrates the importance of studying microbial species under diverse environmental conditions.

HIGH-RESOLUTION SURFACE SALINITY AND TEMPERATURE MEASUREMENTS FROM ARGO FLOATS
With the coming of the Aquarius satellite mission there is an increased interest in the surface salinity field of the global ocean. Validating the Aquarius measurements and interpreting them in terms of the underlying salinity field will be an important task. The global Argo array of profiling floats provides one way to carry out such an exercise, although Argo floats do not generally measure temperature and salinity above depths of 5 meters in the ocean. In order to extend the Argo measurements to the sea surface, we have added auxiliary CTD sensors to several floats that can collect high-resolution (depth intervals less than 20 cm) temperature and salinity data along their profiles through the upper 50 m of the water column. We show examples of these near-surface profiles, discuss their precision and accuracy, and examine the broader implications of such work for the upcoming Aquarius mission.

ALGAL NATURAL PRODUCTS MEDIATE MULTIPLE ECOLOGICAL INTERACTIONS ON CORAL REEFS
How algal species can proliferate in reef habitats and how they can maintain these phase shifts are critical questions to managing coral reef habitats. On two Caribbean reefs we show that some common reef algae (but not all) use chemical defenses to deter reef fishes. In Belize, the sea urchin Diadema antillarum was less discriminating than reef fishes and consumed some of almost all species of algae offered to them. For example, fish were strongly deterred by some brown algal extracts, while the urchins readily consumed them. Herbivorous reef fishes and D. antillarum have different algal preferences (often driven by chemical defenses) and can have differential effects on algal community composition. Algal natural products also mediate competitive interactions with scleractinian coral larvae. Some species of Lyncbya and Dictyota are as well as extracts of some of these spe1. View all higher resolution images for this article cies caused either recruitment inhibition or avoidance behavior in coral larvae. Natural products protect some algae from herbivory (allowing increased space occupation) and reduce coral recruitment, both of which may perpetuate a phase shift from coral to algal dominated communities.

A CASE STUDY DESCRIBING AN OFFSHORE WARM FILAMENT OF THE FLORIDA CURRENT NEAR 30N
Aspects of a surface layer filament flowing eastward of the Florida Current during February-March 2007 are described. The evaluation is based on comparisons between 49 aircraft-deployed xbt profiles and the filament location interpreted from satellite images of sea surface temperature. Using temperatures greater than 23°C to indicate filament waters, the surface thickness varies from 150 m within the Florida Current to 50 m toward the east. The xbt data also reveal a cyclonic eddy coincident with the filament such that the filament was located on the southern flank of the eddy. The filament is sufficiently thick and broad (~50 km) to modify the acoustical properties for Navy training applications. Some speculation is also presented on the potentially significant role of eddies to divert mass and heat from the western boundary surface flow into the subtropical central gyre.

VARIABILITY OF THE DIFFUSE DOWNWELLING IRRADIANCE IN GULF OF MEXICO HYPONIC AND NON-HYPOXIC WATERS
Light availability is a key factor regulating water-column oxygen concentration. In the shallow waters of the Louisianat continental shelf, light availability below the pycnocline may determine the vertical distribution of hypoxia. A 166-channel (350 - 800 nm) Atlantic HyperPRO was used to derive in-situ time-series measurements of diffuse attenuation coefficients, Kd, from a station in hypoxic waters and an in-shore non-hypoxic station. Kd(490) in hypoxic water was 0.08 +/-0.05 m-1 between surface and 15m depth. Kd(490) below 15m started at 0.20 m-1 and increased to a maximum of 0.94 m-1 at the 24 m bottom. Kd(490) in non-hypoxic water was 0.02 +/-0.11 m-1 at surface decreasing to 0.28 +/-0.11 m-1 at 6m depth. Comparisons will be made with supporting physical measurements to understand dynamics of Kd(490) in hypoxic and non-hypoxic waters.

HOW TO RECONCILE CONTRADICTING FORECASTS IN THE COASTAL OCEAN?
Multi-model Super-Ensemble (SE) aiming at combining optimally different models have been shown to improve significantly atmospheric weather predictions. In the coastal ocean, complex, yet poorly understood dynamics, the presence of small-scale processes, the lack of real-time data and limited reliability of operational models so far prevented the proper application of SE methods. Here, we report results from state-of-the-art super ensemble techniques based on dynamic combinations of SEPT [a (t)rew-train-tom-bottom mounted platform transmitting in near real-time] data and a series of eight operational models ran during an experiment in a coastal area in the Adriatic Sea. Kalman filter and
Particle filter based methods which allow for dynamic evolution of weights and associated uncertainties are shown to increase flow speeds (10%) as compared to single models. The latter method copes with non-Gaussian error statistics and reduces the uncertainty by a further 30%.

HIGH FREQUENCY RADAR NETWORK WITHIN THE MID-ATLANTIC REGIONAL COASTAL OCEAN OBSERVING SYSTEM

High Frequency (HF) radar has been established as an important component of Mid-Atlantic Regional Coastal Ocean Observing System (MARCOOS). The HF radar network currently consists of 26 sites with multi-pulse and nested coverage from Cape Hatteras to Cape Cod with high-resolution coverage of the four major estuaries in the region. This network provides regional surface current maps to improve United States Coast Guard search and rescue operations, mitigate hazardous material spills as well as improve rip current forecasting. The radial current files are aggregated into the national data archival system. Specific applications include assimilation into a statistical model and three dynamical models with the goal of improving surface current forecasts for search and rescue. Test bed activities will routinely compare these forecasts with drifters released into the coverage area to determine the parameters necessary for inclusion into the Coast Guard search-planning tool, SAROPS. The MARCOOS HF Radar network has moved from small isolated systems to a single integrated regional system, a model that is being scaled around the world.

DISTRIBUTION OF TRANSPARENT EXOPOLYMER PARTICLES ALONG AN ESTUARINE SALINITY GRADIENT

Transparent exopolymer particles (TEP) play an important role in organic matter sinking fluxes in marine ecosystems. Little is known about the importance of TEP in estuaries, however. We examined the distribution of TEP along a salinity gradient in North Carolina’s Neuse R. Estuary (NRE). In summer 2007, TEP was positively correlated with salinity. Even though several large phytoplankton blooms, which are a source of TEP were found in the upper NRE, TEP did not deviate from a conservative mixing line at those locations. We hypothesize that estuarine features, like salt plumes, could play a determining role on the formation and distribution of TEP. The formation may be inhibited by the lack of cations. This inhibition of TEP formation in the lower salinity regions of estuaries may have important implications for phytoplankton sinking fluxes and estuarine oxygen dynamics, as it is in these regions of estuaries where large blooms often form and where phytoplankton-fueled bottom water hypoxia can be problematic. Results will be presented from the in situ TEP monitoring as well as from time-course experiments in which TEP concentrations were observed in mesocosms with and without added cations.

FLUID – GAS EXPULSION ON THE DEEP GULF OF MEXICO CONTINENTAL SLOPE: GEOLOGIC FRAMEWORK FOR CHEMOSYNTHETIC COMMUNITY SITES

Massive sediment input to the Gulf’s northern continental slope and associated salt wedge formation events can also be detected in ocean color satellite imagery, providing a regional perspective complementing the observatory results. These events do not happen at all locations equally, but form distinct geospatial patterns primarily related to the patterns of forcing, namely wind and insolation. Attempts have been made to model diurnal warming events as seen over a region through use of remote sensing techniques. Comparison of these modeled events to those as seen from space will be presented. Also, comparison of model results to ship and other in situ platforms will be shown. Use of modeling parameterizations allows for an examination of global fields of diurnal warming and its variability over a variety of temporal and spatial scales.

CFAMS: A NEW RADIOCARBON MEASUREMENT TOOL FOR MARINE GEOCHEMISTRY

Continuous-Flow Accelerator Mass Spectrometry (CFAMS) is a new analytical tool that will open new research doors in measuring radon. Carbon, and other diagenetic gases. The CFAMS uses samples by cesium sputtering, this new technique involves direct measurement of CO2. Advantages to this approach include more rapid and less expensive measurements, lower blank, and simpler chemistry. More importantly, this approach allows direct interfacing of the resulting gases and liquid chromatographs, laser ablation/combustion systems, progressive pyrolysis combustion units, and Kiel devices. The first group permits radionuclide analysis of individual compounds with unprecedented rapidity and accuracy, illuminating carbon flow in the environment, and environmental forensic and opens the door to radionuclide analysis of sub-microgram samples. The second group permits detailed spatial mapping of radionuclides in structures like oil spills, speakerboxes, and tropical (ring less) trees. The third group allows operational separation of individual

PARTICLE MOBILIZATION FROM MID-SHELF SAND SEDIMENTS OF THE SOUTH ATLANTIC BIGHT IN RESPONSE TO PHYSICAL FORCING

The BOTUMS-UP project established a pilot benthic observational on the continental shelf off Georgia (~26 m depth), building on existing offshore monitoring infrastructure, and offshore Navy tower. Shelf sediments in this area are predominately permeable sands. Light at the bottom is often sufficient for benthic microalgae photosynthesis. One aspect of the study examines the role of physical disturbance in resetting the benthic system, removing fine particles and contributing to high permeability and high biogeochemical activity in surface sediments. Initial results from spring- fall 2007 are presented, focusing on fine particle export from the sands in response to physical forcing, and subsequent settling. Turbidity and chlorophyll fluorescence measured near-bed (0.5-2.0 m above the bottom) and in the water column track changes in suspended particles and chlorophyll (the latter potentially including suspended benthic microalgae). These data are combined to yield observations (including wind, surface waves) and results from other benthic packages (including near-bed velocities and bed form evolution). Major particle suspension events can also be detected in ocean color satellite imagery, providing a regional perspective complementing the observatory results.

LOCAL AND SURFACE INTENSIFICATION OF TIDAL CURRENTS AND MIXING IN THE INDONESIAN SEAS

In the Indonesian Seas, North and South Pacific Waters are transformed by mixing into Indonesian Throughflow Water with much of the mixing attributed to tides. To investigate barotropic and baroclinic tides in the Indonesian Seas, they were simulated using the Regional Ocean Model System (ROMS) with forcing by four tidal constituents, M2, S2, K1, and O1. The intricate topography of the region along with interactions between the Pacific and Indian Ocean tides resulted in strongly depth dependent velocities and internal tides were generated by all constituents. Extensive interactions occurred in the internal tidal fields between a beam and its own reflections, between internal tides generated at different locations (i.e. different sides of a channel, or beams generated nearby), between the barotropic and baroclinic tidal beams, and between beams of the different constituents. Extremely complex internal tidal fields resulted with high variability, both spatially and during a tidal cycle. Additionally, propagation was often trapped in the surface layer. Regions away from topography showed a Garrett-Munk (G-M) dependency in spectral levels. However, spectral density was elevated at higher frequencies in regions of high
internal tide generation. And the elevated spectral density persisted well away from the topographic features near the surface, but not deeper in the water column. Intense mixing was also found to be localized over topographic features.

HURRICANE-INDUCED DEPTH OF CLOSURE Derived FROM AIRBORNE LASER BATHYMETRY INDICATES HYDRODYNAMIC AND GEOLOGIC CONTROLS IN SOUTHEAST FLORIDA

Reported here is a method that identifies an event-dependent depth of closure (DOC) using airborne laser bathymetric data. The measured DOC was compared horizontally and vertically to DOC positions that were calculated in the traditional manner (Hallermeyer, Birkemeier, and Nicholls equations) and to geomorphic units at 1046 locations spaced 100 m along the coastline. Calculated DOC values were on average 2.8 m deeper than the measured DOC in the northern end of the study area. Diachastic channel fields match the measured DOC to the north, with a vertical difference of 0.3 m and a horizontal difference of 161 m, on average. Because diachastic channels are hydrodynamically formed, the northern study area appears to be hydrodynamically controlled. To the south, small horizontal differences (90 m, on average) between hardgrounds and measured DOC suggest geologic control south of Hillsboro Inlet. Because this study measured an event-dependent DOC where waves generated by two hurricanes were larger than normal, the measured DOC represents a deeper DOC that rarely changes over time.

COSEE OCEAN LEARNING COMMUNITIES: COLLABORATIVE PARTNERSHIPS START AT HOME

The core mission of the Centers for Ocean Sciences Education Excellence (COSEE) is to promote partnerships between research scientists and educators through a national network of regional hubs and centers. This network fosters collaborative initiatives that benefit the network and beyond. To address the challenging issue of ocean sciences education informed by scientific research, COSEE supports partnerships between research institutions, formal, and informal education institutions. COSEE Ocean Learning Communities, a collaborative experiment between the UW College of Ocean and Fishery Sciences and College of Education, the Seattle Aquarium, and The College of Exploration. The theme of COSEE OLC is to study how to foster Learning Communities that cultivate ocean sciences-literate citizens aware of the ocean’s impact on their life. To facilitate educational efforts with disparate regional contexts, the OLC leadership team provides a collaborative approach within its structure. This presentation will highlight some of the management, and team-building strategies adopted by the center. The authors will discuss the challenges of the first few months of operation and the approaches that have improved communication, and started the development of a common language, and a better understanding of the various cultures involved in the center. How each culture strengthens and enriches the goals of the center fosters the emergence of an Ocean Learning Community.

ADVANCED SYSTEMS FOR PREDICTING COMPLEX FEATURES OF REGIONAL OCEAN CIRCULATION

Large-scale, mesoscale and small-scale features constitute the generally complex circulation and flow of the regions of the ocean. The identification of the dominant currents, meanders, eddies and waves and their efficient description in terms of critical parameters, both in physical and phase spaces is essential to facilitate regional dynamical studies, simulations, and real-time forecasting. The role of feature models in advanced ocean observing and prediction systems is extremely important. The concept of such systems for field and parameter estimations has three major components: (i) an observational network: a suite of platforms and sensors for specific tasks, (ii) a suite of interdisciplinary-dynamical models and (iii) multivariate data assimilation schemes. Model-model, data-data and data-model compatibilities are essential. Systems are becoming increasingly modular, based on distributed information providing shareable, scalable, flexible and efficient workflow and management functionality. Multi-scale examples using the Harvard Ocean Prediction System that are presented in this tutorial include: the Gulf Stream, the Brazil Current, upwelling in the California Current System off Monterey Bay, and nested regional climate change modeling of the Gulf of Maine.

A FRAMEWORK FOR ASSESSING THE REPRESENTIVITY OF FISH DIVERSITY IN NATIONAL MARINE CONSERVATION AREAS AND NATIONAL PARKS OF CANADA

In Canada, zoning is used in National Marine Conservation Areas (NMCA) and Coastal National Parks (NPs) to conserve biodiversity that is representative of a greater natural marine region. In this study, 3 elements of species diversity (richness, evenness and relatedness) were used as a measure of biodiversity, and they were evaluated to assess the representivity of protected zones. In this poster, I test the assumption of equivalent species diversity among examples of the same habitat, and discuss a framework for selecting habitats in order to fully protect and conserve representative regional species diversity. I have used fish species and abundance data collected by beach seine for eelgrass meadows (Zostera marina) and gravel beaches from Pacific Rim National Park Reserve of Canada, located on the west coast of Canada. Two questions were addressed in this poster: 1) Are eelgrass meadows equivalent to gravel beaches in the fish species diversity elements that they represent? and 2) Do all examples of eelgrass meadows or gravel beaches equally represent fish species diversity of the greater natural region?

INTERACTIONS BETWEEN PHYTOPLANKTON, MICROCOOZOOPLANKTON AND MESOZOOPLANKTON IN NEARSHORE SYSTEMS ALONG THE WEST COAST OF PENINSULAR FLORIDA, USA

The fates and impacts of nutrients transported by rivers represent critical drivers of coastal ecosystems. One conceptual model for large rivers with discharges bearing sediment and nutrients predicts that phytoplankton production controls to yield i) lower phytoplankton biomass, phytoplankton production, zooplankton abundance, and zooplankton grazing in low light environments near river mouths; ii) highest phytoplankton biomass and production in partially mixed zones where settling improves light availability, nutrients remain available, phytoplankton production species microzooplankton grazing and mesozooplankton abundances remain low; and iii) lower phytoplankton biomass and production further offshore where higher mesozooplankton abundances raise grazing pressure and nutrients become depleted or diluted (Dagg & Breed 2003). The generality of this model was tested in three systems along Florida’s Gulf coast using field samples and 24-h incubations of phytoplankton with and without zooplankton. Results differ from predictions, with phytoplankton biomass normally peaking near river mouths, phytoplankton production following a similar pattern or remaining constant, mesozooplankton abundance and grazing being similar across zones, and mesozooplankton abundances remaining constant. Patterns are attributed to scale-dependent, spatiotemporal interactions among processes.

HISTOPATHOLOGICAL ANALYSIS OF THE LIVER OF FLATFISH ACHIRUS LINIATUS IN A POLLUTED ESTUARY IN BRAZILIAN COAST

The Santos estuarine system, in Brazilian southeast coast, is an intensely populated area and contains an industrial pole and the major harbor of Latin America. Two estuaries of low hydrodynamic and bordered by mangroves, flows into a bay, adjacent a continental shelf. In the 50 and 60’s decade, this region showed high contaminants index because of they multiples resources. The local fauna showed bioaccumulation of hydrocarbon and PCBs in its tissues. Measures were taken to mitigate such damage and as a result there were a quantitative reduction and a qualitative improvement of the industrial effluents. With the propose to investigate the regional real state, livers of the flatfish Achirus lineatus, collected at the Santos Bay, were studied because of its key role in metabolism and subsequent excretion of xenobiotics. Sample histopathological analysis showed the presence of Melano-Macrophage Centres and others structural alterations at the liver that can be an indicative of environmental stress. The present aim is monitoring the impact of the antropic activities at the region using biomarker that will allow, with others studies, assess the fish population resilience.

REDUCING UNCERTAINTY IN THE DETECTION OF ANTHROPOGENIC DIC CHANGES

An ocean model (MOM4 with GFDL’s TOPAZ biogeochemistry model) is used to evaluate the changes in DIC and DOC estimated along Repeat Hydrography sections P16, P17, P20, and P2 in the Pacific and A16 in the Atlantic. The model is forced with reanalysis fluxes over the period 1958-2006. The first goal in using the model is to identify changes in DIC which are due to natural variability in the circulation of the ocean. For this natural vari-
LANTHANIDES PROFILES OF THREE BROWN SEAWEEDS ON THE COASTAL ZONE OF SANTA ROSALIA MINING DISTRICT, BAJA CALIFORNIA PENINSULA, MEXICO

The polluted coastal sediments of the Santa Rosalía mining region have specific rare earth element (REE) shale normalized patterns, characterized by a light REE enrichment and positive europium anomaly. The aim of our research was to evaluate the possibility of a transfer of lanthanides from the sediments of this area into a biota. The concentrations of eight REEs in brown seaweeds Sargassum sinicola, Padina duriavella and Dictyota dichotomy, collected in 2004-2005 along the shore with both pristine, and polluted environments, were measured by a neutron activation analysis. REE shale normalized patterns of the seaweeds, with some exceptions, do not follow the signatures of the surface sediments. The majority of the seaweeds samples display the shale normalized patterns similar to a sea water, characterized by dissolved heavy REE enrichment. Only a very limited number of the seaweed samples had other pattern, displaying Eu positive or negative anomalies, also seen in the soil and sediments of the mining region. It could be presumed that bioaccumulation of REEs into brown seaweeds is controlled mainly by the seasonally changed water transport along the coast.

MAKING GLOBALLY CONSISTENT WATER LEVEL MEASUREMENTS

In this presentation, we review the feasibility of making centimetric accuracy globally consistent swath measurements of water level for both oceans and fresh water bodies. The feasibility of such a measurement must strike a fine balance between technological feasibility (and cost), orbit and sampling design, and understanding of the end-to-end error budget (including physical and technical limitations), and sophisticated calibration techniques. In the first part, we will present the measurement concept behind wide-swath altimetric/interferometric techniques and review the suite of instruments required to make the measurement and the technology trades which are involved in designing an optimal configuration. In the next section, we provide a detailed description of all the error sources which make up the measurement and examine our current ability to deal with each of them. Finally, we conclude with the continuous calibration techniques which are required to obtain a globally consistent data set and present the accuracies expected for the proposed Water/EHydrosphere Mapper mission.

GROWTH AND REPRODUCTION OF INVASIVE KELP SPROOPHYTES (UNDARIA PINNATIFIDA), MONTEREY HARBOR

Biological invasions are attributed to about half of all endangered species declines worldwide. Undaria pinnatifida is an annual brown subtidal alga (Phaeophyceae; Laminariales), native to Japan, China and Korea, where it is cultivated and sold as wakame. The only invasive kelp in the world, Undaria was introduced to Monterey Harbor in 2001. The purpose of this study is to better understand the growth patterns of this invasive alga, Undaria pinnatifida, in the newly invaded range of the Monterey Bay, California. We characterized in-situ sporophyte growth of Undaria in Monterey Harbor and tested how simulated grazing damage (~80-90% of blade removed) affected sporophyte reproductive capacity (max. sporophyll size). In Monterey Harbor, average sporophyte growth rates were greater, and average maximum sporophyte total length were longer, when compared to the previously published data from Santa Barbara Harbor. Damaged sporophytes grew slower, proportional to that of smaller plants, however, maximum sporophyll size (reproductive capacity) was reduced. Further study is needed to determine whether sporophyte growth exhibits seasonal patterns like other Undaria populations worldwide, and the level of disturbance that is likely to result in reproductive failure.

THE COLOMBIA CURRENT: AN EASTERN TROPICAL PACIFIC COASTAL CURRENT, EARLY OCEANOGRAPHIC CHARACTERISTICS

Newly gathered hydrographic data from the Colombia Pacific Ocean is combined with remote sensing data to reassess the properties of the coastal current named Colombian Current by Wooster (1959). New hydrographic data were occupied along the Colombian Pacific coast during March of 2006, making 41 stations with measurements of CTD. On the other hand, sea surface temperatures (SST) were obtained from the MODIS-AQUA satellite and sea surface wind speed and wind direction stem from QuickScat, both averaged for March 2006.Finally geostrophic velocity was computed for the Colombian Current area at several layers.The SST during the month of March of 2006 was especially low in the oceanic zone, reaching temperatures between 19 °C and 24 °C The dynamic topography indicated the presence of a surface coastal current flowing towards the north and a crosscurrent to 400 m of depth never before described.Upwelling curl associated with the left (southeast) flank of Panama Jet generates a cyclonic eddy in the Panama Bight and SST cooling in its center. In the Panama Bight, the curl dipole produces a cyclonic circulation with northward flow along the Colombian coast.

LABORATORY TESTS OF HYDRATE FORMATION IN POROUS MEDIA INFLUENCED BY BIOPRODUCTS

After observing the catalytic effects of synthetic surfactants on gas hydrate formation in a DOE-sponsored gas storage process, we extended the study to biosurfactants and bio-polymers promoting hydrates in ocean sediments, where microbial activities around gas hydrate accumulations are prolific. This paper discusses laboratory results from forming gas hydrates in water-saturated porous media: (1) evaluates samples from all possible biosurfactant classifications for influences on hydrate formation, (2) studies possible transport phenomena that would distribute bioproducts to hydrate accumulation sites, (3) investigates culturing a microbial species previously identified around Gulf of Mexico (GOM) hydrates, separates surfactant from the culture broth, and evaluates collected surfactant for hydrate promotion in porous media, (4) investigates adsorption, orientation, and interaction of bioproducts with specific mineral surfaces and their hydrate formation effects, (4) reports hydrate morphology effects that vary with biopolymers, and (5) evaluates biosurfactants and biosurfactants/minerals as nucleation for hydrate crystalization.

INTERACTIVE IRRADIANCE AND NUTRIENT EFFECTS ON THE PHOTOSYNTHESIS OF NODULARIA SPUMIGENA

The photosynthetic efficiency of Nodularia spumigena was investigated under different nutrient and light conditions. In axenic cultures, the strength of phosphorus flux was strongly dependent on irradiance levels as they changed with light, vertical nutrient distribution, and the behavior of the dinoflagellates. In addition, it formed a vector of phosphorus flux downwards due to sinking cells. The strength of phosphorus flux was strongly dependent on irradiance levels as they changed with light, vertical nutrient distribution, and the behavior of the dinoflagellates.

COMMUNITY ENGAGEMENT: A CRITICAL ROLE IN OCEAN OBSERVATORIES

A series of new facilities is being planned at the NSF’s Ocean Observatories Initiative. These observatory systems and their linking cyberinfrastructure network have the potential to revolutionize ocean science research and education. The full impact of these observatories will most likely be achieved only if these new ocean observing assets are catalytically integrated with the broad range of currently existing research and education programs, facilities, and partnerships. In the education realm, some of the major challenges that we will discuss include: (1) formulating ocean science topics educators, textbook developers, and students are most interested in; (2) integrating data into teaching and learning developments in new technologies, social networks, and bilingual settings; (3) expanding local or regional successes into collaborative efforts with a nation-wide impact; (4) enhancing the size, intellectual scope, and diversity of the ocean education community; (5) emphasizing the creative opportunities enabled by the novel observatory projects (real-time data, the ability to control/configure sensors and mobile assets, high-bandwidth infrastructure for images); and (6) developing partnerships between networks of scientists, educators, and technology specialists.
Vertical habitat shifts in California current mesozooplankton: copepods vs. chaetognaths

We seek to determine whether vertical habitats of specific mesozooplankton groups are related in a consistent manner to the hydrographic or biotic structure of the water column, and are therefore likely to vary in a predictable manner with climate-related changes. To address this issue, we have examined vertical habitats of zooplankton in hydrographically distinct regions of the California Current as part of the CCE-LTER (California Current Ecosystem-Long Term Ecological Research) process cruises. Vertically stratified samples collected with a 202-Amesh MOCNESS have been digitized at 2400 dpi with a scanning device (Zooscan), then classified into distinct zooplankton taxa using an automated machine learning algorithm. Based on construction of a confusion matrix from which have consistently identified with sufficiently high fidelity include non-eucalanoid copepods, eucalanids, chaetognaths, and euphausiids, with correct identification rates ranging from 91% for non-eucalanoid copepods to 79% for eucalanids. Copepods, but not chaetognaths, showed higher vertical migration (DVM) behavior that differs by body size and geographic region. In offshore, more optically transparent waters, copepods show larger amplitude DVM, presumably associated with increased visual predation risk.

Spatial patterns in hypoxia and zooplankton in the Gulf of Mexico

High resolution mapping of zooplankton, oxygen and physical properties of the water column in the northern Gulf of Mexico were conducted during four summers of differing freshwater input and wind-mixing. Our results show inverse relationships of hypoxia and water column-integrated zooplankton biomass. The spatial patterns of hypoxia and zooplankton exhibit significant annual and short-term variation due to differences in freshwater discharge, wind direction and intensity. Elevated areas of zooplankton biomass (hot spots) were associated with physical discontinuities and onychites. We compare estimates of hypoxic waters and plankton biomass in the northern Gulf of Mexico to other coastal systems to gain a better understanding of the effect of hypoxia on pelagic resources.

Latitude heat flux variability in the tropical Pacific from observations and models

Tropical Pacific evaporation is a key metric for coupled model evaluations with respect to air-sea exchange. The evaporative fluxes at the sea-surface represent a tight connection between the ocean and the atmosphere that depends on wind, SST, air humidity, bulk parameterizations and boundary layer physics. At the same time the Tropical Pacific, which is an extended body of water, is the primary driver of the tropical atmospheric circulation and is well observed (by buoys, ships and satellites). The air-sea interaction at the tropical Pacific is described by several different physical mechanisms and scales of variability: for example the Warm Pool vs. the Niño3 region, the ENSO variability and the Madden-Julian Oscillation. Here, we compare the magnitude and variability of latent heat flux, wind and humidity in the Tropical Pacific from satellite derived datasets and in situ observations and investigate the fidelity of climate models with respect to evaporative fluxes in the Tropical Pacific.

Current measurements in rivers from space by along-track interferometry

The along-track interferometric synthetic aperture radar (along-track InSAR) technique permits a high-resolution imaging of surface current fields from aircraft or satellites. Results from the Shuttle Radar Topography Mission (SRTM) and theoretical findings indicate that spaceborne along-track InSARs are suitable for current measurements in rivers if the water surface is at least 200-300 m wide and sufficiently rough for microwave backscattering at slanting incidence. The German satellite TerraSAR-X, which was launched in June 2007, will be the first to offer along-track InSAR capabilities during some longer period in an experimental mode of operation. In this presentation we give an overview of basic principles, SRTM results, and predicted current measuring capabilities of TerraSAR-X. SRTM-derived currents in the lower Elbe river (Germany) are shown to agree well with numerical hydrodynamic model results. Simulation results for TerraSAR-X indicate an even better data quality. Depending on width, surface roughness, and relative flow direction of a river, current estimates with an accuracy better than 0.1 m/s will be possible with an effective spatial resolution of a few hundred meters to kilometers.

Interaction between diazotrophic bacteria and mangrove roots under different nutrient conditions

The ecological interaction between diazotrophs and mangrove roots was studied in a peat-based sediment located in Belize. A long-term fertilization experiment was established in 1998. Trees are fertilized at six-month intervals with phosphorus and nitrogen. Diazotrophy was measured by the acetylene reduction technique and compared with roots distribution in the sediments. The molecular diversity and community structure of diazotrophs in bulk sediment vs. rhizosphere (area directly around the roots) at different nutrient conditions was analyzed by PCR amplification of nifH sequences and TRFLP. We found that N2 fixation rates range from 0.2 to up to 34 nmol ethylene/dry wt/h with a significant difference among nutrient treatments and sediment depth. Undenitrified and N-fertilized sediments have lower rates that vary with root distribution. However, biological nitrogenase-like sequences have higher N2 fixation rates regardless of root distribution. Preliminary results of the nifH-TRFLP fingerprints showed that only ~20% of operational taxonomic units observed in the rhizosphere are found in bulk sediment indicating a distinct diazotrophic community associated with the mangrove roots.

Airborne observations of wind-wave spectra in the Gulf of Tehuantepec

We present the analysis of airborne observations of surface waves collected during the Gulf of Tehuantepec Experiment (GOTEX) in 2004. This study is concerned with the evolution of the directional wave number spectrum in fetch-limited conditions. The directional spectrum is characterized through spectral properties (i.e., significant wave height and peak wave number), projections and moments. The main features of the observed spectrum, which highlight the approximate self-similar nature of the wave field, are used in formulating a parameterization of the directional wave number spectrum in the 2D wave plane which depends on the effective fetch and wind stress. The parameterization of the directional distribution in the Cartesian plane reproduces the main properties of the measured spectrum, and is simpler than the polar parameterization of Hwang et al. (2000) by a Fourier series. Our results are discussed in the context of previous observational and theoretical studies.

How does Changjiang River Plume spread in East China Sea and Yellow Sea?
The fresh water plume discharging from the Chiangjiang River estuary takes two dramatically different paths: the East China Sea between the summer and winter seasons. A 3D hydrodynamic model based on Regional Ocean Modeling System (ROMS) is developed to better understand the physical mechanisms responsible for the movement and spreading of the fresh water plume in the East China Sea and Yellow Sea (ECYS). ECYS is dominated by upwelling favorable wind in summer and stronger downwelling favorable wind in winter. Taiwan Warm Current flows northward throughout the year but is stronger in summer, carrying warmer and saltier water originated from Taiwan Strait and the Kuroshio branching. During the summer, the prevailing southerly wind together with Taiwan Warm Current pushes the plume in a north-east direction toward the Korean Peninsula. In contrast, the strong northerly wind in winter forces the plume to move south along the Chinese coast. We conduct a series of numerical experiments to illustrate how river runoff, monsoon winds, the large-scale currents and tides affect the dispersion of the fresh water plume and mixing with the shelf water in the ECYS.

CORAL COMMUNITY CHANGE ALONG A SEDIMENT GRADIENT IN FOUHA BAY, GUAM, MICRONESIA

Alterations within Pacific Island watersheds have led to the degradation of coastal coral reefs and an accompanying loss of ecological, cultural and economic resources. This study from Fouha Bay, Guam, found a sediment output of approximately 2,515 tons/year, yielding 303 tons/km2/year from the adjacent watershed (La Sa Fuu), with rates ranging from 235 mg/cm2/day at the river mouth to 10 mg/cm2/day at the channel mouth. A model derived from this study, 31% of sediments collected in the sediment traps placed in the inner part of the bay and 15% in the outer part were attributable to resuspension of previously deposited material. The model calculating distance over which sediment deposition (50 mg/cm2/day) reversely affect corals was done at 86 m offshore. This finding was consistent with the Moving Window Analysis results, which indicated a transition of 100 m in to more a diverse coral community. The data generated from this study were used to guide the adjacent community of stakeholders on ways they could apply science to policy development and implementation for the protection of their reef resources.

TSUNAMI RUNUP IN HAWAII: THE DESCRIPTION AND RECURRENCE OF EXTREME EVENTS

Hawaii's tsunami runup hazard is described using information from published sources, the National Geophysical Data Center's (NGDC) Global Tsunami Database, and Honolulu's tide gauge. A general description of tsunami source regions, exposure, and historical runup heights on Oahu is presented first. Far-field, near-field, and mega-tsunami sources are considered. The methods section presents the NGDC tsunami runup observations with a series of charts separating runup observations by island coastlines and discusses variability as a function of source region, earthquake magnitude, and exposure. Local topographic focusing and sheltering is evaluated using published tsunami refraction maps. Population increases within Oahu's coastal regions have amplified the need for a probabilistic assessment of expected maximum runup of future events. Runup measurements from far-field source regions were extracted from NGDC for Honolulu and Waialua. Extremal statistics yielded runup recurrence intervals and associated risk for the two locations. Adding 100-year sea level rise scenarios published by the Intergovernmental Panel on Climate Change (IPCC) to the runup significantly decreases the return period of given tsunami runup values at Honolulu and Waialua and greatly increases possible future risk.

THREE DIMENSIONAL HYDRODYNAMIC AND EUTRIFICATION MODEL SET-UP FOR THE MOSQUITO LAGOON, FL

The Mosquito Lagoon (ML) is a sub-basin of the Indian River Lagoon (IRL) on the East Central Florida coast, ~54 km long and ~4 km wide with depths averaging 1.5 m. Tidal fluctuation varies less than 15 cm seasonally and circulation is wind dominated. The tide entering ML from its sole inlet (Ponce De León Inlet) is of limited reach and ML’s configuration makes it especially sensitive to sudden influxes of pollutants from increasing human activities within its watershed. Previous studies have indicated the overall health of this system is declining. Implementation of a coupled hydrodynamic-eutrophication model (EFDC/HM3D) of the entire ML will aid in establishing the current state of the ML and system is declining. Implementation of a coupled hydrodynamic-eutrophication model is of limited reach and ML’s configuration is declining. Implementation of a coupled hydrodynamic-eutrophication model (EFDC/HM3D) to the runup significantly decreases the return period of given tsunami runup values at Honolulu and Waialua and greatly increases possible future risk.

PATTERNS OF ANTIBIOTIC RESISTANCE IN NORTHEASTERN COASTAL VERTEBRATES

The prevalence of antibiotic-resistant bacteria in the marine environment is a significant human health concern, but the degree to which marine mammals, seabirds and sharks harbor these organisms is not well documented. This project sought to identify the patterns of antibiotic resistance in vertebrates from coastal waters of the northeastern United States. 152 bacteria were isolated from tissues and fecal material of 157 vertebrates. Bacteria of clinical interest comprised 50% of organisms isolated. 380 isolates were tested for resistance to a suite of 16 antibiotics. Sixty percent were resistant to at least one antibiotic, while 46% were resistant to multiple antibiotics. A multiple antibiotic resistance (MAR) index value greater than 0.2 was observed in 60% of the resistant pathogens, suggesting exposure of the animals to significantly contaminated sites. Groups of antibiotics with commonly co-occurring resistance were identified. Structuring of resistance patterns based on sample type (live/stripped/ bycaught) but not animal group (mammal/bird/shark) was observed. Antibiotic resistant bacteria were widespread in marine vertebrates, geographically and taxonomically, and illustrated a potential linkage between marine and human health.

THE ROLE OF FISH AND ULTRAVIOLET RADIATION IN STIMULATING ZOOPLANKTON MIGRATION

Previous research has demonstrated that fish and ultraviolet radiation (UV) both can elicit a behavioral response in freshwater zooplankton and stimulate deeper migration into the water column by day. However, experimental studies of UV-induced migration have been conducted in the absence of fish, and thus the relative importance of these two factors in diel vertical migration is not known. In June 2006 we conducted a factorial experiment (presence and absence of caged fish and UV) in 15 m deep mesocosms in transparent (1% diel vertical migration is not known. In June 2006 we conducted a factorial experiment (presence and absence of caged fish and UV) in 15 m deep mesocosms in transparent (1% UV-transparent mesocosms, with rates ranging from 235 mg/cm2/day at the river mouth to 10 mg/cm2/day at the channel mouth. Significant effect on the vertical distribution of Daphnia in the presence or absence of UV. The presence of fish and UV in controlling the depth distribution of Daphnia. Daphnia avoided the surface UV in transparent mesocosms, with the presence of fish had no significant effect on the vertical distribution of Daphnia in the presence or absence of UV. The relative importance of UV and fish as drivers of vertical migration is likely to be determined by the concentrations and chromophoric properties of dissolved organic matter and the consequent UV transparency of the water.

VARIABILITY OF TERRESTRIAL INPUTS TO THE WAIPOA CONTINENTAL SHELF: EVIDENCE FROM STABLE CARBON ISOTOPES AND C/N OVER RECENT AND HOLOCENE TIME SCALES

Stable carbon isotopes and C/N from box cores and giant piston cores are presented from the Waipaoa continental shelf, North Island, New Zealand, to characterize transitions in storm event signatures, erosion and climate changes pre and post Polynesian and European influences. Abrupt δ13C and C/N oscillations within discrete layers in box cores signify rapid changes in terrestrial input during recent wet and dry storm deposition. Previous authors report sediments from two shelf depocenters (north and south) have similar physical characteristics, however there is no δ13C overlap between these sites, and the northern depocenter has a much more terrestrial δ13C signature than the southern, highlighting different modes of modern transport to these locations. Giant piston cores retrieved aboard the R/V Marion Dufresne in February 2006 date to 18 ky bp and show variations in allochthonous and autochthonous carbon sources and Quantity, over longer time scales. shelf break, northern depocenter and slope cores have depleted δ13C signatures with depth, revealing the transition between lowstand (late Pleistocene) and modern highstand conditions.
Loss terms include macro- and micro-zooplankton grazing. Results from laboratory experiments and constrained with weekly measurements of chlorophyll a that show interannual variability. The primary production model was parameterized with estimates of photosynthesis vs irradiance response, mixed layer depth availability for krill larvae in the water column prior to winter. Our primary production model is aimed at better estimating biomass in winter sea ice and estimating food for krill larval development. In the austral fall, ice formation results in suspended algae cells in the water column being entrained into the shear layer that resembled an inverted rough boundary layer; however, wake production shifted from a balance between advection, drag and pressure gradient at the upstream end of the kelp forest to a balance between drag and pressure gradient for fully developed flow. Within the kelp array, some TKE was generated by shear production in a sub-canopy layer that resembled an inverted rough boundary layer; however, wake production shifted from a balance between advection, drag and pressure gradient at the upstream end of the kelp forest to a balance between drag and pressure gradient for fully developed flow. A MODELING EXPLORATION OF CONNECTION BETWEEN SEA SCALLOP POPULATION IN THE MIDDLE ATLANTIC BIGHT AND THE HURRICANE紐約

The interannual variability in the dispersion and settlement of the sea scallop larvae spawned on Georges Bank (GB) was explored using an individual-based scallop population dynamics model. The model consisted of four pelagic life stages (egg, trophophore, veliger and pediveliger) and three benthic life stages (juvenile, young adult and adult). The model results supported the findings from the scallop video survey made in recent years on GB and MAB.

The constraint of carbon export by iron supply to the subarctic Pacific is believed to have contributed to past global climate change. Quantifying iron inputs to these regions therefore is essential to our understanding of this ocean-atmospheric coupling. Each year, mesoscale (~100 km) eddies transport coastal waters to the open ocean. We measured dissolved iron in coastal waters, a 2007 Haida eddy off the Queen Charlotte Islands (Haida Gwaii), and oceanic waters. Our findings show that surface (-80 m) iron concentrations within the eddy were drawn down to oceanic levels, but concentrations in deeper waters remained tenfold higher than outside the eddy. Our calculations indicate that iron influx to the eastern subarctic Pacific surface region (~200 m) from this eddy is comparable to annual aerosol iron inputs. Considering that eddies form annually at 2 other locations, eddy transport may be a major iron source to this HNLC region. However, unlike aerosol inputs, eddy transport of iron likely would be less prevalent at low sea level stands during glacial times, offering a potential feedback mechanism for regulating global climate.

GLIDER-BASED OBSERVATIONS OF THE KUROSHIO

Beginning in April 2007, a fleet of 2-4 gliders has conducted continuous surveys of the Kuroshio offshore of the Philippines and Taiwan. The primary technical objective is to demonstrate the utility of a glider fleet for sampling strong boundary currents. Scientific objectives are to characterize the structure and evolution of the Kuroshio and its meso-scale field. Glider transects of the surface to 1000 m in roughly six-hour intervals traveling 6 km through the water, traversing approximately 2000 km over the course of a 3-4 month deployment. Observed variables include pressure, temperature, salinity, depth-averaged velocity, dissolved oxygen, and optical properties. A salinity maximum is observed at 100-200 m, strongest in the region of the northward flowing Kuroshio. Low salinity intermediates have structure on roughly 50 km horizontal scales. Consecutive sections, occupied weeks apart, show the evolution of salinity anomalies in this intermediate layer. Northward velocity is more variable, with shorter horizontal scales, than is eastward velocity. The observations are ongoing, and by March 2008, 9 months of continuous coverage should be achieved.

The input of fresh water to the Gulf of Maine sets up a coastally trapped, buoyancy-driven Gulf of Maine coastal current response due to seasonal freshwater discharge and variable sea level. The Gulf of Maine coastal current is characterized by a surface jet that extends from the mouth of the Penobscot Bay to the Cape Cod Canal. The current is strongest during years with high freshwater discharge, and it is weaker during years with low freshwater discharge due to the northward advection of the North Atlantic Current (NAC) through the Cape Cod Canal.

IS MONA PASSAGE A BIOGEOGRAPHIC BARRIER? A HYDROCORTALS PERSPECTIVE
The Mona Passage, between the islands of Puerto Rico and La Hispaniola, has been proposed as a biogeographic barrier limiting the dispersal of marine organisms between the Eastern and Western Caribbean. The aim of this work is to explore the former hypothesis by studying the populations connectivity of an important, but underestimated component of the Caribbean reef; the hydromedusa Millopora alcicornis. Samples of Millopora alcicornis were collected from the island of Mona and the southwest coast of Puerto Rico. A DNA segment of the COI was amplified from each specimen. Sequence analysis of 120 colonies resulted in a total of 50 haplotypes, of 8 them shared between the locations. AMOVA analyses revealed that the within-population component of variability was significantly larger than the among-population component, implying the absence of populations structure. Fst neutrality test indicated an excess of rare mutations in specimen from Mona (P = 0.006) suggesting a population expansion. These preliminary results suggest that the Mona Passage is not an effective barrier for the dispersion of M. alcicornis.

POPULATION DYNAMICS OF CALANUS FINMARCHICUS IN RELATION TO TROPHIC TRANSFER IN THE WESTERN GULF OF MEXICO: THE ROLE OF STORAGE LIPIDS
While its centers of abundance rest in the deep, central basins of the Gulf of Mexico, C. finmarchicus is also abundant and dominant in the megafaunal communities of the coastal shelf and ledges. We present data acquired from the Northeast Consortium PULSE and UNH Coastal Observing Center time series fixed stations showing life cycle and interannual patterns of abundance in the western Gulf, notably the dramatic decline of C. finmarchicus between 2003 and 2005 on Jeffery’s Ledge. We apply recent understanding of control of C. finmarchicus dormancy to develop a hypothesis for the role of climate-forced, bottom-up processes in determining zooplankton lipid levels in the Gulf of Mexico. Availability of storage lipids in late stage Calanus may be an important factor controlling distribution and nutritional condition of herring and tuna around Jeffery’s Ledge during summer.

PHOTOBIOCHEMICAL PRODUCTION OF HYDROGEN PEROXIDE AND SUPEROXIDE BY PHAEOCYSTIS ANTARCTICA IN RESPONSE TO IRON LIMITATION
We report studies of the extracellular concentrations of hydrogen peroxide and superoxide in cultures of Phaeocystis antarctica, a marine Prymnesiophyte phytoplankter, treated with various phosphorus inhibition and exposed to different iron regimes. Concentrations of hydrogen peroxide and superoxide were determined using flow injection analysis techniques involving chelominescence of acridinium ester and methyl cyridina luciferin analogue (MCLA) reagents. The results suggest that the photobiocchemical production of reactive oxygen species (ROS) is influenced by iron bioavailability, and that hydrogen peroxide, and its immediate precursor superoxide, are produced as a result of inefficient electron transfer reactions in the photosynthetic apparatus. The results establish that ROS can be produced in seawater by phytoplankton as a result of inefficient photosynthetic electron transport processes, which can be induced by iron-limitation. The ROS produced in this manner may make some forms of iron more available to the phytoplankton.

HIGH RESOLUTION BOTTOM BOUNDARY LAYER MEASUREMENTS, BED STRESS AND SUSPENDED SEDIMENT MEASUREMENTS
Suspended sediment and sediment transport are two important processes to understand for water quality and shoreline management. In lakes and reservoirs multiple physical processes contribute to sediment resuspension and transport, including boundary turbulence, breaking and non-breaking internal waves, wind generated waves and tributary inputs. Mixing near boundaries caused by bottom boundary layer turbulence and internal waves is examined using high resolution (1.5 cm depth cell size) pulse coherent Doppler profilers. Multiple acoustic velocimeters are used for comparison to the profiler data estimates of turbulence levels and bed stress. Profilers provide the unique look at the boundary layer structure as it undergoes accelerations related to changes in discharge, barotopic and baroclinic forcing. By fitting a modified boundary layer model, bed stress estimates can be directly calculated from the data. Coupled acoustic and optical backscatter measurements provide details regarding sediment load and turbidity and identify under which conditions sediment is resuspended or advected through the sampling volume.

210Pb-DERIVED AGES FOR THE RECONSTRUCTION OF TERRESTRIAL CONTINENTAL HISTORY INTO THE MEXICAN PACIFIC COAST: POTENTIAL AND LIMITATIONS
Alteration of the natural landscape, due to urban development, road construction and agricultural practices resulted in increasing deliveries of land derived sediment and pollutants into coastal waters along the coastal states of Sinaloa and Oaxaca (Mexico). Isotopic proxies such as δ¹⁸O, δ²¹⁰Pb, trace metals and nutrients data, as well as ²¹⁰Pb-derived geo-chronologies from shallow marine sedimentary records have been used to reconstruct the history and rates of the resulting environmental changes and potential contamination of coastal ecosystems. From a few examples of ²¹⁰Pb profiles in estuaries and marine sediments from the area, we intend to discuss in particular the difficulty of obtaining reliable sedimentary records in such active and complex settings. Conditions for obtaining additional information from other short-lived natural isotopes (e.g. ³⁷Csl) are also briefly examined. Whereas coastal sediments may generally be seen as a sink for most contaminants, some of the records from the study area illustrate situations where post-depositional re-suspension likely due to extreme climate events may lead to a potential remobilization of contaminants.
PROJECTED CHANGES IN ANTARCTIC SEA ICE IN THE AR4 CLIMATE MODELS: IMPLICATIONS FOR ADELIE AND EMPEROR PENGUIN HABITATS

Using observations of Adélie and Emperor penguins and their needs for nesting and food as guidelines, we examine how the IPCC-AR4 coupled climate models predict that their habitat will be altered under global warming scenarios. Russell et al. (2006) compared 18 of the coupled climate models included in the latest IPCC report on the basis of how well they simulated the Southern Ocean circulation. That study used the strength of the Antarctic Circumpolar Current as a proxy for the overall health of the model simulation. In that analysis the most important factor to determining the quality of the ACC simulation was the strength and position of the Southern Hemisphere westerly winds. In this comprehensive analysis, we will address which of the AR4 climate model simulations of the Southern Ocean best represent the distribution and seasonality of sea ice, what changes are projected in the ocean circulation, sea ice extent seasonality and thickness around Antarctica under global warming conditions and what are the implications for ice-obligate species of penguins, like the Adélie and Emperor.

LANDSCAPE INDICATORS OF WATERSHED IMPAIRMENT - NUTRIENTS

Complex interactions between anthropogenic activities in watershed landscapes and biological and chemical impairment require that appropriate indicators of watershed impairment be developed. We use refined nutrient budgets and their relationships to nitrogen and phosphorus discharges to develop a classification system for estimating the level of watershed impairment from landscape characteristics. We then apply this classification system to National Hydrography Dataset Plus (NHD+) watersheds in the Chesapeake Bay drainage. Preliminary classification attempts explain between 20 and 70 percent of the variability in nutrient discharges depending on nutrient and physiographic province. Our classification system uses a small set of easily attainable landscape characteristics and nutrient budgets. We will combine this nutrient impairment classification system with one for biological and hydrological impairment to obtain an overall classification of watershed impairment using landscape indicators.

MEASURING SUSPENDED SEDIMENT CONCENTRATION USING HIGH RESOLUTION CURRENT METERS

Acoustic sensors measuring currents in high resolution have been around since the 90s. Recently researchers have started using them to provide information on suspended sediment load. Acoustical devices tend to be less prone to bio-fouling compared to electrical devices and the combination with high frequency velocity measurements allows for a direct estimate of turbulence fluxes of particulate material (e.g. Fugate and Friedrich, 2002). Here we present results of a careful lab evaluation of three such sensors; Two acoustic Doppler Velometers providing acoustic backscattering at two different frequencies (16MHz and 6MHz) and a Modcular Acoustic Velocity Sensor providing acoustic attenuation at 1.5MHz. We assess the concentration over which we get a linear response and compare measurements of beads of different sizes with the expected theoretical response. Field data is also presented to showcase the performance of this technology in comparison with tried and true optical sensors.

SCALES AND PROCESSES OF PHYTOPLANKTON THIN LAYER PATCHINESS IN A COASTAL UPWELLING SYSTEM, FROM SYNOPTIC MULTIDISCIPLINARY MAPPING BY AUV

Using synoptic multidisciplinary mapping we describe phytoplankton thin layer patchiness in the highly dynamic coastal waters of Monterey Bay, California. Intensive observations were conducted in Monterey Bay during 2005 and 2006 as part of the ONR program Layered Organization in the Coastal Ocean (LOCO). High-resolution mapping by the MBARI AUV Dorado was conducted over nearly 1000 km of survey track within the bay, providing detailed observations of variability in thin phytoplankton assemblages and their environment. The relatively high speed of this AUV permits synoptic mapping, and its diverse sensor payload permits description of physical, nutrient, and optical properties. Horizontal scales of thin layer patches, ranging from sub-km to >10 km, are described using optical backscatter and chlorophyll fluorescence sections. These scales are related to meso and small-scale dynamics described by physical and nutrient sensors. Measurements of the particle size distribution reveal higher degrees of patchiness within thin layer structures characterized as contiguous in optical backscatter and chlorophyll fluorescence. This variability is related to biological and physical processes evident in the time-series of AUV-derived maps.

FROM PHYSICS TO FISH: INFLUENCE OF OCEAN WINDS ON THE PELAGIC ECOSYSTEM IN EUPHEMISING REGIONS

Upwelling of nutrient-rich, subsurface water sustains high productivity in the ocean’s eastern boundary currents. Environmental variability is considered the major cause of decadal fluctuations characteristic of fish populations in these regions, but the mechanisms relating atmospheric physics to fish production remain unexplained. Two atmospheric conditions influence different types of coastal upwelling: alongshore wind stress, resulting in rapid upwelling (higher vertical velocity, w); and wind-stress curl resulting in slower upwelling (low w). We present a mechanism relating production of Pacific sardine (Sardinops sagax) in the California Current Ecosystem (CCE) with wind-stress curl over the past six decades. Records of density, nutrient depth, and chlorophyll concentration in the upper ocean suggest that this is supportive of this mechanism. The size structure of plankton assemblages is related to the rate of wind-forced upwelling, and sardine feed efficiently on smaller plankters generated by slow, curl-driven upwelling. Since the 1970s, wind-stress curl has been responsible for nearly 80% of annual, wind-forced upwelling in the southern CCE. Prior to the 1970s, coastal, alongshore wind stress played a more important role than curl in ecosystem variability.

IMRINGER CURRENT ANTICYCLONES IN THE LABRADOR SEA OBSERVED IN THE HYDROGRAPHIC RECORD OF 1990-2004

A significant fraction of the lateral heat transport into the Labrador Sea’s interior, needed to balance the net heat loss to the atmosphere, is attributed to one kind of eddies, the Imringer Current anticyclones. In this study we discuss the evolution of these anticyclones as inferred from the analysis of hydrographic data from the Labrador Sea from 1990 to 2004. The 29 anticyclones identified naturally fall into two categories: unconvected and convected. The properties of the unconvected anticyclones are closer to those of the boundary current, including a fresh (and sometimes cold) surface layer. They are never observed in winter and are located near the boundaries. The convected anticyclones, on the other hand, are characterized by a mixed layer and are found throughout the year. A one-dimensional mixed layer model suggests that the convective eddies are formed during wintertime cooling acting over an unconvected eddy. This result has important implications regarding the release of the eddies’ heat and freshwater anomaly. Finally, we find a clear trend in the eddies’ properties towards warmer and saltier conditions after 1997.

NUTRIENT-DRIVEN SELECTION AND GENETIC CONNECTIVITY OF COASTAL AND ESTUARINE DIATOM POPULATIONS

The timing, location and magnitude of diatom blooms in coastal and estuarine regions are difficult to predict based solely on environmental parameters. In the diatom Ditylum brightwellii, genetically distinct populations can have different physiological characteristics indicating that both environment and genetics can regulate bloom dynamics. Here, I examine how previously-identified estuarine populations of D. brightwellii are connected to coastal populations using microsatellites, high resolution genetic markers. In the spring of 2007, 335 single-cell isolates were collected along a 1300 km transect from the estuarine waters of Puget Sound, WA to the coastal waters of Southeastern AK. The transect was sampled twice over one month to examine spatial and temporal patterns of population structure. At least two genetically distinct populations were identified that bloomed under significantly different exposure to solar irradiance and silicate acid concentrations, suggesting that environmental selection may regulate bloom dynamics of distinct populations. By simultaneously examining the relative impacts of nutrient-driven natural selection and connectivity between estuarine and coastal populations, this research is beginning to unravel how interactions between environmental conditions and genetic variation drive diatom population dynamics.

DISSOLVING OF AEROSOL IRON IN SEAWATER USING FLOW INJECTION CHELUMINESCENCE DETECTION

The bioavailability of iron limits primary production, influences phytoplankton community structures in the ocean and therefore indirectly impacts climate change. However, the solubility of aerosol Fe from dry atmospheric deposition into seawater is poorly understood and varies according to the approach used to quantify its dissolution. To better understand the dissolution of aerosol iron, an array of chemical (i.e. aerosol sources, model siderophores additions) and physical (i.e. light conditions, temperature, aerosol concentrations) variables were investigated under controlled conditions using an automated sampler and flow injection analysers. The kinetics of the dissolution of dissolved iron
from urban aerosol were determined in filtered (0.2 μm) North Atlantic surface seawater. From initial studies, iron dissolution from Plymouth Urban Particulate Material (PUPM) and NIST 1648 (dark/25°C/2mlg−1) in surface seawater showed a fast release of dissolved iron (up to 0.45 % solubility) with the maximum dissolved iron concentration occurring within the first two hours followed by a decrease, reaching pseudo-equilibrium after 7 days (down to 0.06 %). Further studies defining the impact of physical and chemical factors on the dissolution of Fe will be presented.

GRAZING AND NUTRIENT RELEASE FROM ACARTIA TONSA COEPODES FEEDING ON TOXIC PRODUCING KARLODINIUM VENIFICUM: INTERACTIONS OF TOP-DOWN AND BOTTOM-UP CONTROL

The karlotoxin-producing dinoflagellate, Karlodinium venificum, is increasing in concentration and range in Chesapeake Bay. However, it is unknown if these toxins affect zooplankton grazer metabolism, such as nutrient regeneration – a potentially significant source of fuel for these harmful algal blooms. Using both non-bloom and bloom concentrations of K. venificum, we conducted a grazer nutrient release experiment with Acartia tonsa coeopodes, plus a 7-day bioassay in which A. tonsa excretia products were added to K. venificum culture. Copepods exhibited 40 times higher ingestion rates while feeding on bloom concentrations (205 μg Chl a/individual/day) compared to non-bloom concentrations, yet release rates were lower by 30% for DOC and 50% for NH₄⁺. Organic nitrogen release was too low to unambiguously evaluate in both treatments. During the bioassay, Chl a remained higher, and a larger drawdown of nutrients occurred in copepod excretia additions relative to controls. These results suggest that while copepods have the potential to effectively graze on and provide nutrients for K. venificum, nutrient release may be compromised by the toxin, leaving less bioavailable nutrients for phytoplankton and bacteria.

ESTIMATING OCEANIC PRIMARY PRODUCTIVITY: AN EVALUATION OF OCEAN COLOR ALGORITHMS AND GENERAL CIRCULATION MODELS

Modeling oceanic primary productivity (PP) is crucial for biogeochemical studies, especially in order to better understand the carbon cycle on a global scale. We have expanded the PP Algorithm Round-Robin (PPARR) project into its fourth exercise by quantifying the skill of ~20 models (including both ocean color algorithms and biogeochemical general circulation models) in reproducing in situ PP data from various regions across the globe. Taylor diagrams, cumulative distribution functions and other statistical approaches were used to compare model performance in both open-ocean and coastal regions. Estimates of PP in the Sargasso Sea show that ocean color-based model skill was most sensitive to surface chlorophyll concentration followed by sea surface temperature and mixed layer depth. In the equatorial Pacific, skill in estimating PP was most sensitive to surface nitrogen inflow but was correlated with diatoms. However, model performance was not sufficiently high to support new biological oceanographic studies.

WAVELETS

A wavelet-based method has been developed to automatically detect and characterize layered structure in oceanographic data from various autonomous sampling platforms including the Dorado AUV (Monterey Bay, 2003-present), Seagliders (Washington coast, 2002-present), and Slocum gliders (Gulf of Maine, June-July 2006). Depth profiles of fluorescence, optical backscattering, particle size distribution, and beam attenuation have been processed to derive objective estimates of peak width(s), intensity(ies), and depth(s). Additional metrics, related to more subtle characteristics of peak shape, have also been developed. Initial results from the wavelet-based processing are encouraging and are consistent with human-assisted characterizations of layered structure in the datasets we have evaluated. By discerning continuous depth profiles into separate features of interest (i.e., layers), we can compactly represent and query the important information contained in these large multi-parameter datasets and determine how the distribution of layers relates to physical, ecological, and biogeochemical processes in the ocean. This representation of the data facilitates its incorporation into existing geographic information systems, whose foundation is based upon the analysis of geographically discriminated features such as points, lines, and polygons.

RELATIONSHIPS BETWEEN BENTHIC ORGANIC CARBON FLUX, OXYGEN PENETRATION, AND PLANKTON PROVINCES IN THE SOUTHERN OCEAN

Based on the comparison between benthic oxygen fluxes derived from oxygen microprofiles measured at sediment cores (ex situ) and by means of free fallinglander systems (in situ), a correction function was set up that was applied on existing ex situ flux data in order to revise the database for the Southern Ocean. Organic carbon fluxes range from 0.5 to ~3.5 mgC m⁻² d⁻¹. Oxygen microprofiles were measured at 134 sites in different sub-regions mainly of the Atlantic Sector of the Southern Ocean. Oxygen penetration depths and benthic organic carbon fluxes were derived from the profiles and investigated in respect to regional characteristics. In the Scotia Sea (~3000 m water depth) oxygen penetration depths of less than 15 cm were observed in deep-sea sediments. In contrast, the oxic zone extends to several decimetres in abyssal sediments of the Weddell Sea and south-eastern South Atlantic. The depth of oxygenation reflecting sedimentary long term organic matter influx was found to be correlated with diatom key species characterizing different regions of the surface ocean. From the partly very high fluxes derived from micro sensor data it can be concluded that episodic and seasonal sedimentation pulses are important for carbon supply to the sea floor even at great depths.

WE A NEW MODEL OF ANTARCTIC SEA ICE ALGAL PRODUCTION: A TIMESERIES FROM 1997-2003

We constructed a coupled physical-biological model describing Antarctic sea ice dynamics and associated ice algal production. Using satellite-derived ice cover, snow depth, and ice advection, as well as climatological light and atmospheric forcing, the model grows and melts sea ice using a multi-layer approach to create a reasonably realistic sea ice environment. Internal ice conditions (e.g., temperature, nutrients, and salinity) and a multi-spectral optical model of light attenuation are used to characterize the algal growth environment in discrete model layers. The model domain covers a portion of the south-eastern South Atlantic. The depth of oxygenation reflecting sedimentary long term organic matter influx was found to be correlated with diatom key species characterizing different regions of the surface ocean. From the partly very high fluxes derived from micro sensor data it can be concluded that episodic and seasonal sedimentation pulses are important for carbon supply to the sea floor even at great depths.
Measurements of flow velocity at 2 Hz sampling rate at high spatial resolution together with suspended sediment concentration, temperature, salinity and dilute suspension flocc size in about 5 m depth on the muddy shelf fronting the Atacbfalaya Bank (Iaramillo et al. 2007 - Proceedings of ‘Coastal Sediments 2007’ V1, 661-670) allow to observe coupled wave-current-sediment dynamics and to estimate the characteristics of sediment and its effects on wave-current turbulence. A boundary layer model for fine sediment transport (Hu et al. 2007 - J. Geophys. Res. 112, C02011) is used to reconstruct near bed suspended sediment concentration and simulate its effects on the velocity field. This effort is made in preparation of a series of field experiments to be conducted in early spring, 2008 on the Atacbfalaya Bank to study the vertical structure of waves and turbulence in the presence of fluid mud layers. The experiments will employ coherent vertical and horizontal arrays of Acoustic Doppler Velocimeters sampling the velocity field at 20 Hz to separate the effects of waves and turbulence (Feddersen and Williams, 2007, J. Atmos. and Oceanic Technol., 24, 102-116).

ROLES OF ECOSYSTEM COMPONENTS FOR BIOGEOCHEMICAL CYCLING IN THE HNLC SUBARCTIC PACIFIC: IMPORTANCE OF TOP-DOWN CONTROL

Ecosystem responses were quite different between SEEDS-I and SEEDS-II, a series of iron-enrichment experiments in the HNLC subarctic Pacific. During SEEDS-I, diatoms Chaetoceros debilis responded to the iron-enrichment, consumed nitrate and silicic acid and formed an extensive bloom (Chla = 20 mg m$^{-3}$). Heterotrophic dinoflagellate Gymnodinium sp. responded to the diatom increase and prevented further development of the bloom. The model experiment showed most diatoms were grazed by Gymnodinium sp. and the nitrate and silicic acid were remineralized surface mixed layer after experiment. During SEEDS-II, diatom fraction in phytoplankton assemblage decreased, and silicic acid consumption was not accelerated. The weak response of diatoms was due to the grazing of copepod Calanus plumchrus which consumed most of new production and transported carbon and nitrogen to the deep by their ontogenetic vertical migration. In spite of large difference in the bloom magnitude, the nitrate consumption was similar each other, and the nitrogen flux was larger during SEEDS-II than SEEDS-I. Biogeochemical responses to perturbations are largely influenced by ecosystem components, and top-down control is a key factor of the biogeochemical cycling in the HNLC subarctic Pacific.

SPATIAL AND TEMPORAL VARIABILITY OF LOW LEVEL NITRATE, NITRITE, AND AMMONIA DISTRIBUTIONS FROM A COASTAL UPWELLING ZONE TO OILGOTRICHOTIC WATERS

Nitrigen inputs from recycling, nitrogen fixation, atmospheric deposition, vertical and lateral advection (filaments and eddies) provide the basis for oceanic primary productivity. These nitrogen compounds come from different sources and are found in different forms due to microbial activity via processes such as nitrogen fixation, remineralization, nitrification, and denitrification. A transect from Monterey Bay, California to an oligotrophic station approximately 800 km offshore in the California Current was done in July 2007. Nitrate profiles were measured with an In Situ Ultraviolet Spectrophotometer (ISS) instrument mounted on a CTD rosette. These measurements were made with a vertical resolution of 0.8 m and an estimated detection limit of 0.2 µM. In addition, discrete samples were measured shipboard using a 1 m (nitrite) or 2 m (nitrate and ammonia) path length flow cell. These low level nitrate, nitrite, and ammonia measurements had detection limits of about 4 nM, 2 nM, and 15 nM, respectively. The spatial variability of these nutrients along this transect will be presented along with 24 hour time series stations that examined temporal variability.

sensing, characterization of endmember variability is important on at least two fronts. First, efforts to retrieve salinity via satellite if absorbance is considered as the slope of the salinity-fluorescence relationship changes. Second, with a combined understanding of the zero salinity fluorescence variability and fluorescence-to-DOC relationships, it may be possible to diagnose sources and sinks of terrestrial DOC within river plumes using circulation models and ocean color data.

EDDY HEAT DIFFUSION AND SUBANTARCTIC MODE WATER FORMATION

Subantarctic mode waters (SAMW) form in the deep winter mixed layers occurring north of the Subantarctic Front (SAF). The recent increase of hydrogenic and surface drifter data in the Southern Ocean allows a better spatial representation of the distinct regions of SAMW formation. This study focuses on the thermodynamical processes acting on the winter mixed layer heat budget. Eddy heat diffusion play a substantial role in the local heat balance, whereas its action vanishes with large-scale averaging. South of the western boundary currents and north of the SAF, the eddy heating plays an important role in specific regions, counterbalancing the cooling of the mixed layer by Ekman advection and air-sea fluxes. Specifically, the eddy diffusion term reduces the tendency for mixed layer destabilisation north of the SAF in the Western Indian Ocean downstream of the Agulhas Retroflection and in the Western Pacific downstream of Campbell Plateau. This role for mixed layer eddy fluxes emphasizes a large-scale control of mixed layer properties by topography and mesoscale processes in the Southern Ocean.

CONTINUOUS BARRIER ISLAND DETERIORATION FOLLOWING HURRICANE KATRINA

During Hurricane Katrina, the Chandeleur Islands in eastern Louisiana lost 85% of their surface area. The average shoreline retreat along the island chain was 286 m, likely the largest retreat ever reported for a storm. All of the visible sand on the islands was stripped off, reducing peak elevations from >6m to <3m, leaving only marsh fragments in the storm’s wake. In the 12 months following the hurricane, the islands continued to erode rapidly, in some places greater than an additional 200 m of landward retreat. At this time, the islands were composed mostly of mud that was bound by the roots of marsh grasses, and barriers were vulnerable to extreme erosion by relatively small waves. In fact, 58% of the length of the island chain experienced net erosion during the one year following Katrina. The remainder of the shoreline length underwent accretion of sand that built the shoreline seaward as is usually observed on sandy beaches following a storm. However, by the end of the 12 months following Katrina, the elevations of the islands had not increased appreciably. The consequence of this erosion was that the islands remained vulnerable to complete inundation during future storms, even those significantly less intense than Katrina. The talk will include results from a recently completed lidar survey that will allow these analyses to be extended to 24 months following Katrina, and will further define the extent that the Chandeleur Islands have been pushed towards complete failure.

PARASITE INFECTION OF PLANKTONIC DINOFLAGELLATES IN A COASTAL TROPICAL AREA OF THE SOUTHERN ATLANTIC

Infection of planktonic dinoflagellates by the parasitic protist Amoebophrya sp. was studied during the decline of a late-summer dinoflagellate assemblage in the Cabo Frio upwelling area, Southeastern Brazil (23°0’20”S, 42°0’40”W). The microplankton community was initially dominated by dinoflagellates, mostly Ceratium falciforme, with cell densities up to 6 x 10^4 cells^1, shifting to a diatom-dominated community over a 4-week period. Parasite infection was detected by epifluorescence microscopy after whole-cell in situ hybridization of FITC-tagged, rRNA probes designed towards Amoebophrya 18SrDNA sequences. Ceratium falciforme was the most infected dinoflagellate species, with high est percentages of infected cells (up to 6.7%) detected during and after the population hybirdization of FITC-tagged, rRNA probes designed towards Amoebophrya 18SrDNA.

DEEP-WATER CARBON AND DIATOM FLUXES FROM A NATURALLY IRON FERTILIZED PHYTOPLANKTON BLOOM IN THE POLAR FRONTAL ZONE OF THE SOUTHERN OCEAN

The CROZEx natural iron bloom and export experiment (CROZEX) examined the development and fate of a naturally occurring phytoplankton bloom in the vicinity of the Crozet Plateau in the Indian Sector of the Southern Ocean. Peak chlorophyll concentrations within the naturally iron-fertilised region north of the plateau were an order of magnitude higher than those in the high-nutrient low chlorophyll (HNLC) “control” region to the south. Deep (>2000m) sediment traps indicate that the annual fluxes of organic carbon were 0.82 ± 0.07 g C m^-2 yr^-1 in the north and south respectively. The four-fold increase in annual carbon flux is the first demonstration that the addition of iron to an otherwise HNLC system increases the export of carbon to the deep ocean. Fluxes were characterised by high biogenic silica content (35-80%), the diatom flux assemblage was dominated by Eucampia antarctica in the north and Fragilariopsis kerguelensis in the south. Molar ratios of Fe/C decreases have been calculated and are compared to previous artificial and natural fertilisation experiments. The results have important implications for glacial-interglacial CO2 cycling and iron fertilisation as a potential climate mitigation strategy.

NITROGEN AND CARBON PRODUCTIVITY IN THE RETREATING ICE REGION OF THE EASTERN BERING SEA DURING 2007

The eastern Bering Sea supports large standing stocks at every trophic level from plankton to fish, birds and marine mammals. Some of this productivity can be linked directly to the ice edge that historically develops there by March. Extensive sampling was done from an ice breaker in this region in April and May 2007 as this ice edge retreated. Incubation rate measurements for new (nitrate) and ammonium as well as for carbon (primary) productivity were done in on-deck incubations. The results document the importance of the ice edge in fostering intense productivity in the marginal melt ponds. Rates of carbon productivity were maintained above 2 g C m^-2 d^-1 and new productivity was maintained above 10 mmol nitrate m^-2 d^-1 across an extensive region of the outer shelf for several weeks. The nitrogen/Fe ratio was also high suggesting a large export of carbon to shelf sediments. The ice edge enhancement of productivity was much greater in the western, outer shelf edge of the ice than it was in the eastern, inshore region and suggests that factors in addition to surface stabilization were important to the spatial patterns. The patterns in plankton production corresponded closely to those of acoustically-mapped macro-fauna and suggest a biological system subject to extensive change to ice conditions.

SATELLITE-BASED ESTIMATES OF EDDY KINEMATICS

Fifteen years of sea-surface height fields constructed from the merged TOPEX, Poseidon, ERS-1, ERS-2, and Jason altimeter datasets are analyzed to investigate the kinematic properties of global ocean eddies. An objective eddy tracking algorithm is used to identify coherent features in the global data set. Geostrophic streamlines in a co-moving eddy frame are then constructed from the sea surface height observations associated with tracked eddies, and analyzed to obtain estimates of Lagrangian parcel motion induced by the eddy motions. Of particular interest is the extent to which propagating eddies repre- sented, translating cells of isolated fluid. The Lagrangian transport properties of the field of tracked eddies are computed, and the corresponding implications for nonlinearity of the eddy dynamics are considered.

LIGNIN-PHENOLS IN DENSITY FRACTIONS OF LOUISIANA CONTINENTAL MARGIN SEDIMENTS: RIVER TO CANYON TRANSPORT

Major rivers, and associated deltaic environments, provide the dominant pathway for the input of terrestrial particular organic matter (POC) to marine sediments, and play a disproportionately important role in transporting POC to the ocean. However, the dynamics of carbon cycling and transport in deltaic environments is complex and largely understood. In order to better understand the partitioning and transport of POC, we used lignin-phenols as biomarkers in different density-fractions of sediments across the LCM (Louisiana Continental Margin). We sampled stations in the river proper, adjacent shelf, and Mississippi Canyon (MC). Lignin concentrations and (Al/Alv) ratios were
significantly higher and lower, respectively, in the low density fractions. Low-density fractions showed a more angiosperm dominated leafy or grassy signature, compared to a more angiosperm woody signature in high-density fractions. High-density fractions were more degraded during transport to the MC. Density fractions were helpful in determining the relative importance of selective degradation and aggregation/locculation processes during cross-shelf transport. Most of the lignin degradation within the bulk sediment signature is largely from selective loss in the low-density fractions.

PHYSICAL MECHANISMS FOR SHELF RECRUITMENT OF CALANUS FINMARCHICUS OFF THE WEST COAST OF NORWAY

The shell population of the copepod Calanus finmarchicus along the coast of Norway is initialized each spring from over-wintering individuals from the Norwegian Sea. C. finmarchicus is an important food source for the larvae of the Norwegian Spring Spawning herring that result in improved coastal products capturing the finer scale coastal and estuarine processes. In order to produce higher resolution MODIS bio-optical properties, the 250m and 1000m land/atmosphere bands were coupled with the 1000m ocean bands to produce pseudo-250m ocean bands. We compare several atmospheric correction techniques applied to the MODIS imagery to determine the best method for removing the atmospheric effects in the imagery. The atmospherically corrected pseudo-250m reflectances are then used in bio-optical algorithms to produce higher resolution ocean color products. The higher resolution inherent optical products (IOPs) are compared to the atmospheric corrected reflectances to demonstrate that improved atmospheric correction and higher spatial resolution IOPs result in improved coastal products capturing the finer scale coastal and estuarine processes.

FUTURE DIRECTIONS IN OCEANS AND HUMAN HEALTH RESEARCH

The Oceans and Human Health Act of 2004 established an Interagency OHH Program and required preparation of a ten-year plan to define "the goals and priorities for Federal research which most effectively advance scientific understanding of the relationship between the oceans and human health."

SPORELLINE EROSION, SHORE PROTECTION, AND NEARSHORE SEDIMENT DYNAMICS IN CHERESAKE BAY

In many lakes and coastal plain estuaries, shoreline erosion is a significant contributor to the sediment budget and a leading cause of high nearshore turbidity. This is especially true where other sediment sources are relatively small and where shorelines are exposed to episodically high storm waves. Shore protection measures halt shoreline erosion locally, but it is not clear how they affect nearshore turbidity or sediment dynamics. We carried out nearshore monitoring in the pigalional proglacial Old Bay during the falls of 2002 and 2003 and the summers of 2006 and 2007 in two eastern shore tributaries of mid-Chesapeake Bay to examine these situations. Observations of waves, tidal height, currents, temperature, salinity, and turbidity were obtained with moored instruments and nearshore hydrographic surveys. These measurements were complemented by shoreline and bathymetric surveys and sediment sampling. The results show that nearshore turbidity and sediment dynamics are dominated by wave events in combination with water surface elevation. Turbidity levels quickly fall to a seasonally varying background level after the end of an event. Turbidity levels offshore unprotected shorelines and adjacent protected shorelines are similar due to rapid dispersion.

TIDAL CREEK ECOSYSTEMS: SENTINEL HABITATS FOR ASSESSING THE CONSEQUENCES OF RAPID DEVELOPMENT ON SOUTHEASTERN COASTS

Meandering shallow tidal creeks are a dominant feature of Southeastern estuaries and provide nursery grounds for many fish and crustaceans. The shores of these creeks are also preferred sites for human development. Research throughout the Southeast has found linkages between surrounding watershed land use (e.g., impervious cover) and the ecological condition (i.e., physical-chemical and biological conditions) of headwater tidal creeks. This habitat has served as a platform for testing the new technologies and methods, including genomic and pathogenic measures, being developed in association with the Hollings Marine Laboratory Oceans and Human Health Center of Excellence. This research has shown that these headwater creeks have the potential to serve as sentinel habitats and a reliable testing platform for assessing the impact of watershed development on ecosystem and public health; however, most estuarine monitoring programs do not sample these habitats. Headwater tidal creeks are the appropriate scale to assess the impacts of land use change in the watershed as well as providing appropriate scale for making land use decisions.

EFFECTS OF APPLIED VOLTAGES AND OXYGEN CONCENTRATIONS AT THE ANODE ON POWER OF A MICROBIAL FUEL CELL

Oxygen contamination of the anode chamber of an MFC could affect power generation in an MFC, and possibly the composition of the microbial community. Purging the anode chamber with air or pure oxygen for 16 hours, however, did not affect power genera-
tion. After the oxygen in the anode chamber was scavenged by aerobic bacteria, power sharply increased and returned to previous levels indicating no permanent damage in performance. When there were high concentrations of substrate in the anode chamber, the oxygen flux from the cathode chamber into the anode did not affect dissolved oxygen concentrations (DO). During operation of two MFCs in stack mode (in series), charge reversal occurred whereby one cell could charge the other cell. Applying a voltage of 2 V to a two-chambered MFC (the positive terminal of a power supply was connected to the anode) did not affect power generation. However, applying 3 V for 3 h resulted in a 15 h lag phase suggesting injury to the bacteria, but performance was restored when the applied voltage was removed with an external load of 1 kΩ.

ON THE ORIGIN AND IMPORTANCE OF SWESTIES

Pingree (Phil. Trans. Roy. Soc. A, 354, 1-45) first observed a SWESTY (Anticyclonic Shallow Subtropical Subducting Wetted Propagating Eddies) in the eastern North Atlantic. These are mesoscale long live eddies (nearby 3 years) whose source region is south of the Canary Archipelago. They propagate westward along 26º N at least until 50º W. A unique feature of the SWESTIES combining altitude, density and numerical modelling (ROMS and processes oriented models). Preliminary results suggest that SWESTIES may originate as consequence of the Canary Current perturbation by the Canary Archipelago. Anticyclonic eddies are shed all year long by the central islands, Gran Canaria and Tenerife, and during fall by the flow acceleration between the eastern islands (Fuerteventura and Lanzarote) and the African Coast. ROMS model results indicates that these eddies introduce strong variability (KE) along 26º N, comparable to that generated by the Azores frontal region. Therefore Anticyclonic eddies shed by the Canary Islands may be very important for the zonal transport and mixing of physical and biological properties along the Subtropical Gyre.

KILO NALU NEARSHORE REEF OBSERVATORY, OAHU, HAWAII

INTERDISCIPLINARY OBSERVATIONS OF PHYSICAL, GEOCHEMICAL AND BIOLOGICAL INTERACTIONS

The Kilo Nalu Observatory supplies data and power connections to a suite of instruments over an array of stations extending from 10 to 20 m water depth, enabling individual user-transparent access. The Kilo Nalu Observatory is designed to support biological, physical and oceanographic research in the coastal zone of Hawaii, specifically along the nearshore regions of Kualoa. The Observatory is a virtual laboratory that travel along the coast to the Gulf of Alaska often encounter eddies that frequent the Gulf of Alaska. They spend weeks foraging within these eddies, where they frequently dive to a depth of -500 m, several times a day. This yields a unique dataset of high frequency, long duration and deep temperature-depth profiles that can be used to examine the spatial and temporal evolution of the thermal structure of the eddies in the Gulf of Alaska. A comparison of the elephant seal dive patterns within and outside of eddies is used to understand how elephant seals utilize these “hot spots”.

THE EFFECTS OF TEMPERATURE ON SCYPHOMEDUSAN CHRYSOAORA QUINQUECIRRA SWIMMING AND MORTALITY

In the Chesapeake Bay, an abundant summer population of scyphomedusan Chrysaora quinquecirra annually crashes in the fall. The fate of this gelatinous biomass is not well understood, but field observations suggest that sea nettles descend out of the visible layer as temperature approaches the lower limit of their tolerance. We designed mesocosm experiments to evaluate the effects of temperature on the swimming ability and mortality of C. quinquecirra. Here, we summarize the challenges faced in keeping sea nettles in captivity and present preliminary results. Pulsatia rates of sea nettles in the mesocosms were comparable to in situ pulse rates for C. quinquecirra. These initial observations suggested that the swimming ability of C. quinquecirra was not interrupted as a result of capture or this artificial environment. An unexpectedly early disappearance of sea nettles in 2007 prevented the completion of the experiment, but preliminary results support the hypothesis that sea nettles descend in the water column at temperatures below 15 degrees C.
SP THE LINKS BETWEEN THE SOUTHERN OCEAN AND LOW LATITUDE SURFACE AND BOTTOM WATERS

Subantarctic Mode Water (SAMW) is the primary pathway by which nutrients that are lost to the deep ocean by organic matter export are returned to the main thermocline. We use ocean model simulations and observations to illustrate how biological and physical processes in the SAMW formation regions of the Southern Ocean determine the low silicic acid and high nitrate concentrations of the main thermocline, and how these processes are also responsible for determining the silicic acid concentration of the deep ocean. We also discuss model simulations of how SAMW formation responds to global warming in the NOAA GFDL CM2.1 coupled climate model and what the implications of this may be for low latitude biogeochemical processes.

SEASONAL AND INTER-SEASONAL VARIABILITY OF MARINE BIOLOGY IN THE KUROSHIO EXTENSION WITH AN EDDY RESOLVING COUPLED PHYSICAL-BIOLICAL MODEL

Seasonal and intra-seasonal variability of chlorophyll a in the Kuroshio Extension region is investigated using a simplified four-component ecosystem model embedded in an eddy-resolving ocean general circulation model. The model captures the realistic seasonal variability of chlorophyll-a distribution associated with the mesoscale eddy activities, sub-mesoscale front variability, Kuroshio meander, and upwelling. The generated cyclonic and anticyclonic eddies along the Kuroshio meander affect the ecosystem dynamics. In winter, the generated westward cyclonic eddy at the south of Kuroshio meander shallows the nutriline layer and maintains the high biological productivity. During one month, high chlorophyll a in the cyclonic eddy extends to about 200-300 m depth. The cyclonic eddy has a diameter of about 100-200 km and the westward speed is about 5 km/day. The biological production responds to the upshift and deepens of nutriline with the variability of mesoscale physical phenomena.

DECADAL SEA LEVEL VARIABILITY IN THE SOUTH PACIFIC IN A GLOBAL EDDY-RESOLVING OCEAN MODEL HINDCAST

Sea level variability and related oceanic changes in the South Pacific from 1970 to 2003 are investigated using a hindcast simulation of an eddy-resolving Ocean general circulation model for the Earth Simulator (OFES) along with sea level data from tide-gauges since 1970. The model captures the realistic seasonal variability of chlorophyll-a distribution associated with the mesoscale eddy activities, sub-mesoscale front variability, Kuroshio meander, and upwelling. The generated cyclonic and anticyclonic eddies along the Kuroshio meander affect the ecosystem dynamics. In winter, the generated westward cyclonic eddy at the south of Kuroshio meander shallows the nutriline layer and maintains the high biological productivity. During one month, high chlorophyll a in the cyclonic eddy extends to about 200-300 m depth. The cyclonic eddy has a diameter of about 100-200 km and the westward speed is about 5 km/day. The biological production responds to the upshift and deepens of nutriline with the variability of mesoscale physical phenomena.

DIRECT NUMERICAL SIMULATION OF SALT SHEETS AND TURBULENCE IN A DOUBLE-DIFFUSIVE SHEAR LAYER

We describe three-dimensional direct numerical simulations (DNS) of double-diffusively stratified flow interacting with infrared sheet. The extreme difference in diffusivity (and thus minimum length scale) between heat, salt and momentum in seawater is replicated for the unsheared case. The Schmidt number is much smaller than unity, indicating that turbulence. They then decay as the mean gradients that drive mixing diffuse. In the turbulent flow. Subsequently, two distinct mechanisms of secondary instability combine to lead the flow to a turbulent state. These instabilities are now under investigation using linear stability analysis. Turbulent diffusivities of heat and salt are largest just prior to the onset of turbulence. They then decay as the means gradients that drive mixing diffuse. In the turbulent state, the effective salinity diffusivity is smaller than that calculated by previous investigators for the unsheared case. The Schmidt number is much smaller than unity, indicating that salt sheets are less effective at transporting momentum than is often assumed.

STRUCTURE AND MODIFICATION OF THE SOUTH PACIFIC EASTERN SUBTROPICAL MODE WATER

We examine the structure and modification of South Pacific Eastern Subtropical Mode Water (SPETMW) by analyzing all available temperature/salinity profiles (26,787 profiles) obtained by Argo floats from July 2004 to June 2007. SPETMW is located in 35-55°S, 160-70°W and characterized by temperature of 17-25°C, salinity less than 34.5psu, density of 24.5-25.8kg/m^3, and potential vorticity magnitude less than 5.0 x 10^-10 m^2/s kg^-1. Examination of the vertical structure of SPETMW reveals that it is truly vertically uniform water, that is, thermostad, halostad, and pycnostad simultaneously only immediately after the formation period; it is pycnostad but neither thermostad nor halostad otherwise. The temperature compensating surface temperature and salinity vertical gradients of SPETMW result in the formation being favorable for salt export or rapid salt intrusion processes. We use ocean model simulations and observations to illustrate how biological and physical processes in the SPETMW formation regions of the Southern Ocean determine the low silicic acid and high nitrate concentrations of the main thermocline, and how these processes are also responsible for determining the silicic acid concentration of the deep ocean. We also discuss model simulations of how SPETMW formation responds to global warming in the NOAA GFDL CM2.1 coupled climate model and what the implications of this may be for low latitude biogeochemical processes.

ESTIMATING THE ERROR IN THE MERIDIONAL HEAT FLUX USING SATELLITE DATA

The oceanic meridional heat flux (MHF) can be estimated through the surface heat budget based on the net heat exchanged at the interface. The advantage of this method over the most direct approach from measurement of temperature profiles and velocity estimates is that our ability of using satellite data to estimate the oceanic meridional heat flux is extensive, and our objective is to estimate the error, identifying its components using data and evaluate the associated error. Latent and sensible heat fluxes are derived from microwave sensors (SM1/1 and TRMM). Radiation fluxes (ISCCP) and heat storage anomalies from sea surface height (TOPEX/Poseidon and Jason-1) complete the heat balance equation. We compare our results with direct measurements in the literature for the Atlantic Ocean. The total MHF as a function of latitude from the satellite data is apparently underestimated compared to direct oceanographic measurements. There is an increasing trend in the difference toward the north. We correct the MHF estimates by removing the linear meridional trend in the satellite data. Through a reverse calculation, the net surface heat flux over the Atlantic can be estimated from the derivative of the uncorrected MHF. The correction removes the surface heat flux that could not be attributed to the total heat flux that agrees with the direct measurements are on average about 10W.m^-2. This result is not intended to correct the surface heat fluxes but to prove that even a little deviation can lead to a significant bias in the total integrated heat flux.

A NOVEL RADIATIVE TRANSFER APPROACH FOR IMPROVING SATELLITE BASED CHLOROPHYLL ESTIMATES IN THE PRESENCE OF CDOM

The concentration and absorption properties of biogeochemical constituents in the water column are critically important to remote sensing reflectance (Rrs) measurements of ocean color and estimates of chlorophyll concentration. While variability in absorption properties is due to both dissolved and particulate colored material, satellite algorithms cannot differentiate between these spectral signals. As a result, retrieved Rrs spectra are often dominated by the spectral absorbance of CDOM which overlaps chlorophyll and can account for 50% or more of total absorption at 443nm (Siegel et al., 2002). Consequently, CDOM can be a source of one of the largest errors in SeaWiFS global and regional chlorophyll datasets (Gregg and Casey, 2004). In this study, we investigate the use of CDOM absorbance in a forward model to retrieve more accurate chlorophyll estimates. CDOM estimates are obtained from bio-optical surveys and in situ time series (GoMOOS) in the Gulf of Maine which are incorporated into an exact RT program to quantify the influence of CDOM on nLw. The OC4 chlorophyll algorithm is then applied to corrected nLw yielding more accurate chlorophyll estimates.
SEA-GOING AND LABORATORY RESEARCH EXPERIENCES FOR UNDERGRADUATES COUPLED WITH OCEAN OBSERVATORY SEA-TRUTHING AND DATA INTEGRATION

Since 2003, the College of Charleston Transect Program has provided multidisciplinary research opportunities for undergraduate students, which includes a 5-day research cruise and full semester Oceanographic Research laboratory course. In November 2007 the program will pilot the integration of data associated with two continental shelf moorings (CAP2, CAP3) off the coast of Charleston, SC, in cooperation with the Carolina Coastal Ocean Observing and Prediction System (Caro-COOPS). Transect Program data will be used in student independent research analyses. The Transect Program serves to educate and train future ocean scientists in oceanographic research and technology, and is being proposed for implementation throughout the southeast region with numerous partner institutions. An additional program goal is to establish a long-term monitoring program of benthic and pelagic habitats on the continental shelf, coupling at-sea data collection with continuous real-time ocean observatory data. Research results and data inventory are available online for use by educators and scientists.
matter to sediments and a barrier to further infiltration of fines from the water column. Fine particle distributions are largely uncorrelated with bulk sedimentary chlorophyll. Chlorophyll concentrations show a steady exponential decline with depth, with an increase of chlorophyll concentrations indicative of degradation. Total fines show a similar decline in the surface, but grow into higher concentrations at depth. Shallow chlorophyll concentrations record recent downward mixing of benthic algae and bed filtration of planktonic algae. Minima in fines inventories are hypothesized to record the maximal depths of seasonal reworking by storms, with higher concentrations at depth resulting from both relict deposition and slow infiltration from shallower depths.

UNDER-ICE INTERACTION AND MIXING OF SPRING FLOODWATERS WITH CONTINENTAL SHELF WATER IN THE ALASKAN BEAUTIFUL SEA

Spring floods transport more than half of the annual amounts of river water, suspended sediment and dissolved solids from northern Alaska to a frozen Beaufort Sea. In this study, offshore hydrography, water samples, and time series measurements were obtained through the ice during the period of spring breakup to determine the interaction and extent of mixing of under-ice river plumes from the Sagavanirktok and Kuparuk Rivers with offshore shelf waters. A 1-2 m thick under-ice river plume was traced >15 km offshore, and the fate of riverborne physical parameters in coastal seawater was found to be variably controlled by mixing and the volume and timing of the river discharge. Offshore transport and dispersion of spring floodwater under 2-3 m thick ice were linked to the seasonal river hydrographs with noticeable inter-annual variations that were due to river flow and the cooling and refreezing of flood waters during a given year. Observed variations in river flow and mixing with coastal seawater during this multi-year study provide insights to possible future responses to environmental change and increased river runoff in the Arctic.

WIND INDUCED COASTAL CURRENTS IN THE NORTH MEDITERRANEAN MICROTIDAL SEA

The Northern Mediterranean coastal circulation is dominated by the cyclonic large Northern current and the Rhone river region of freshwater influence. The observed coherent structures on the continental shelf are mainly driven by the wind forcing as observed from satellite images and drifted buoys and HF radar surface currents measurements. The sensitivity of the coastal flow to the wind forcing both at mesoscale (continental and offshore winds) and sub mesoscale (land breezes) has been investigated using process oriented, realistic and climate scale (10 years) modeling. Observations on the wind shear are shown to control sub-mesoscale coastal circulation, inducing vortices, filaments, dense water formation and fronts. As a result, scales of oceanic response to the wind forcing are shown to lock on the local external and internal Rossby radius as well as bathymetric undulations in the case of microtidal coastal flows.

DYNAMICS OF PHYTOPLANKTON, DETRITUS, AND COLORED DISSOLVED ORGANIC MATTER IN HYPOXIC AND NON-HYPOXIC GULF OF MEXICO WATERS.

Hypoxia commonly occurs seasonally west of the Mississippi Delta due to enhanced nutrient concentrations resulting in large algal blooms. Understanding mechanisms responsible for hypoxia is crucial in meeting a national mandate to decrease this hypoxic region. This project investigates the contributions of light absorption from phytoplankton, detritus, and colored organic matter (CDOM) constituents in the water column. An in situ, time-series measurement of absorption conducted was conducted in surface and bottom waters, at an offshore hypoxic station and a near shore non-hypoxic station. Water samples were analyzed for particulate ($a_\lambda$) and detrital ($a_\lambda$) absorption coefficients using the quantitative filter pad technique. CDOM absorption ($a_\lambda$) was analyzed with a dual beam spectrophotometer. Surface in situ absorption constituents will be synthesized with the larger spatial coverage of Moderate Resolution Imaging Spectroradiometer (MODIS) derived surface absorption constituents.

THE EVOLUTION OF NONLINEAR INTERNAL WAVES IN THE MID-ATLANTIC RIGHT DURING SW06: NONHYDROSTATIC HINDCASTS

An intense field program, Shallow Water 2006 (SW06), was conducted in the Mid-Atlantic Bight off of the New Jersey coast from late July to early September 2006. The goal of the program is to understand the environmental processes that affect shallow water acoustic propagation. Nonlinear internal waves (NLIWs) are generated by barotropic tides interacting with topography and with the internal stratification in the ocean, by meanders and eddies from the Gulf Stream and by atmospheric forcing. The waves form a complex field of baroclinic internal waves which dominate much of the dynamics of the coastal ocean. A very high resolution, nonhydrostatic (NRL-MIT) model system is used to conduct hindcasts of the SW06 experiment. It is forced at the open boundaries by the hydrostatic NRL LISB NCOM model which has 1km resolution. The NRL-MIT model hindcasts are being conducted at several resolutions from 100m to 30m. NLIWs with amplitudes of 50m and greater are being generated by the model. The hindcasts are being analyzed and compared with data from SW06.

THE RETENTION OF COPEPOD RESTING EGGS IN PATCHES OF SEAGRASS IN COMPARISON TO BARE SEDIMENT IN A HIGH ENERGY AREA

To avoid unfavorable seasonal conditions, some species of zooplankton produce resting eggs that do not immediately hatch. These eggs sink to the ocean bottom and remain there until they experience favorable conditions. The eggs tend to behave similarly to other fine particles in the water column, and will accumulate in areas of high deposition and low resuspension. Seagrass beds are known to be environments that promote the accumulation of fine sestonic particles by inhibiting resuspension, so we hypothesized that they may serve as reservoirs for copepod resting eggs. Two years of field sampling on two sites in the northern Gulf of Mexico has revealed that viable resting eggs of the copepod Acartia tonsa are more abundant in grassy areas in comparison to adjacent sandy areas during times of the year when the seagrass canopy is high. However, this trend disappears in the winter when the seagrass blades have died off and the sediment in the beds is more easily resuspended. Further investigation could elaborate on why the observed patterns occur.

DEEP SUBPOLAR GYRE FRESHENING: JUST A RESULT OF THE NAO?

Recent studies show a significant freshening of the Subpolar Gyre in the North Atlantic and in the Nordic Seas during the last decades of the 20th century. Several mechanisms have been proposed to explain single aspects of that freshening, including surface fresh-water fluxes as well as the latitudal import of fresh water out of the Arctic and the exchange of scale circulations in the subpolar gyre. An integrated concept of the mechanism is still missing. Based on a hierarchy of sensitivity experiments with realistic and simplified forcing conditions for the period 1958-2000, using the global NEMO ocean-sea-ice model, a complete freshwater budget for the sub-/artic/and subpolar basin has been assessed which resembles the observational estimates. We found a strong relation between the subpolar freshwater content variability and the North Atlantic Oscillation (NAO), in particular at depth. We also found observational evidence for this implication using salinity records taken close to the Ocean Weather Ship (OWS) Bravo.

VARIABILITY IN THE QUALITY OF FLOODWATERS FOR WETLAND RESTORATION IN SOUTH SAN FRANCISCO BAY

The largest tidal-wetland restoration project on the west coast of the US is underway in South San Francisco Bay (SSFB). A major objective of this project is the conversion of salt-evaporation ponds to a mix of wetland habitats. Hydrologic reconnection to the bay will provide water, sediment, and tidal energy needed for this restoration. Water quality in SSFB is affected by many hydrologic factors, including inflows from local streams, mixing with water from North San Francisco Bay, and discharges from waste-water treatment plants. Therefore, the quality of the SSFB water available for wetland flooding can vary over multiple time scales. Fixed-site monitoring of basic water-quality variables over the last two decades provides historic data showing influences of tides, storms, seasonal weather patterns, inter-annual climate variability, and multiple-year droughts. Fixed-site records and data from other monitoring and research programs allow estimation of some water-quality variables certain times of the year. In winter, however, near-real-time observations now available on the Internet may be particularly useful because large, primarily weather-driven changes in water quality are common.

Schlenker, K., Kingsborough Community College, Brooklyn, NY, robert.schlenker@kingsborough.edu

THE MIDDLE SCHOOL STUDENTS OCEANOGRAPHIC SCIENCE AND TECHNOLOGY PROGRAM, A MULTIDISCIPLINARY, MULTI-METHOD APPROACH

The Kingsborough Community College Department of Physical Sciences has a 40 year history involving oceanography outreach. The KCC Office for College Advancement and NYS Education Department promote the academic mission of the College through outreach programs such as this. In this unique program, Brooklyn urban Middle School students participated in one of three two-week summer sessions. Students were introduced to a wide range of standards based geoscience concepts through the lens of oceanography. It is believed that this early exposure to oceanography in the form of personally relevant experiences will better prepare students for success in their continuing geoscience education. In this program, students engaged in classroom and shipboard activities. Shipboard activities included water quality testing and organism tows in New York Harbor while aboard the USP Pioneer. Classroom activities included using GIS, collecting oceanographic buoy data, building and using quadrants, and analyzing Ocean Drilling Program integrated and Seasonal Ocean Drilling Program materials and data. Quantitative evaluation of student’s reasoning and observational skills was accomplished using the Science Achievement for Middle School Students.

EVIDENCE FOR BACTERIAL MERCURY METHYLATION AT THE OXIC/ANoxic INTERFACE OF THE HYPERSONAL ORCA BASIN

A profile of suspended particulate matter was collected in June of 2003 across the oxic/anoxic interface of the Orca Basin, northern Gulf of Mexico. At each depth, as much as 1000-1500 L of seawater or brine was passed through an autonomous in-situ filtration device. Subsamples of the frozen filters were digested for total particulate Hg analysis and extracted by distillation for particulate methyl Hg analysis. Concentrations of these two Hg fractions, both measured by time-resolved ICP-MS, are substantially elevated at the oxic/anoxic interface. Bacterial sulfide production is confined to the same depth interval as the particulate Hg concentrations throughout the brine, whereas none could be detected in the overlying seawater. Selected filters will be analyzed for 16S rRNA genes and the presence of putative mercury-methylating bacteria. This appears to be the first report of active mercury methylation in a hypersaline anoxic environment.

SEASONAL VARIABILITY IN THE COMPOSITION OF DISSOLVED ORGANIC MATTER IN NORTHEAST U.S. RIVERS: IMPLICATIONS FOR TERRESTRIAL INPUTS TO THE COASTAL OCEAN

Rivers are the primary link between terrestrial carbon sources and the ocean. Export of dissolved organic matter (DOM) from ancient OM-rich continental rocks via rivers may impact isotopic distributions, estimates of terrestrial OM input, and carbon remineralization in ocean margins. DOM from northeast U.S. rivers was examined over two seasons using 1H-NMR spectroscopy to assess these potential terrestrial contributions. GIS was also used to characterize watersheds' lithology, land use, and variations in leaf area index (LAI). Variability in DOM composition between rivers was low in spring. Increases in aliphatic-H and decreases in carbohydrate-like and aromatic components were noted in summer for two of the smallest watersheds draining OM-rich lithologies and having the greatest ranges in river discharge and LAI. This suggests that smaller watersheds may respond more rapidly to increased terrestrial water inputs, downstream from OM-rich rocks. Fall and winter studies of DOM in these rivers may show smaller inputs from terrestrial vegetation, and should be carried out so that their corresponding impacts on the coastal ocean may be evaluated.

RIVER PLUME EXPERIMENTS WITH THE HYBRID COORDINATE OCEAN MODEL: APPLICATION TO THE MISSISSIPPI RIVER DISCHARGE

Numerical simulations using the Hybrid Coordinate Ocean Model (HYCOM) are employed to study the development and evolution of river plumes, as a first step to understand the dynamics of the Mississippi River buoyant plume. Both process-oriented and realistic experiments are performed. Idealized domain experiments on a rectangular, mid-latitude f-plane, simulated the general structure of a buoyant plume, with an offshore anticyclonic bulge and a meandering coastal current. Different experiments were performed to evaluate the factors that influence the plume development and the sensitivity to mixing parameterizations. The offshore extent of the bulge, the strength of the coastal current and the vertical stratification were dependent on the bottom/coastal topography, the amount of river discharge and the available mixing. Simulations on the Northern Gulf of Mexico (NGoM-HYCOM) high resolution (~18 km grid) domain (nested within the Gulf of Mexico GoM-HYCOM model) focus on the particular characteristics of the Mississippi River plume and in particular interactions of the buoyant outflow with both shelf circulation and offshore circulation, which is dominated by the Loop Current.

FRESHWATER FRACTIONS, PATHWAYS, AND MEAN RESIDENCE TIMES OF WATERS IN THE SURFACE LAYERS OF THE ARCTIC OCEAN DERIVED FROM TRACER DATA

The Oden 2005 trans-Artic section provides a new, high-quality tracer dataset with unprecedented resolution of the Canadian Basin of the Arctic Ocean. Using multiple tracers from this cruise, the water masses in and above the pycnocline are decomposed into their end members including Pacific and Atlantic inflow, as well as meltwater and sea-ice meltwater fractions. Measurement and eddy errors are propagated through an inversion technique to properly constrain the water mass estimates. We place the results into a dynamical context using satellite-derived sea-ice transit times, tritium/He-3, and CFC-derived tracer ages, and coupled sea-ice/ocean GCM output. Rapid transports in topographically guided boundary layers and zones of sluggish transport at the base of the pycnocline away from the boundaries are easily identified. The tracer-derived transit times are compared with time scales of surface sea-ice transport and basin-scale freshwater residence times from end-member mass balances and models to make a first estimate of residence time variances.

FACEDERED AND DISPERSED FLOW AT SAND BOILS AND THROUGH POROUS SEDIMENTS: RELEASE OF NATURALLY OCCURRING ISOTOPES AND MEASUREMENTS OF TRANSIT TIMES

Fluid flow through porous sediments is an efficient mechanism transferring nutrients and trace gases, otherwise consumed by microbial activity or precipitated as minerals, into the bottom water. For tidal flat sediments of the Weser Estuary (Germany), we present a multi-tracer approach applied for investigations of submarine groundwater discharge and a 2D model considering fluid flow through permeable sediments. For simulation of discharge rates pore water studies, measurements of natural radio nuclides as well as flow-meter chambers were applied. The ecological impact of the release of nutrients and methane were considered and related to the spatial distribution of benthic organisms. In total an area of several square kilometres is affected by groundwater dis-
charge. Discharge occurs at distinct locations (‘sand boils’) and as dispersed flow through the sediments. Discharge rates of more than 100 L per day were measured at sand boils. Emanating fluids are enriched in nutrients as well as CH4. Furthermore, porous water profiles measured in “regular sediments” revealed the importance of diffusive discharge. A 2D numerical model, driven by hydraulic gradients, density, or permeability was developed. We applied the model to porous water profiles measured along transects crossing sand boils. The 2D model provides information about the complex interaction between the flow field, microbial degradation of methane and fluxes through the sediments-water interface.

SEASONAL AND DECADAL VARIATIONS OF WEST GREENLAND CURRENT SALINITY AND THE IMPACT ON THE CENTRAL LABRADOR SEA.

Convection in the central Labrador Sea (LS) is closely related to the stability of the water column, thus thermal and haline stratification. Recent research has shown the influence of West Greenland Current (WGC) water anomalies on central LS top 200m salinities, on seasonal to decadal time scales. The LS is therewith highly affected by salinity changes in the WGC system. Seasonal and decadal analysis of these pathways was performed with an extensive constructed database. On the seasonal time scale eddy mixing at the Cape Desolation and southern branch of the WGC bifurcation south of Davis Strait are responsible for two different seasonal cycles in the central LS. Phases of high EKE in the LS show only one freshening whereas low EKE phases show two distinct freshenings within the seasonal cycle. For the decadal time scale it was found that variability of the upper central LS salinity has its main origin in reduced offshore salinities in the WGC at salinities above 34.7, thus with Inningmer Current (IC) origin. This is also found for the well described Great Salinity Anomalies (GSAs). Spectra and regression analysis of several areas within the LS suggests a 12-13 year salinity minimum phenomena emerging via the IC extension. Variations in WGC shelf water seem to have only very little influence on decadal central LS salinity variability. Thus the commonly believed arctic origin of GSAs in the central LS is discussed in reference to the found pathways.

CLIMATE-DRIVEN VARIABILITY OF MARINE PRIMARY PRODUCTION AND AIR-SEA CO2 FLUX: COMPARISON OF CLIMATE CARBON CYCLE MODELS WITH OBSERVATION-BASED ESTIMATES

One important aspect in climate carbon cycle modeling is the validation of model output by observational data. The current study compares results from three fully coupled atmosphere-ocean carbon cycle models (IPSL, MPIM, NCAR) with data and observation-based estimates from (inverse) modeling. In particular, available satellite data that derive marine productivity from ocean color and results from (inverse) modeling are used to constrain marine primary productivity (PP) and air-sea CO2 exchange. The results show a good agreement between the regions that dominate the global signal in PP variability in both models and satellite estimates. Nevertheless, two of the models (MPIM, NCAR) are too strongly iron limited, which dampens the impact of climate variability (stratification, SST) on nutrient supply and PP. In IPSL the observed PP and PP via nutrient supply can be confirmed. Spatial correlations and seasonal variability of Delta pCO2 are moderately well reproduced by all three models and the resulting air-sea CO2 fluxes are close to results from ocean inversions. In summary, the results are promising that coupled climate carbon cycle models have reached the stage where they are not only able to represent climatological mean state, but also reproduce some of theodynamics of internal (climate) variability.

ASSESSMENT OF THE SOUTHERN OCEAN SOLUTION IN THE ECCO2 DATA SYNTHESSES

Global ocean circulation models often do not adequately resolve high latitude processes, hence the characteristics and flow of deep and bottom waters often remain unrealistic. We present the assessment of the optimized solution of the ECCO2 data synthesis with respect to various Southern Ocean metrics as well as sensitivity experiments. The sensitivity studies were not only performed in order to determine the impact on the hydrography of the Southern Ocean, the Antarctic Circumpolar Current (ACC), and the global overturning but also to further improve the model solution. The sensitivity experiments comprise runs with increased salt fluxes and with imposed southern boundary conditions representing a regime from ice shelf-ocean-interactions. While the optimized solution serves as a baseline experiment, the first sensitivity experiment simulates the increase of salinity fluxes due to brine rejection during sea ice formation in future climate scenarios with changes in sea ice conditions. The second experiment investigates the impact of freshwater introduced in the southern hemisphere in individual basins on both regional and global scales. Excess evaporation enhances salt fluxes and modifies the hydrography consequently. The impact in the Arctic is strengthened the ACC and the meridional overturning. Additional freshwater stabilizes the water column and results in a reduction of the ACC transport as well as the meridional overturning.

EDUCATION AND OUTREACH IN A NETWORK OCEAN WORLD

The ocean drives global climate, is the fuel tank for extreme weather, and accounts for half of the carbon on Earth. For human society the ocean provides food, natural resources, an economic engine, an untapped source of all renewable energy, and is an ultimate sink for products we produce. This combined with many observations that oceans are changing dramatically is improving ocean literacy a clarion call for our time. Oceanography is developing an observatory-based approach in which scientists continuously interact with instruments, facilities, and other scientists to explore the earth-ocean-atmosphere system remotely. A recently funded COSEE effort is focused on building the scientist-educator partnerships to create a Networked Ocean World (NOW). COSEE-NOW will serve as a facilitator for quality education and public outreach by focusing on three goals. The first are the development and dissemination of tools through targeted surveys and improved cultural competency practices. Secondly our goal is improve collaboration/coordination between scientists/educators by building online community and interactive GIS observatory communities that will deliver the information through a range of formal/informal education forums.

REMOTE DETECTION OF MARINE MICROBES, SMALL INVERTEBRATES AND HARMFUL ALGAE USING MOLECULAR PROBE TECHNOLOGY AND THE ENVIRONMENTAL SAMPLE PRECESSOR (ESP)

The Ocean Observing Initiative is creating unique opportunities for deploying sensor systems in a distributed ocean observational context. We are exploring that potential through the development of the Environmental Sample Processor (ESP, http://www.mbari.org/microbial/esp). Near real-time observations are achieved through DNA probe and probe arrays. Filter-based sandwich hybridization methodology enables direct detection of ribosomal RNA sequences indicative of groups of Bacteria and Archaea, as well as a variety of invertebrates and harmful algal species. An antibody-based technique is used for detecting domoic acid, an algal toxin. To date the ESP has been deployed in ocean waters from near surface to 1000m depth. Shallower water deployments have emphasized application of all four types of assays in single deployments lasting up to 30 days. Deep water applications have focused on detection of Bacteria and Archaea in the water column as well as invertebrates associated with cold seeps and whale falls, with operations lasting several days. Current work emphasizes incorporating a 4-channel real-time PCR module, extending operations to 4000m depth and increasing deployment duration.

DETECTING EMILIANIA HUXLEYI BLOOMS IN GLOBAL AVHRR IMAGERY

Bloom of the coccolithophorid Emiliana huxleyi profoundly affect marine ecosystems, impacting the biogeochemical and optical properties of the waters in which they occur through their production of coccoliths. Documenting the distribution pattern and its variability will permit us to assess the impact these blooms have on the carbon cycle and to model the response to climate variability and change. In order to document the interannual and longer-term variability of coccolithophorid blooms on a global scale, NOAA AVHRR imagery dating from 1982 to the present was used to yield a continuous, global time-series of remote sensing reflectances in which E. huxleyi blooms can be detected. Though less sensitive than satellite ocean color sensors, AVHRR observations bridge annual and longer-term variability of coccolithophorid blooms on a global scale, NOAA AVHRR imagery dating from 1982 to the present was used to yield a continuous, global time-series of remote sensing reflectances in which E. huxleyi blooms can be detected. EDUCATE, AND EMPOWER: SOME THOUGHTS FROM THE OTHER SIDE onshore flow is expected to be high in nutrients, which can then be brought up to the ing of the Alaska Coastal Current and entrainment generates the deep onshore flow. The interannual variability of the first mode is highly correlated with the strength of the Both modes show the flow of high saline, warm water onto the shelf in a bottom layer. of the covariance between salinity and temperature time series across the Seward Line. Oscillation. Two dominant modes of cross shelf circulation are identified through analysis coho salmon and eulachon, a local fish species. Both studies suggest that the onshore flow is driven by a combination of physical processes, including wind-driven upwelling and the effect of coastal freshwater discharge. Satellite observations and field measurements during SEDGES confirm the presence of high chlorophyll concentrations in the subarctic Pacific. The ecosystem model is used to further explore the mechanisms behind the onshore flow and its impact on the ecosystem. The model results are compared with observations in SIT to assess the model's ability to simulate the observed patterns. The model's predictions for the future are discussed in terms of potential changes due to climate change.

INTEGRATION OF OCEAN OBSERVING SYSTEMS DATA IN UNDERGRADUATE CURRICULA SOEST at University of Hawaii is launching a regional ocean observing system to inte- grate cutting-edge research programs with delivery of operational online data focused on Hawaii waters. The information will supplement existing observ- ing programs that are currently incorporated into undergraduate courses. The Global Environmental Science (GES) B5 degree program utilizes information from local observ- ing systems at three levels in the curriculum. In an introductory seminar, GES majors learn about time-series measurements, in situ monitoring, and integrated sampling programs as conducted through the HOT program, the Kilo Nulo Observatory, and the CRIMP-CO2 buoy in Kaneohe Bay. Data from these observatories are incorporated in an upper division class, Interpretation of Earth-System Computer Databases, where students download and manipulate data from tide gauges, the HOT program, the TAU array, and from satellites. Finally, all GES majors complete senior research projects, many based on research with our existing ocean observing programs. The incorporation of ocean observ- ing data in the GES curriculum successfully exposes students to cutting edge science and technology as they master valuable skills in obtaining, analyzing, and interpreting these observations.

INTERANNUAL VARIABILITY OF THE ONSHORE FLOW OF HIGH SALINE, COLD WATER ONTO THE SHELF IN THE NORTHERN GULF OF ALASKA The Northeast Pacific GLOBEC (GLOBal ocean Ecosystems dynamics) program (October 1997 to December 2004) collected hydrographic data along the Seward Line that stretches from the inner shelf (59.8N, 149.5W) and extends over 200 km beyond the continental slope (58.1N, 147.8W). The complex of the interannual hydrographic vari- ability in this area stems from the interacting influences of local forcing such as winds, coastal freshwater discharge, eddies, and fronts with remote forcing like El Niño-Southern Oscillation. Two dominant modes of cross shelf circulation are identified through analysis of the covariance between salinity and temperature time series across the Seward Line. Both modes show the flow of high salinity, warm water onto the shelf in a bottom layer. The interannual variability of the first mode is highly correlated with the strength of the alongshore wind stress. While, the second mode suggests that offshore surface spread- ing of the Alaska Coastal Current and entrainment generates the deep onshore flow. This onshore flow is expected to be high in nutrients, which can then be brought up to the euphotic zone by upwelling produced by Ekman pumping.

A METHOD FOR RECOVERING THE TWO-DIMENSIONAL SLOPE FIELD OF OCEAN SURFACE WAVES USING AN IMAGING POLARIMETER We present a passive optical remote sensing technique for recovering shape information about a water surface, in the form of a two-dimensional slope map. The method, known as Polarmetric Slope Sensing (PSS), uses the relationship between surface orientation and the change in polarization of reflected light to infer the instantaneous 2-dimensional slope across the field-of-view of an imaging polarimeter. For unpolarized skylight the polarization orientation and degree of linear polarization of the reflected skylight provide sufficient information to determine the local surface slope vectors. A controlled laboratory experiment was carried out in a wave tank with mechanically-generated gravity waves. A second study was performed from a pier on the Hudson River, near Lamont Doherty Earth Observatory. We demonstrated that the two-dimensional slope field of short grav- ity waves could be recovered accurately without interfering with the fluid dynamics of the air or water, and these observed water surface shapes appear remarkably realistic. The combined field and laboratory results demonstrate that the polarimetric camera gives a robust characterization of the fine-scale surface roughness features that are intrinsic to wind-driven air-sea interaction processes.

IRON LIMITATION OBSUCES SIMILARITIES BETWEEN SEASONAL PLANKTON CYCLES IN THE SUBARCTIC ATLANTIC AND PACIFIC Satellite estimates of phytoplankton carbon provide an alternative to chlorophyll for as- sessing phytoplankton biomass. Here, we show that phytoplankton carbon concentrations in the subarctic Pacific reach a late summer maximum that rivals peak concentrations during the North Atlantic spring bloom. This finding is at odds with previous studies, which concluded that persistently low chlorophyll concentrations in the subarctic Pacific are indicative of low biomass, and that the accumulation of phytoplankton is limited by low iron concentrations and strong grazing pressure. In contrast, we propose that the low chlorophyll concentrations do not reflect the seasonal cycle of phytoplankton biomass, because iron limitation suppresses cellular Chl:C ratios. Satellite observations and field measurements during SEDGES confirm the suppression of Chl:C ratios under ambient iron concentrations in the subarctic Pacific: inside the iron-fertilized patch, Chl:C ratios were three times higher than in the surrounding waters. This physiological response to iron is consistent with culture studies and model simulations and has to be taken into account when chlorophyll observations are used to infer ecosystem behavior.

ZOOPLANKTON PRODUCED FLUORESCENT DISSOLVED ORGANIC MATTER (FDOM) IN THE GREAT SOUTH CHANNEL In the Gulf of Maine, the endangered North Atlantic Right whale feeds primarily on the copepod Calanus finmarchicus. Previous work has shown zooplankton contribute to the FDOM pool through excretion products. Zooplankton FDOM, referred to as Peak Z, is unique from previously defined FDOM peaks. In other studies, the vertical distribution of Peak Z has been found to be correlated with zooplankton abundance. In May/June 2007 we took water column FDOM samples in the Great South Channel off of Cape Cod to examine the spatial and temporal presence and distribution of Peak Z. In addition, we are determining if the distribution of peak Z has any correlation with feeding North Atlantic Right whales. Samples were obtained from several transects lines as well as two separate 24 hour stations. At each station, water samples for FDOM were collected from depths of 2 meters and either the pycnocline or chlorophyll maximum. We will be presenting data on the vertical and spatial distribution of Peak Z and discussing its relationship to sightings of right whales, zooplankton abundance, and water column structure.

EFFECT OF FLOCCULATION PROCESSES ON THE TRANSVERSE DISTRIBUTION OF COHESIVE SEDIMENT IN TIDAL ESTUARIES An idealized model is discussed to gain fundamental knowledge about the physical mechanisms underlying the distribution of sediment in estuarine cross-sections. In this presentation the effect of a nonconstant settling velocity of cohesive sediment (due to floccu- culation processes) on sediment trapping is studied. The flow is governed by the shallow water equations and forcing is due to tides, river discharge, horizontal density gradients and wind. The sediment transport is computed from a concentration equation, in which erosion of sediment by the bed shear stress is limited by the availability of sediment. An across-channel varying availability coefficient is resolved from imposing a morphody- namic equilibrium condition such that there is no net evolution of the bed. The model is applied to a 500 m wide cross-section of the Ems estuary in Germany. In that transect, observations of flow, sediment concentration and salinity were collected over a full tidal cycle. The preliminary comparison of model results and observations over part of a tidal cycle shows an improved agreement between model results and observations when floccu- culation effects are incorporated.

IN SITU ANALYSIS OF PHOTOSYNTHETIC GENE EXPRESSION OF THE SMALLEST KNOWN EUKARYOTE, OSTREOCOCCUS SPP. The ubiquitous marine picocyanobacterium, Ostreococcus, is an early-diverging class within the green plant lineage. We evaluated gene expression of Ostreococcus spp. light harvesting
complex (LHC) by applying reverse transcriptase PCR (RT-PCR) from environmen-
tal samples collected every three hours during a 24-h cycle, off the coast of California. Corresponding light levels and other parameters were also measured at the time of collec-
tion. Preliminary steps in RT-PCR optimization were taken to enable semi-quantitative re-
sults through relative quantitative PCR. We designed species-specific primers for a variety of targeted LHC genes and for a TATA transcription factor binding site to use as a house-
keeping gene control. Our results show that differential expression of the LHC2 gene oc-
curs over the 24-h cycle. LHC2 transcripts were found to be present between 1200hr and 2200hr, while dropping below detectable levels at all other times. This suggests that Ostreococcus spp. only expresses light harvesting genes when photosynthetically active. In addition, the lack of detectable levels of mRNA shortly following sunset suggests that the instability of mRNA within Ostreococcus cells may be similar to that within prokaryotes.

A REAL TIME SYSTEM FOR PREDICTION OF COASTAL CIRCULATION AT GREAT LAKES BEACHES

A nested grid hydrodynamic circulation model with outer grid horizontal resolution of 2 km and nested grid horizontal resolution of 100 m has been developed for several coastal locations around southern Lake Michigan. The nested model domain is on the order of 20 km in the alongshore direction and 10 km in the offshore direction. The nested grid is driven by coarse grid boundary conditions generated from an operational whole lake model. Both models are run in real time using wind fields derived from surface weather stations and around the lake. The domains of the high resolution nested model generally include one or more tributary inflows. The flow rate from the tributary is set based on real time USGS stream flow reports. The model is fully three dimensional, but for visu-
alization purposes a two-dimensional advection model is used to simulate the dispersion of the tributary plume. Time series of tributary water concentration at beaches near the tributaries are presented as potential indicators local water quality. The model is updated four times a day and graphical results are available on the World Wide Web.

MODELING TROPHIC TRANSFER OF TOXINS TO PREDICT HEALTH RISKS FOR MARINE MAMMAL POPULATIONS

Bottlenose dolphins are apex predators, exposed to persistent chemical contaminants that biomagnify through the food chain and to harmful algal bloom (HAB) toxins that are transported through the food chain. A comparative study along the southeast U.S. coast and Gulf of Mexico has identified “hot spots” for dolphin exposure to anthropogenic chemicals and for HAB-associated toxin exposure in regions of the Gulf of Mexico where mortality events, involving hundreds of dolphins, have occurred repeatedly over the last 8 years. While localized pollutant sources have been identified for some areas, a clear expla-
nation for increased or higher exposures has been elusive for others. Dolphins are oppor-
tunist feeders and their diet composition varies across regions, season, and in response to alterations in the environment. We demonstrate a mathematical model to explore the influence of prey composition on likely exposure of dolphins to both chemical and HAB toxins. We apply the model using toxin concentrations measured in potential prey species and examine how shifts in trophic feeding level alter the risk of toxin exposure.

IN SEARCH OF AN ELUSIVE SCALE FOR THE RELATIVE HYDROPHOBICITY OF EXOPOLYMERIC FORMING SUBSTANCES

While it has been shown that aquatic exopolymeric substances (EPS) may undergo selec-
tive assembly (Chin et al, Nature 1998), little is known about the relative importance of EPS association in determining a relative scale of hydrophobicity for gel-forming EPS. But as more data were acquired, relationships between HCA and chemical composition of EPS showed promise for determining a relative scale of hydrophobicity for gel-forming EPS, but neither this source of mining, nor this potentially significant climate feedback, is included in current state-of-the-art coupled climate models. We examine results of hypothetical 21st century simulations where CO2 increases at 1% per year. Our results suggest that transient mixing from tropical storms might play a significant role in the location and magnitude of ocean heat uptake in a warming climate, particularly as the intensity of tropical storms increases.

HURRICANE-INDUCED MIXING AND ITS EFFECT ON OCEAN HEAT UPTAKE AND CIRCULATION IN 21ST CENTURY CLIMATE CHANGE EXPERIMENTS

A parameterization of hurricane-induced mixing is incorporated into a coupled climate model of intermediate complexity. In our model, transient diapycnal mixing representing the aggregate effect of tropical storms is added to a background field of diapycnal mixing; the strength of this transient mixing is a function of the potential intensity of tropical storms, with the parameterization varying with the climate system. Neither this source of mixing, nor this potentially significant climate feedback, is included in current state-of-the-art coupled climate models. We examine results of hypothetical 21st century simulations where CO2 increases at 1% per year. Our results suggest that transient mixing from tropical storms might play a significant role in the location and magnitude of ocean heat uptake in a warming climate, particularly as the intensity of tropical storms increases. Monte Carlo simulations find an average of 0.48°C of ocean heat uptake in our model is arguably a better match to observed ocean warming in the past 50 years, in comparison with a version of our climate model without this parameteriza-
tion. Changes in the model's large-scale ocean circulation in the 21st century are also com-
pared with and without the effect of hurricane-induced mixing.

WAVELET APPROACH TO THE ANALYSIS OF SEDIMENT CONCENTRATION AND HYDRODYNAMIC DATA IN THE SURF ZONE

Typical understanding of sediment transport revolves around identifying waves and the accompanying near-bed turbulence. The traditional theory covering large scale oceanic processes is highly nonlinear and turbulent. The traditional theory covering large scale oceanic processes is based on advective control calculations in addition to the rela-
tionships to sediment concentration. However, it is less common to adopt methodologies that concentrate on scrutinizing local characteristics of these processes observed in time series. Here we utilize a new approach to study local features observed in hydrodynamic and sediment concentration data based on the wavelet transform. The data analyzed is from the cross-shore sediment transport study obtained during the CROSSTEX conduct-
ed at O.H. Hinsdale Wave Laboratory, Oregon State University. Preliminary results using the wavelet transform to velocity time series in alongshore and cross-shore directions during beach accretion show a correlation of high sediment concentration events and turb-
ulent intermittent velocity patches which are associated with steep waves. Approximately 60% of the steep waves have turbulent patches associated with them while less than 50% of these events are also correlated for high concentration events. The statistical results suggest that a wavelet framework is useful to understand the complex interactions between sedi-
ment suspension and steep wave/breaking wave turbulence. Such analysis is also critical in guiding subsequent numerical modeling efforts.

LARGE-SCALE OCEANIC TURBIDITY EXPLORED WITH SATELLITE OBSERVATIONS AND NUMERICAL MODELS

The large scale flow in the ocean is quasi-two-dimensional because of density stratification and Earth's rotation (so it's in geostrophic balance). It also has enormous Reynolds number and is highly nonlinear and turbulent. The traditional theory covering large scale oceanic currents (and also atmospheric winds) is geostrophic turbulence theory, and is traditional-
ly studied in idealized numerical model simulations or rotating tank laboratories. Satellite observations of the surface currents began in late 1992, and recently provide long enough records to study equilibrated geostrophic turbulence throughout the World Ocean. For the last few years we have been studying these oceanic observations from the turbulence perspective and comparing the results with idealized numerical model experiments. New phenomena we've discovered include the inverse cascade of baroclinic kinetic energy and highly anisotropic current structures that persist much longer than the timescale of the turbulent flow. Analysis of satellite observations from the turbulence perspective is prov-
ing useful in providing information on the energy cycles of the ocean.

SENSITIVITY ANALYSIS OF A 1-D OCEAN CARBON CYCLE MODEL IDENTIFYING THE ORIGINS OF UNCERTAINTY

Two major unknowns in the attempt to balance the global carbon cycle are the flux be-
tween the atmosphere and the ocean, and the flux between the atmosphere and the ter-
restrial biosphere. Ocean carbon cycle models have been developed to directly address the first of these and in doing so quantification of the second. These models are highly complex, rep-
resenting many different physical and biological processes and the interactions between them.
Many of the parameters which govern these processes are poorly understood and highly uncertain, resulting in large uncertainties in model predictions. This work uses a sensitivity analysis to identify specific sources of uncertainty in the HadC3M GCM (Hadley Centre Ocean Carbon Cycle) model used by the UK Met Office in their HadCM3 GCM. This enables research to be focussed into model parameters that contribute significantly to output uncertainty, while parameters with negligible effect can safely be fixed. It also informs the interactions between parameters and whether their importance is global or regional. Results for different locations in the North Atlantic will be shown and discussed.
IS THERE LIFE BEYOND HYDROSTATICS? SOME IDEAS ON NLIWS PARAMETERIZATION

Conventional wisdom holds that realistic modeling of Nonlinear Internal Waves requires nonhydrostatic models. Unfortunately, the solution of the ensuing three-dimensional elliptic problem is very expensive numerically, which greatly limits the spatial and temporal extent of the problems that can be studied. In this talk, we explore a relatively simple way to go beyond hydrostatics without incurring the steep price of a fully non hydrostatic model. Rationale and application to both structured and unstructured grids will be discussed.

IMPORTANCE OF LATERAL CIRCULATION TO ESTUARINE STRATIFICATION AND MIXING

Traditionally the interaction between the along-channel density gradient and the vertical shear in the along-channel flow is assumed to control estuarine density stratification. The interaction between lateral density gradients and transverse circulations can have significant impacts on both the creation and destruction of density stratification. As a result, these lateral processes play a key role in determining when and where mixing occurs in an estuary. This is illustrated by using field observations and a three-dimensional numerical model of the Hudson River. Both the model and observations show that strong lateral stratification of the density field creates significant stratification over the shoal regions during the flood tide. Unlike the pattern attributed to longitudinal tidal straining, maximum stratification occurs over the shoal at the end of flood tide due to lateral straining. Much of this stratification is then mixed away during the ensuing ebb. As a result, the most intense mixing in the Hudson River is observed during the ebb tide over regions flanking the deepest portions of the channel. The creation of stratification by lateral flows at tidal time scales allows for intense mixing to occur and continue throughout the spring tide, even though the sub-tidal stratification is at a minimum. The intensification of lateral flows during spring tidal conditions contributes significantly to the spring-neap variability in mixing.

NITROGEN NUTRITION AND TOXICITY OF PSEUDO-NITZSCHIA SPP. ALEXANDRIUM CATENELLA AND DINOPHYCIS SPP. BLOOMS IN THE BENGUEL

Harmful Algal Blooms are a regular occurrence on the west coast of South Africa, in the Benguela upwelling system. This talk explores the relationships between nutrient regime, species selection and toxicity at a monitoring station in this region. In March 2006 Pseudo-nitzschia spp. reached concentrations of 13 x 10^6 cells L^-1, representing 82% total phytoplankton carbon, with chl-a as high as 57 g L^-1. Dissolved acid concentrations were 0.3-3.3 g L^-1, with cellular quotas increasing 5-fold as cell numbers dropped after the bloom. Nitrate was depleted from <10 to <0.1µM in a few days. Cell numbers remained high for another 4 days, sustained by regenerated nitrogen, with f-ratios dropping to <0.5. In contrast, a bloom of Alexandrium catenella (450,000 cells L^-1, 26 µg chl-L^-1) occurred in March 2007 at high nitrate concentrations (17µM), displaying high f-ratios (0.6-0.9), and were outcompeted by diatoms as nitrate decreased. In April, Dinophysis acuminata reached 31,000 cells L^-1, representing 61% of phytoplankton carbon. Nitrate concentrations were very low (<0.5µM) and production rate was based on regenerated nitrogen, as shown by the extremely low f-ratios (<0.1). Nutrient kinetic experiments showed that Pseudo-nitzschia had the highest maximum uptake rates, whereas Dinophysis had the highest affinity for nitrate, ammonium and urea.

STRUCTURE OF NEAR-INERTIAL BAND GENERATED BY HURRICANE GEORGES BETWEEN TWO ISLANDS

Unique observations were acquired before, during, and after hurricane Georges passed through the Mona Passage (MP), between Puerto Rico and Hispaniola. Two acoustic Doppler current profilers and one S4 were deployed in the MP Georges crossed the MP with maximum winds of 49 m/s and 970 hPa having the moorings at the right side of its trajectory (September 22-23, 1998). The oceanic response to George's winds was strong in the mixed layer with magnitude of 118 cm/s at the center of MP and 160 cm/s near Hispaniola. The near-inertial band was bounded by 0.93f and 1.2f, (f represents the local inertial frequency). The near-inertial velocity shows a maximum value of 30 cm/s at the mixed layer. The phase of near-inertial wave propagates upward below the mixed layer and downward radiation of energy reached 300 m depth at the sill of MP after 31 IP (28-38 h). The transfer of energy to other frequency bands and the interaction of the inertial wave with topography generating internal wave are considered as possible mechanisms responsible for the decrease in mixed layer energy.

METABOLIC RESPONSES TO OCEAN ACIDIFICATION

Ocean acidification will lead directly to intracellular acid-base imbalance in marine animals. Most species are expected to tolerate this disturbance via buffering and ion transport, depending on the evolved capacity to handle natural changes in acid-base balance that result from cellular metabolism and environmental variability. Those species with low metabolic rates or from stable environments are expected to be more sensitive to acidification. However, we find here that some species with exceptionally high metabolic rates are nonetheless sensitive to modest changes in the partial pressure of carbon dioxide consistent with that expected by the end of the century. In particular, squid blood demonstrates extreme pH sensitivity that facilitates complete release of oxygen from the blood at the metabolizing tissues, but also inhibits oxygen extraction from the ambient water under conditions of environmental acidification. We find that ~1000 ppm PCO2 results in a significant reduction in activity and consequent metabolite suppression in ommastrephid squid.

EXAMINING THE VALIDITY OF THE OUTER BANKS HF RADAR SYSTEM

A long-range direction-finding HF radar system has been operated on the Outer Banks of North Carolina since fall 2003. The radar footprint typically extends from the nearshore region north of Cape Hatteras to east of the shoreward edge of the Gulf Stream and presents an opportunity to examine shelf/Stream interactions in considerable detail. However, the installation suffers from a variety of noise problems that can severely limit the radar coverage. Also, the large change in current speeds within a given range from the antennas presents unique challenges to the standard processing algorithms used with the system and if not correctly can produce significant regions of incorrect solutions at times. Experimentation with the processing parameters suggest improved solutions are possible. The validity of re-processed solutions are explored for a six-month period of low noise by examining the tidal solutions over the shelf and slope and subtidal flow patterns.

PAST, CURRENT & FUTURE TRAJECTORIES OF WATERSHED NUTRIENT EXPORT: A GLOBAL NEWS APPLICATION TO THE MILLENNIUM ECOSYSTEM ASSESSMENT SCENARIOS

Dramatic global increases in anthropogenic nutrient production on land and negative impacts on marine ecosystems due to runoff from rivers are extensively documented. Recently, the Millennium Ecosystem Assessment (MA) concluded that excessive nutrient loading of ecosystems is one of the major drivers of global ecosystem change. Increased nutrient mobilization is expected to continue for decades in response to economic and population growth.

NUTRIENT IMPACTS ON THE CHESAPEAKE AND ITS SUB-ESTUARIES: RESILIENCE (?) AND RECOVERY (SLOW TO UNDETECTABLE)

Nutrient loads to the Chesapeake and its primary tributaries have increased over the past 200 years, resulting in eutrophic conditions throughout the mainstem of the Bay and some of the lower reaches of its principal tributaries. Analyses of long-term records for discharge, nutrient loads, land use, and plankton responses suggest substantial seasonal and spatial expansion of the spring diatom bloom and associated bottom water hypoxia and anoxia. Nutrient reduction strategies in the basin have resulted in modest reductions in nutrient loads for some systems, but limited detectable planktonic responses. Phytoplankton biomass and productivity remain high, with phytoplankton blooms observed in all seasons, driven by local/regional meteorology and accompanying responsive phytoplankton blooms and bottom water hypoxia. The Global Nutrient Export from Watersheds (NEWS) model, designed to meet these data needs, was recently applied to past (1970) and current (2000) conditions, and compared to four MA future scenarios thru 2050. These scenarios integrate economic, social, and ecosystem processes, and represent plausible futures with contrasting degrees of global cooperation and of sustainability of ecosystem services.

DATA ASSIMILATION INTO REGIONAL OCEAN MODELING SYSTEM OF THE NORTHWEST PACIFIC MARGINAL SEAS BY USING ENSEMBLE KALMAN FILTER: IDENTICAL TWIN EXPERIMENT

Data assimilation scheme strives to determine the optimal state of a system from a set of incomplete and inaccurate observation. Ensemble Kalman Filter (EnKF) of data assimilation is implemented into the Regional Ocean Modeling System (ROMS) configured for the Northwest Pacific Marginal Seas. The regional model has 0.25 horizontal grid resolution and 20 sigma levels in the vertical, and includes the East China Sea, the Yellow Sea, the East/Japan Sea and Northwestern part of the Pacific Ocean. The main focus on this study is to assess the performance and the capabilities of the EnKF before assimilating real observations by the identical-twin experiments, which is a useful tool for both operational applications and observing systems design, prior to actual measurements. In these experiments, we obtain the true state from single model integration with the ECMWF atmospheric forcing and boundary conditions with the ECCO. Pseudo-observations of SST are obtained by adding (identically independently distributed) white noise with mean zero and variance equal to 0.5% of the temporal standard deviation at a grid of 30 observational locations every 10 days. The comparisons between the truth and the estimations from both non-assimilating and assimilating results are beneficial in setting up an effective configuration for the assimilation of real data in near-real time situation.
Riedel, T. & Berelson, W. - Summit will be discussed. Gas results from firn air studies at the WAIS Divide site, West Antarctica, and Greenland on top of polar ice sheets. We find a modern zone of deep air convection 25-30 m thick.

Since benthic fluxes are influenced by sediment grain size, temperature and other induced changes, there is a spatial and temporal variability in sediment-water exchanges in most coastal environments. The aim of the present study was to quantify the annual amount of NH4+ and HPO42− exported from intertidal-muddy and subtidal-sandy areas in order to evaluate their contribution to the lagoon nutrient budget. Porewater NH4+ profiles evidenced a peak in the top-most mudsy sediment (380 µM) suggesting higher mineralization rate when oxygen is more available, while maximum HPO42− concentration (113 µM) occurred in the suboxic layer probably due to phosphorous desorption under reduced conditions. In organically poor sandy sediments, porewater concentrations were always lower than in muddy sediments. Studies developed in this lagoon have shown that N and P entering the system are quickly removed by primary producers, what might explain the low NH4+ (< 4 µM) and HPO42− levels (< 2 µM) in overlying water. These values, 2 to 3 orders of magnitude lower than those found in porewater lead to concentration gradients that drives sediment-water exchanges. Diffusive fluxes predicted by a mathematical model based on geochemical processes, were higher during summer, in both muddy and sandy sediments, while during lower temperature periods fluxes were 3 to 4 times lower. Based on simulated nutrient effluxes, the estimated annual amount of NH4+ and HPO4− exported from intertidal areas was 3 times higher than that released from subtidal areas (22 ton y−1 - NH4+; 2 ton y−1 - HPO4−), emphasizing the importance of tidal flats for the high productivity of the lagoon.

Kawamura, K. & Severinghaus, J. P. - Mamala Bay are affected by physical structure and events. Clearly, thin plankton layer characteristics in dissipate or advected thin layers in most cases. Abrupt current reversals either dis- resolved physical structure. Recurring high frequency internal waves were found to vertically congregate in vertically thin layers. This work will present for the first time the observations of thin layers on the south shore of Oahu, Hawaii. We investigated the formation, displacement, and dissipation of these thin layers as a function of physical structure in the water column, and periodic events forced by shoaling internal tides. Acoustic Doppler Current Profilers (ADCPs) were used to measure currents and backscatter. One ADCP was calibrated to output absolute volume scattering strength from zooplankton. The influence of physical structure and events.

THE INFLUENCE OF PHYSICAL STRUCTURE AND SHOALING INTERNAL TIDES ON THIN PLANKTON LAYERS IN MAMALA BAY, HAWAII.

Plankton distributions in coastal environments have recently been observed to be temporar- ily concentrated in vertical layers. This work was undertaken for the first time to observe the distribution of thin layers on the south shore of Oahu, Hawaii. We investigated the formation, displacement, and dissipation of these thin layers as a function of physical structure in the water column, and periodic events forced by shoaling internal tides. Acoustic Doppler Current Profilers (ADCPs) were used to measure currents and backscatter. One ADCP was calibrated to output absolute volume scattering strength from zooplankton. Thermostat chains measured internal water propagation, and a autonomous profiler resolved physical structure. Recurring high frequency internal waves were found to vertically displace thin layers, but not to dissipate them. Abrupt current reversals either dis- solved or advected thin layers in most cases. Clearly, thin plankton layer characteristics in Mamala Bay are affected by physical structure and events.

HEAVY NOBLE GASES AS TRACERS OF PAST AIR CONVECTION IN ICE CORE RECORDS

Argon, krypton, and xenon abundances and their isotope ratios are diagnostic of turbulent mixing (eddies diffusion), in a number of different environmental settings. Here we outline recent progress made in measurement techniques and show applications to deciphering the paleoclimate record from trapped air in ice cores. These records include past mean ocean temperature (from atmospheric krypton abundance via solubility), local ice sheet surface temperature, indirect records of mechanical disruption of the firm stratigraphy by crevassing and thermal contraction cracks, and passage of atmospheric CO2 and tem- perature variations, all of which are affected by air convection in the firm layer (snowpack) on top of polar ice sheets. We find a modern zone of deep air convection 25–30 m thick in the firm at the Megadunes site, central Antarctica, which demonstrates these heavy noble gas fractionation patterns and allows calibration of the ice core record. Recent noble gas results from firm air studies at the WAIS Divide site, West Antarctica, and Greenland Summit will be discussed.

THE BENTHIC FLUX OF IRON FROM RIVER-DOMINATED CONTINENTAL SHELVES OF THE NORTH PACIFIC.

We present benthic iron flux data from two river-dominated regions along the Oregon- California continental shelf. Multiple sites along the Eel and Umpqua River margins were occupied in Spring and late Summer of 2007. In Spring benthic oxygen fluxes ranged between 2–6 mmol m−2 day−1. Benthic iron fluxes range from ~90 µmol m−2 day−1 to 2500 µmol m−2 day−1, with fluxes generally being higher near the Eel River. These values are more than a factor of four greater than non-river dominated California margin benthic iron fluxes (Eldred et al., GRL 2004). We tentatively speculate that the difference in benthic iron flux is driven by the greater availability of reactive iron within the Eel river sediments. Further, we observe a trend towards exponentially larger iron fluxes as oxygen is depleted within the benthic flux chambers. This result suggests that iron fluxes in excess of 1000 µmol m−2 day−1 occur when oxygen concentrations are low. Preliminary data for samples collected in September 2007 indicate that oxygen fluxes were 40–80% greater in late sum- mer than springtime values. Iron fluxes at both locations are, however, mostly lower com- pared to springtime fluxes, possibly indicating that the reactive sedimentary iron pool has become depleted over the summer.

HISTORIC, HUMAN DIMENSIONS OF CORAL REEF Ecosystems: CONTRIBUTIONS TO MARINE Ecosystem-BASED MANAGEMENT

Marine ecosystem-based management (EBM) is regarded as a promising solution to degradation across many marine ecosystems, largely because it recognizes oceans as com- plex, adaptive, social-ecological systems (SES) and encourages managing for resilience. Conventionally, focus has been on ecological or social systems, rather than integrating the two and using synergies and approaches to managing connectivity in SESs are rather lacking. This research intends to provide managers practical tools for integrating human and ecologi- cal dimensions, by working with diverse experts in the local community. It investigates historical ecology and human dimensions on Kona Coast, Hawaii’s coral reef ecosystems by coupling approaches from both biophysical and social sciences. Investigations of SES dynamics and co-evolution were conducted through interviews and participatory observa- tion with local ocean experts: Native Hawaiians, fishers, divers, aquarium collectors, scientists, conservationists, and others. Ocean experts/observations and perceptions of change unravel an 80-year ecosystem-level history, from watersheds to pelagics. Findings reveal experts’ beliefs about key sources of disturbance and renewal; diverse cultural values of oceans; distinct ecological knowledge systems; and potential sources of cooperation and conflict. Finally, research indicates several SESs operate in concert that are undergoing similar social regime shifts in response to local and remote ecological disturbances.

IRON REDOX DYNAMICS IN THE SURFACE WATERS OF THE GULF OF AQABA, RED SEA

In situ measurements of Fe(II) concentrations and oxidation kinetics were conducted regularly during an eighteen months period in the highly irradiated warm surface waters of the Gulf of Aqaba, Red Sea. Rapid photo-reduction and oxidation rates (up to 200 µM per minute) were documented, with subsequent high turnover rates (10–30 per day) and modest Fe(II) concentration (20–400 µM). Fe(II) oxidation is governed by molecular oxygen throughout the year, while photo-generated short lived oxidants such as hydrogen peroxide became significant following an intensive algal spring bloom. Photoreduction rates varied substantially with highest values in the autumn, despite the fact that seasonal variations in the irradiation flux and the total and filtered iron concentrations were quite small. We suggest that aerosol dust deposition and iron-reacting reagents iron is in the stratified upper waters are responsible for the enhanced autumn photo-reduction rates.

INTER-COMPARISON OF REMOTE SENSING SEA SURFACE TEMPERATURE PRODUCTS DERIVED FROM MULTI-SENSORS IN THE CHINA SEA

The consistency of the AVHRR/MODIS/TMI SST products are evaluated for waters in China Sea and nearby West Pacific regions ([111–130E, 12–32N], in particular to seven sub-regions (Taiwan Strait (TWS), East China Sea (ECS), South China Sea (SCS), Kuroshio water; and three other West Pacific areas that have the same longitude as the ECS, Kuroshio and SCS sub-regions). For the West Pacific waters, the difference among the three SST products is within ±0.2°C and the rms is within 0.4°C with little difference in the two infrared SST values. Differences are relatively larger in the China Sea. For example, for the SCS, the infrared values are always higher (~0.2°C) than that from microwave; for the ECS, AVHRR SST differs by ~0.24°C and -0.07°C (rms values are 0.74°C and 0.96°C) when compared with SST from MODIS/TMI, respectively. In one word, there is no obvious difference among the three SST products in the China Sea and its adjacent regions. However, the SSTs show large differences for frontal areas and/or areas seriously affected by clouds, with larger differences appear in Winter/Spring.

SPATIAL VARIATION IN CORAL DISEASE ON THE MESOAMERICAN BARRIER REEF: BIOLOGICAL AND ENVIRONMENTAL CORRELATES

We examined the prevalence of Yellow Band (YBD) and Dark Spots (DS) coral diseases on the Mesoamerican Barrier Reef system in Belize. Infection rates were recorded at four locations that represent a spectrum of habitat qualities with one oceanic atoll, two barrier reef sites, and one lagoon site. We observed strong spatial variation on a scale of 10s of kilometers with both diseases markedly higher at one barrier reef site than the other three sites. Multiple regression using common indicators of reef health as well as variables from principle component analysis of fish and benthic assemblages improved the models slightly but most of the variance was still spatial in nature. We postulate that the high incidence of disease at this site is caused by periodically low water quality due to seasonal high exposure to continental run-off, and its location within a regional gyre. Our observations are consistent with a broad pattern of differential coral morbidity at sites subject to chronic stress. Reduction of local anthropogenic stressors could greatly improve coral reef health even in the face of global climate change.

LINKING WATER COLUMN DISSOLVED ORGANIC MATTER AND CORAL MICROBIAL COMMUNITIES

Coral reefs in the FL Keys have experienced a significant decrease in coral cover over the past few decades with most reefs currently exhibiting <10% overall coral cover. Environmental factors routinely examined for their impact on coral vitality include nutrients, turbidity, water temperature, and light availability. We are evaluating water column DOM variability near reefs throughout the middle and lower Keys and investigating the direct relationship between microbial communities within corals/surface micropycnocline-charle layer and ambient water column DOM conditions. In the middle and lower Keys, DOC concentrations can range from <100-300 uM C at nearshore patch reefs and from <100-200 uM C along the reef tract. Variability in the magnitude of the DOM pool is strongly correlated with daily and seasonal pulses of FL Bay discharge, but local DOM sources become important during periods of decreased flow from FL Bay. Additional data indicates that the bioavailability of DOM emanating from FL Bay is enhanced by photochemical breakdown of its higher MW pool. We are investigating whether bacterial communities associated with corals are stimulated by DOM that is bioavailable to water column microbes. (Although this work was reviewed by EPA and approved for publication, it may not necessarily reflect official Agency policy).

ATMOSPHERIC TRACE METAL AND LABILE IRON DEPOSITION FLUXES TO THE EQUATORIAL PACIFIC OCEAN DURING EUCFEC2006

In the equatorial Pacific Ocean iron limitation persists despite the existence of the equatorial upwelling (EUC) which carries high loads of nutrients. Deposition of atmospheric particles may constitute an important pathway for which iron is delivered to the remote ocean, where only sparse atmospheric data exists. We collected aerosols between Hawaii and Papua New Guinea during the EUCFec cruise (RV Kilo Moana, Aug-Oct 2006) as part of the larger campaign to characterize the various iron sources to this region. A high-volume cascade impactor operating at 760 L min-1 was used to resolve aerosols in four size fractions. In addition, we measured total atmospheric iron deposition in flux estimates. Samples were digested and analyzed by Inductively Coupled Plasma Mass Spectrometry (ICP-MS) and long pathlength absorbance spectroscopy for trace metals and iron speciation, respectively. Data is interpreted with principal component analysis and HYSPLIT air mass back trajectories.

VARIABILITY OF ARCTIC SUMMERTIME OCEAN-TO-ICE HEAT FLUX ALONG THE 2002-2007 NPS FLUX BUOY DRIFTS

The Naval Postgraduate School Autonomous Ocean Flux Buoy Program has deployed buoys at the North Pole Environmental Observatory each spring from 2002 through 2007. These buoys measure upper ocean temperature, salinity, and velocities at turbulence-resolving scales over the course of year or so as they are carried southward towards and Fram Strait with the Transpolar Drift. Ocean-to-ice heat fluxes are estimated using a bulk method in which the flux is proportional to the product of the interface friction velocity and the departure of temperature from the freezing point. The temperature departure is directly measured and the friction speed is estimated from measured ice velocity using Rosby similarity theory. Over the six years of observation, summer-averaged, ocean-to-ice heat fluxes varied between 9.3 and 4.3 W m⁻², which when integrated over the autumn season correspond to sensible heat fluxes of 0.50 and 0.23 W m⁻². Summer-averaged fluxes were large in 2002 and 2003, small from 2004 to 2006, and large again in 2007. There are no obvious relationships between satellite-determined sea ice concentration and the summer ocean-to-ice heat flux, from which we conclude that the observed variability is most likely due to changes in ice thickness.

MICROBIAL ECOLOGY OF CORALS: INVESTIGATING BACTERIAL COMMUNITIES IN EARLY LIFE STAGES OF CARIBBEAN CORALS

Like many marine invertebrates, scleractinian corals have been shown to harbor diverse assemblages of microbes, but neither the specificity of these associations nor the mechanisms that maintain them across development are well understood. Bacterial communities in planula larvae of the Caribbean corals Porites astreoides and Favia fragum were characterized in this study. Molecular techniques were used to identify microbes associated with larvae, and sequence-specific oligonucleotide primers were designed to survey multiple samples for the presence of particular bacterial species. Fluorescence in situ hybridization (FISH) and microscopy were used to locate particular species within the larvae and determine relative abundance of certain groups of bacteria. In contrast, gamete bundles from the mass-spawning corals Montastrea spp. and Acropora spp. did not contain bacteria or archaea. This study reveals new insight into mechanisms by which reef-building corals maintain specific microbial assemblages during embryo genesis and early development. In addition, these results present the possibility for a bacterial role in larval ecology of some coral species.

FROM PHYSICS TO FISH AT THE SHELF EDGE

The shelf edge of the Celtic Sea is a site of pronounced mixing driven by the internal tide. The associated patch of high surface chlorophyll corresponds to remarkably focused activity of fishing vessels. We use direct observations of primary production, vertical turbulent diffusivity, and nitrate to show that phytoplankton growth at the shelf edge responds to a spring-neap cycle of vertical nitrate flux driven by this mixing. At the same time flow cytometer, size-fractionated chlorophyll, and microscope cell counts show the shelf edge to be a region with a markedly different primary producer community compared to the adjacent open Atlantic Ocean and the Celtic Sea. Cyanobacteria dominate the thermocline communities on either side of the shelf edge. At the shelf edge the narrow region influenced by the internal mixing is dominated by large eukaryotic phytoplankton cells. Thus the internal tidal mixing both fuels the shelf edge primary production with nitrate, and sets the physical conditions that favour a phytoplankton community more suited to supporting larger zooplankton and fish.

source populations, determine the means of introduction and predict persistence and ecological impacts. Such an approach is being used to evaluate the dynamics and impact of the human-mediated introduction of the orange cup coral, Tubastrea coccinea, introduced into the Caribbean and subsequently into Florida, including the Florida Keys National Marine Sanctuary. As observed with many introduced species, T. coccinea can proliferate rapidly, due to production of asexual larvae, and appears to exclude native organisms on particular substrates likely causing a loss of biodiversity. Genetic analyses are being utilized to identify the potential source populations and evaluate levels of genetic diversity and clonal structure. Ultimately, the genetic analysis of the introduction and range expansion of this coral will be used to model biological connectivity throughout the Caribbean and Gulf of Mexico.

IMAGING THE THERMOHALINE STRUCTURE OF THE SOUTH ATLANTIC OCEAN

Seismic reflection profiling has been used to capture snapshots of ocean fine structure in the largely uncharted South Atlantic Ocean using a gridded survey of legacy seismic data from the Falkland Trough. The area is of oceanographic interest as Antarctic Intermediate Water (AAIW) underlain by Upper Circumglobal Deep Water (UCDW) from the Antarctic Circumpolar Current follow the Sub Antarctic Front route around the trough to the Argentinean Basin after exiting Drake Passage. Finestructure imaged in the data occurs dominantly in the boundary layer between the AAIW and UCDW while transitional thermocline regions reflect a more uniform thermohaline character. Disrupted refractions along the slope boundaries reveal displacements due to internal waves produced by wave reflection and generation processes as water loops around the trough, flowing to the West at its Southern edge and to the East along the Northern trough boundary. The survey was shot partly in January and partly in April and differences in the acoustic recording provided interesting insight into the temporal variability of the water masses.

THREE-DIMENSIONAL MODELING OF INTERNAL SOLITON PROPAGATION IN THE ASIAX AREA

Internal solitons are prominent recurrent features in Synthetic Aperture Radar (SAR) images of the South China Sea (SCS). During the field experiment ASIAX 2001, the SAR imagery showed a strong soliton packet passing over the SCS shelf/slope area, coincident in time and location with moored CTD measurements of the passage of a soliton packet. We have conducted a three-dimensional numerical simulation of internal soliton propagation across the same region to see the extent to which these observations can be modeled and to gain some insights into soliton propagation over realistic two-dimensional bathymetry. The initial condition is a depression soliton of ~150 m in amplitude and ~2 km in width in 1 km deep water and ~150 km from the shelf. The result shows the shoaling soliton gradually loses its speed, and at the same time the along-shelf bathymetric variation causes it to refract with a curvature similar to that shown in the SAR image. At the shallow depth, a transition to a multiple-wave packet takes place similar to that observed in situ. This work is sponsored by ONR.

DEEP MIXED LAYERS AND MODE WATER FORMATION FROM ARGO FLOAT PROFILS IN THE SOUTHERN OCEAN

Argo float temperature and salinity profiles are used to determine the mixed-layer depth (MLD) in the Southern Ocean. The deepest mixed layers are found from June to October in the Pacific and Indian Oceans just north of the Antarctic Circumpolar Current (ACC) where Antarctic Intermediate Water and Subantarctic Mode Water (SAMW) are formed. Examination of individual MLDs indicates that deep mixed layers are concentrated in a narrow surface density band corresponding to the density range of SAMW. The deep mixed layers are within the region of strong wintertime cooling just to the north of the ACC, consistent with the idea that deep convection from wintertime cooling leads to the formation of mode water. Although the wintertime cooling from air-sea heat fluxes in the Pacific and Indian Oceans are comparable, the Indian Ocean experiences strong cooling from the Ekman advection, whereas the vertical entrainment in the Pacific is stronger than that in the Indian Ocean. Those differences suggest that the mode water formation in each region may be preconditioned by different processes.

SHIPBOARD LARGE THROUGHPUT CELL CYTOMETRY WITH CINEMATIC DIGITAL HIOGRAPHIC MICROSCOPE
A shipboard, large throughput flow cytometer based on cinematic Digital Holographic Microscopy (DHM) is being deployed. Ability of DHM to suitably image of microorganisms over a large depth (10mm), at a spatial resolution of 11 microns in all directions enables us to perform cytometry without focusing. Setup consists a flow cell of 10x50x5mm (latter being the depth) and an in-line 10X DHM, equipped with a high-speed camera. Collected samples are gravity-driven through the cell at 1fps (speed of 120mm/s, i.e. require 166s/cell). This system in conjunction with an in-situ digital holographic submersible was deployed this summer near Leo-15 to characterize content and concentration of marine particles being transported in turbulent boundary layer, and to investigate how transport is influenced by surface wave. 23 samples (700GB) were collected.

Preliminary analysis shows presence of a large number of clam larvae, whose concentrations correlate strongly with wave phase. On-going data analysis combined with core current flow and concentration measurements by the holographic submersible is expected to elucidate interactions between migrating marine organisms and surface waves.

AN INTEGRATED 2D/3D STORM SURGE MODELING SYSTEM FOR SIMULATING HURRICANE-GENERATED WAVES, CURRENTS, AND STORM SURGE

An Integrated 2D/3D Storm Surge Modeling System, CH3D-SSMS, has been developed and applied to simulate hurricane-generated waves, currents, and storm surge during the 2001-2002 Atlantic hurricane seasons including Isabel, Katrina, and Wilma. CH3D-SSMS consists of a coastal surge model CH3D which can be run in 2D or 3D, a coastal wave model SWAN, a large scale surge model (ADCIRC/UNCHID) and a large scale wave model WW3. We compare 2D and 3D simulations with available observed wave, current, and storm surge data to answer such questions as: Do 3D models yield more accurate results? Are there physical processes that can only be accurately resolved by 3D models? Are 3D models necessary for the simulation of waves, currents or storm surge? For Isabel (2003) and Ivan (2004), the 3D model yields best results (water level, currents, and wave) when wave-current interaction (wave-induced drag, radiation stress, and bottom stress) is included. In addition, the 3D model yields significant vertical and horizontal flow and allows more accurate representation of wave effects on currents and storm surge.

THE TEMPORAL DYNAMICS OF VIRUSES AND BACTERIOPLANKTON IN BERMUDAS INSHORE WATERS AND CORAL REEF ECOSYSTEMS IMPACTED BY SEWAGE OUTFALL.

Microbial communities exist in high abundance and diversity in coral reef environments and play important roles in nutrient cycling within the ecosystem. The effect of sewage plumes on the abundance of viruses and bacteria populations in Bermudan coral reefs is unknown. Here we examine, the seasonal variations in the abundance of virus-like particles (VLP) and bacteria in Bermuda’s inshore waters compared to sites near the main sewage outfall. To determine the affect of sewage contamination on the coral reef ecosystem, the surface microlayer of Perities astreoides was examined from proximities to sewage outfall sites. Initial results using the nucleic acid stain, SYBR green I and DAPI, show that concentrations of VLP and bacteria in the water column varied spatially and temporally. Concentrations were lowest (4.6E09 VLP/L, 4.7E08 bacteria/L) in winter months in the outer lagoon. Concentrations were highest (3.2E10 VLP/L, 3.3E09 bacteria/L) in late summer in a restricted marina. The sewage outfall sites result in elevated concentrations of VLP and bacteria in the water column (5.3E09 VLP/L, 1.1E09 bacteria/L) and the coral surface microlayer (8.0E10 VLP/L, 1.8E10 bacteria/L).

SAN FRANCISCO BAY OUTFLOW PATTERNS

On every tidal cycle a large volume of water flows out of San Francisco Bay and a similar, although different, volume is returned. This raises the question: what happens to the water that returns at different times? In this presentation we will present preliminary results from a set of studies examining the coastal impact of Bay outflow. Recently, HF-radar data has been used to map surface currents, water-following drifters have been deployed in Golden Gate, and moored temperature-salinity sensors have been deployed to monitor coastal locations. Low-salinity waters persist in the northern Gulf of the Farallones, but the bay outflow plume and moored temperature-salinity sensors have been deployed to monitor coastal locations. During northerly winds, the bay outflow is transported south but contact with the coast is minimal beyond Land’s End. The simple patterns indicated by these preliminary results indicate that the time-varying

ROVER: A MOBILE PLATFORM FOR LONG-TERM DEEP OCEAN ECOCLOGICAL RESEARCH

The Rover is a tracked vehicle capable of making long term time-series measurements at abyssal depths up to 6600 m. The Rover is equipped with instruments developed to study sediment community activity and biogeochemistry at multiple sites. Two respirometer chambers on the front of the vehicle measure sediment community oxygen consumption. New instrumentation will include a fluorometry system to detect phytoplankton fluorescence from fresh phytoplankton on the sediment surface and acoustic imaging that will provide profiles of the underlying sediment structure. Three cameras on the Rover provide images of the sediment being measured and a wide-angle view of the immediate surroundings during transects. The Rover can be deployed autonomously for up to six months or tethered to an ocean observatory. The Rover has completed over a dozen autonomous test dives in the Monterey Bay and at Station M (depth 4000m) augmenting ongoing ecological studies. The Rover will be connected to the Monterey Accelerated Research System (MARS) cabled observatory in 2008 for long-term studies at bathyal depths in Monterey Bay, California.

EKMAN DRIVEN VELOCITY PROFILES AND MIXING IN A FAST FLOWING DEEP WATER CASCADE IN THE NORTH ATLANTIC

The overflow of deep water across the Wyville Thomson Ridge at the southern end of the Faroe-Shetland Channel carries cold Norwegian Sea Deep Water down a narrow gully and into the Rockall Trough. It is intermittent with maximum transports of order 2 Sv (making it at times a significant ocean current). The 3D nature of the flow is emphasised. Its body is geostrophic, and during high flow the velocity profile is greatly sheared in the bottom 50 to 60 m - maximum speeds (> 1.5 m/s) are observed up to 100 m above the seabed. Ekman dynamics cause a strong leftward flow (looking downstream) at the bottom which is compensated by a return flow in the upper layers, the strength of which is revealed in animations of the velocity profile. Small (Thorpe) scale overturns indicate strong mixing particularly in the lower part of the overflow. Internal tidal currents become significantly amplified during large overflow events but appear to have a marginal impact on bottom transport. These processes combine to produce a distinctive water mass that emerges into the Rockall Trough.

GENOME-WIDE EXPRESSION DYNAMICS REVEAL DEI L PATTERNS OF METABOLIC SWITCHING IN THE UNICELLULAR DIATOMIC MARINE CYANOBACTERIUM CROCOSPHAERA WATSONII WH 8501

Unicellular diatrophic cyanobacteria can contribute a significant fraction of new nitrogen in the world’s oceans. Some species/phylotypes of this group of organisms exhibit a diel switch of expression of some metabolic genes, yet the pattern of metabolic switching among the entire functional repertoire is poorly understood for any marine cyanobacteria. Using a whole-genome microarray, we monitored gene expression in the marine unicellular diatrophic cyanobacterium Crocosphaera watsonii WH 8501. Our results demonstrate pronounced diel oscillations of the key metabolic pathways. Expression of photosynthesis and carbon fixation (i.e., Calvin cycle) genes increased during the day, whereas transcripts for nitrogen fixation increased at night, accompanied by an elevated transcription of enzymes that participate in respiration (e.g., cytochrome c oxidase), the urea cycle and glycogen hydrolysis. The period of cell division, occurring in the early morning based on flow cytometry results, was preceded by evening expression of the replication gene dnaA and dawn expression of genes for cell wall/cell membrane synthesis and cytokinesis (e.g., lpxA, ftsI, ftsZ). In a broader context, our transcriptome data strongly suggest a global regulatory switch operating marked changes in cellular metabolism that reflect the diel cycle.

OBSERVATION OF A MASSIVE BLUE ALGAE BLOOM EVENT IN THE CHIN S TAI LAKE DURING THE SPRING OF 2007 USING THE MODIS DATA

During the spring of 2007, a massive blue algae bloom broke out in the Tai Lake, one of the largest inland lakes in China. This massive bloom event eventually became an environmental crisis that choked off the drinking water supply for the nearly two million residents in WuXi City in the China southeast region. In this presentation, we provide MODIS results that demonstrate the remote sensing capability for monitoring & observa-

Turtles (Dermochelys coriacea) satellite-tagged during 2004-2007 at Playa Grande, Costa Rica. The region used by the turtles over the tracking period spanned the eastern tropical and South Pacific Ocean. At high latitudes (12°N and 40°S), and between longitude 130°W and the coast of Central and South America. Home-range utilization distribution maps at the 95% level indicated that turtles occupy an inter-nesting area of ~1.2 million km², and a post-nesting home range of ~13.2 million km². Turtle movements within intersecting habitats suggest that relatively small expansions of existing marine reserves could significantly enhance protection. Turtle movements moved rapidly (>4km/day) southwest through an open-ocean corridor spanning from Costa Rica past the Galápagos Islands. South of 105°, the turtles moved into areas of low MKE and chlorophyll. Turtle swimming speeds decreased (~<25km/day) and they dispersed widely; taking meandering paths at low speeds into a region characterized by very weak current variations, very low phytoplankton standing stocks, and the absence of dynamic oceanographic features.

**DOES TEMPERATURE STRUCTURE PHYTOPLANKTON COMMUNITY COMPOSITION IN THE ROSS SEA, ANTARCTICA?**

The Ross Sea polynya experiences one of the largest phytoplankton blooms in the Southern Ocean. Energy flow potential within the Ross Sea food web is primarily set by diatoms and prymnesiophytes, the latter dominated by Phaeocystis antarctica. We investigated physical, chemical, and biological factors that drive phytoplankton taxonomic composition and nutrient uptake in late austral spring. Principal components analysis (PCA) and ordination plots showed that from 2001 to 2005, increased dissolved nutrients (INIE), size fractionated chlorophyll, sample depth, BS, POC, PON, temperature, and pigments. The temperature-based PC explained 13% of the variation in the data set, and other linear regressions were performed to assess the relationship between temperature and other phytoplanktonic variables. A significant relationship between increases in sea surface temperature and phytoplankton nitrate removal (R²=0.76, p<0.0001) was observed. Additionally, P. antarctica abundance appears to be favored under colder conditions while diatoms are abundant when surface temperatures are higher. Significant interannual differences in surface temperature were observed and are likely driven by changes in solar heating, stratification, or by water mass intrusions, suggesting that physical processes may impact phytoplankton assemblage nutrient removal. This is an abstract of a proposed presentation and does not necessarily reflect EPA Policy.

**PREDICTING THE CLIMATE CHANGE RESPONSE OF DISSOLVED AND COLLOIDAL TRACE ELEMENTS IN THE YUKON RIVER BASIN**

In an ongoing study, dissolved and colloidal trace elements are being determined in rivers and streams within the Yukon River Basin in Alaska and Canada. Within this basin, climate change is likely to affect landscapes, organic matter generation and transport, and weathering reactions, all of which can affect the trace element composition of surface waters. Therefore, linkages between the trace elements and controlling factors such as landscape and DOC are important for understanding the climate change response of the trace elements. For many trace elements, the chemical control can be explained generally by a simple model balancing organic complexation with adsorption or precipitation (for Fe). pH also plays a role by proton competition for binding sites. With regard to landscape, forest cover correlated with dissolved Fe and DOC. Chemical and landscape relationships, however, are non-linear which therefore suggests a non-linear response of trace elements to climate change.

**HOT SPOTS FOR EASTERN PACIFIC LEATHERBACK SEABRACE TURTLES (DERMOCHELYX CORIACEA)**

We describe coastal and pelagic hot spots for 46 critically endangered female leatherback turtles (Dermochelyx coriacea) satellite-tagged during 2004-2007 at Playa Grande, Costa Rica. The key of the initiation of the huge ice reduction in the summer of 2007 lies in the precondition of sea ice before melt season. The clockwise Beaufort Gyre was the strongest since 1979, which was twice larger than that in 2005 (previous recorded minimum ice year), even though the anticyclonic atmospheric forcing did not show significant differences between 2004/2005 and 2006/2007 winters, suggesting less stress from the coast. The strengthening of sea ice motion was caused by less sea ice cover along the southern Queen Elizabeth Islands before melt onset, which was established by mechanical crash of thin multi-year sea ice existing there. By this activation of large-scale sea ice motion, thin first-year ice formed in the southern Canada Basin was carried north beyond 80°N in the western part of the gyre, and relatively heavy ice in the northern Canada Basin was delivered to the south. The resultant distribution of sea ice before summer created a favorable condition for huge ice reduction. The activation of sea ice motion would be a catastrophic change in ice-ocean coupled Arctic climate.

**LOW-LEVEL WIND IETS AND THEIR MODIFICATION BY SST FRONT IN THE WEST OF THE TSUGARU STRAIT**

We investigate responses of a coastal wind jet flowing through the Tsugaru Strait to SST front from a case study on 7-9 June 2003. In summertime, easterly wind blowing over the northern Japan often forms strong wind jets in the western exit of the Tsugaru Strait with width of 20 km. On the other hand, the Tsushima Warm Current flows into the Tsugaru Strait and the current boundary forms SST front. Under this situation, easterly wind jet blows over the SST front along the wind jet axis. We look into the evolution and distribution of the wind jets in the west of the Tsugaru Strait by using high-resolution wind field from RAPSARAT and SeaWinds. Based on the results, using meteorological numerical model MM5, the simulated surface wind fields are analyzed, and it is discovered that wind speed rapidly decreases from >100-200 km from the terrestrial gaps around the strait and that they shows diurnal variation. Along the wind jets, pairs of positive and negative wind shear (curl) bands extend. By comparing an experiment with constant SST field, these shear bands are intensified.

**EXPERIMENTAL STUDIES ON BACTERIAL PRODUCTION OF MARINE HUMIC SUBSTANCES**

Humic substances (HS) have been known to be one of the main components of refractory dissolved organic matter (DOM) in the ocean. Although recent studies indicate that HS are produced through bacterial metabolic activities, bacterial participation in the production of HS has not been proved experimentally. In the present study, we carried out the incubation experiments using mixtures of bacterial assemblage and glucose, to elucidate the relationship between bacterial growth and the concentration and molecular weight composition of HS. A rapid decrease in dissolved organic carbon concentration was noticed during days 1-5 and this coincided with the increase in bacterial number. The humic-like fluorescence intensity (Ex/Em=335/410nm) increased in the initial 20 days and more than 60% remained on maximum on day 20. After that, the fluorescence intensity decreased and stabilized after 70 days. These results clearly show that bacteria transform labile DOM to recalcitrant HS. The size exclusion chromatography showed that the retention times of some peaks of natural sea water sample were identical with those of the incubated sample, strongly suggesting that bacteria play an important role as a producer of the recalcitrant DOM and HS.

SEASONAL VARIATION OF THE LOW SALINITY INTERMEDIATE WATER IN THE SOUTH OF SUBPOLAR FRONT OF THE EAST/JAPAN SEA

Seasonal variation of the low salinity intermediate water (East Sea Intermediate Water, ESIW) in the south of subpolar front of the East/Japan Sea was studied by using historical oceanographic data observed by the Maizuru Marine Observatory (MMO) of Japan and the Korea Ocean Research and Development (KORDI). To obtain the water characteristics of the ESIW for isopycnal surfaces, depth, temperature, salinity and depth profile data were interpolated every 0.01 interval of potential density. And then the interpolated values were averaged at the same potential density. On the representative potential density of the ESIW (sigma theta=27.2), depth, potential temperature and salinity were analyzed. The salinity on the isopycnal surface of 27.2 sigma theta varied with seasonally in the south of the subpolar front (south of 38°N); high in winter and low in summer. However, near south of polar front the salinity was the lowest in spring and then increased with time. In the Ulleung Basin, the salinity was lower than the Yatomo Basin and low in both of winter and summer. This implies that flow path and intrusion time of the ESIW into the two basins are different each other.

CLIMATE CHANGE IMPACTS ON ANTARCTIC MARINE ECOSYSTEM AND KRILL FISHERY

Life of Antarctic krill, which supports predators as well as fishery, is strongly associated with sea ice, inherently subjected to climate changes. Concurrent examination of sea ice and chlorophyll from the satellite imagery identifies a number of critical areas for the maintenance of krill population that undergo predictable sea ice development and subsequent algal blooms. Field survey and analyses of recent sea ice indicate that part of the Western Weddell Sea is more important as krill source than previously thought but the sea ice in the area is likely to suffer a fairly rapid decline when climate change proceeds at current rates. Continued loss of sea ice beyond natural variability will result in much less over-winter grounds available for krill population. This should drastically alter the fate and distribution of krill population, and hence the well-being of predators as well as the behavior of krill fishery. Control of fishing efforts, which is already limited in affecting the dynamics of krill, will do little to impact either the predators or the krill fishery in any way, and will be over-written by climate changes.

SEASONAL CHANGES OF VERTICAL DISTRIBUTION OF MESOZOOPLANKTON IN THE KOREA STRAIT

The profile of a fixed site at station M (54.77 N, 129.13 E) in the Korea Strait was studied from March 2006 to February 2007 to understand the relationship between the annual pattern of thermal stratification and the seasonal variation of mesozooplankton composition. Environmental factors such as temperature, salinity and chlorophyll a, which strongly influence the proliferation and diversity of mesozooplankton were also investigated. The population of copepod was the largest among mesozooplankton groups. There were 27 genera and 66 species of copepods. Mesozooplankton was classified into 19 groups to the minimum and 32 groups to the maximum during the study due to the seasonal variation and depth of water column. The number of mesozooplankton groups fluctuated after March 2006 and increased from September. The greater number of mesozooplankton groups was found at the lower part of water column than at the upper part. Copepod dominated mesozooplankton community during the study. The proportion of copepod among mesozooplankton groups was from 24.5% to 96.8% during the study and was smaller in April and May compared to the rest of study period. Dominant copepod species were Paracalanus parvus, P. crassirostris and Oithona similis. This study will discuss the smaller in April and May compared to the rest of study period. CONTRIBUTION OF N FIXATION TO NEW PRODUCTION IN THE WESTERN NORTH PACIFIC ALONG 155°E

N fixation and nitrate assimilation were evaluated using 15N tracer in February and March 2007 along 155°E meridian from the equator to 44°N in the western North Pacific. N fixation was observed only south of 28°N where nitrate+nitrite (N+N) were depleted below 30 m, ranging from 12 to 152 μmolN/m²/d. The highest N fixation rate was observed at 24°N, which was accompanied by a depletion of phosphate (<10 mM), suggesting exhaustion by diatoms. The integrated nitrate assimilation rates varied between 184 and 349 μmolN/m²/d in the area from the equator to 24°N, and no significant latitudinal trend was observed. Nitrate assimilation was more active toward the equator. After N and oxygen fixation, nitrate fixation became insignificant. The contribution of N fixation to new production (N fixation plus nitrate assimilation) ranged from 2% to 37% with a mean of 15% in the N+N depleted region, and the highest contribution occurred in the central part of the subtropical gyre (24°N). The present results clearly show that N fixation is an important source of new nitrogen in the western North Pacific.

PARAMETERISING SUBGRID-SCALE EDDIES IN AN ANISOTROPIC, ADAPTIVE MESH OCEAN MODEL

The Imperial College Ocean Model (ICOM) is a finite element ocean model that uses an anisotropic, fully unstructured, tetrahedral mesh that can be adapted to the properties of the flow as it evolves. Despite the ability of such a mesh to resolve small scale eddies, it is still impractical, and indeed impossible, to resolve all scales of motion. At some point the effects of subgrid-scale eddies must be parameterised. The challenge posed by ICOM is that the definition of ‘subgrid-scale’ changes both across the domain and as the mesh adapts to the evolving flow. Here we present how the Gent-McWilliams parameterisation scheme can be implemented within such a model. The inclusion of this scheme is of vital importance as, along with an isopycnal diffusion scheme, it provides an adiabatic eddy closure that greatly reduces spurious mixing between water masses - a common cause of problems in ocean models. We will focus on the results of applying this model to an idealised wind driven gyre.

HYDROTHERMAL SYSTEMS AS NATURAL ANALOGUE OF CCS

Hydrothermal systems are suitable for natural analogue of a high CO2 environment in the ocean. Hydrothermal vent fluids are highly enriched in CO2 and the CO2 rich fluids are released into the ocean as a hydrothermal plume. Observation of the hydrothermal-CO2 would provide opportunity for understanding physical-chemical behavior and diffusion process of liquid CO2 in the ocean, and environmental assessment of oceanic high CO2 environment. Observation of hydrothermal-CO2 droplets was carried out at the hydrothermal system on the Okinawa Trough. The rising CO2 droplets were tracked by an ROV, and based on pH and pCO2 in seawater near the CO2 droplets were measured during their ascent. The observation results suggest that the discharged hydrothermal-liquid CO2 does not cause pH depression to extend to a wide area. The results of pH mapping showed only localized pH depression at the CO2 venting site. At the NW Eefuku submarine volcano, hydrothermal-liquid CO2 dispersion was observed by using a towing multi-layer monitoring system. Low pH plume of 100m high and 200m wide was detected above the summit of the NW Eefuku submarine volcano.

IMPACT OF ANTHROPOGENIC COMBUSTION EMISSIONS ON THE INPUT OF SOLUBLE IRON TO THE SURFACE OCEAN: ESTIMATES FOR THE NORTH ATLANTIC BASIN

The results of several recent studies challenge the reigning paradigm that continental soil dust provides the only significant atmospheric source of dissolved iron to the surface ocean. This evidence includes correlations between the water solubility of aerosol iron and atmospheric loadings of elemental carbon and aluminum-normalized vanadium, both of which are associated with fossil-fuel combustion emissions. These observations suggest that the relative solubility of aerosol iron, hence the aerosol flux of dissolved iron to the ocean, may be impacted by anthropogenic combustion products. Based on our recent work in the Bermuda region, we have developed a method to estimate the relative solubility of aerosol iron from bulk aerosol concentrations of Fe, V and Al. We apply this method to a large body of published data for North Atlantic sites where aerosol composition ranges from fine dust to fine anthropogenic (I). Our results suggest that anthropogenic emissions contribute ~75% of the aeolian flux of dissolved iron to the ocean near Bermuda, and ~95% near Ireland, implying that human activities have profoundly affected the global iron cycle.
the continental shelf. CDW is around 3°C warmer than the surface freezing point and when it has access to the base of an ice shelf, high melt rates result. In early 2007, we undertook an intensive observational program to investigate the oceanographic regime of the Bellingshausen Sea. A number of CTD sections were occupied, including across troughs that are thought to act as conduits for CDW on-shelf transport, and across the fronts of the floating ice shelves. Results will be presented and discussed in the context of CDW transport from the shelf break to the ice shelves, and the impact of this circulation on the ice shelves.

LONG TERM ASSESSMENTS OF STREAM ECOSYSTEM HEALTH WITHIN A WATERSHED IMPACTED BY HIGH POPULATION GROWTH RATES

We compared the findings of two biotic and physicochemical surveys conducted thirty years apart at impaired sites within the South and East Codorus Creek Branches of the Susquehanna River Watershed. Species richness and the number of intolerant species dramatically decreased during the three decades at both sites. Although there were minor decreases in diversity within the East section, diversity values were greatly reduced in the South over that same period. We also observed increases of the percent Salmonids from 0 to 3 and 0.3 to as high as 5 within the East and South branches respectively. Additionally, we assessed control sites during the latter survey and determined that fish communities were significantly different between control and impaired sites evidenced by the lower number of parasitized fish, greater biomass, and greater numbers of salmonids and other pollution intolerant fish at the control sites. The higher total phosphorus concentrations and suspended sediments in the impaired sites mostly likely explain the low number of pollution intolerant species and the need for restoration in these impaired areas.

REDUCING RECRUITMENT UNCERTAINTY IN ALASKAN SABLEFISH STOCK ASSESSMENT THROUGH THE APPLICATION OF ENVIRONMENTAL SATELLITE INFORMATION

Sablefish are a fast-growing, highly valuable groundfish species that are widely distributed in the North Pacific. Adults are typically found in depths greater than 200 m along the continental slope, shelf gullies, and deep fjords. Very little is known about the early life history of these fish. They are assessed as a single population and do not recruit to the fishery or survey until four to five years of age. Therefore, information to estimate recent recruitment is sparse and highly variable. The objectives of this project are to evaluate the various sources of early life history data and explore integration of satellite-derived environmental time series within the sablefish stock assessment model to reduce the uncertainty of recent recruitment estimates. Model recruitment estimates show high autocorrelation and potential decadals shifts, which are supported by the survey data. Reducing recruitment uncertainty may increase efficiency in harvest decisions through more reliable future harvest projections.

THE IMPACT OF SATELLITE ALTIMETERS ON UPPER OCEAN PARAMETER SIMULATIONS

We investigate the relative impact of the number of satellite altimeters on the U. S. Navy's operational ocean data assimilation system. Satellite altimeter data are assimilated into the NRL Layered Ocean Model (NLOM) to produce dynamically interpolated sea surface height (SSH) fields. These are used with optimally interpolated sea surface temperature (SST) fields by the Modular Data Assimilation System (MODAS) to produce three-dimension

NEAR-SURFACE EDDY DIFFUSIVITIES IN THE SOUTHERN OCEAN

Near-surface eddy diffusivities are presented for the Southern Ocean. Recent studies (Marshall et al. 2006) have used the "effective diffusivity" approach to calculate stream-wise average eddy diffusivities for the Southern Ocean from tracer fields advected by velocities derived from altimetry. The results to be presented here will instead focus on more local eddy diffusivities. On a basin-scale, the focus is on eddy diffusivities in the Pacific sector. On a more regional scale, the focus is on diffusivities associated for example with eddies which apparently reside in the same location for months. Two possible extensions to the effective diffusivity calculations are described which provide local eddy diffusivities, one based on tracer calculations confined to small patches, and the other incorporating information from Lagrangian particle trajectory calculations. The results are considered firstly in the context of observations of the motion of drifters with the aims of validating the approach and characterizing the characteristics of the observations. Secondly, the results are considered in the context of physical processes, such as the influence of bottom topography, which may lead to enhanced values of eddy diffusivity. Thirdly, the results of a multi-year calculation in the Pacific region are presented to highlight interannual variability in the eddy diffusivities and to investigate the mechanisms generating this.

MODELING OF UPWELLING/RELAXATION EVENTS DURING AUTONOMOUS OCEAN SAMPLING NETWORK (AOSN) EXPERIMENTS

Predictions of upwelling/relaxation events during Autonomous Ocean Sampling Network (AOSN) Experiments (Summers of 2000, 2000 and 2006) are evaluated. The modeling system consists of an implementation of the Navy Coastal Ocean Model (NCOM) of the Monterey Bay area. The model is forced with atmospheric fluxes from the Coupled Ocean-Atmosphere Mesoscale Prediction System (COAMPS), and with open-boundary conditions from a basin-scale NCOM-based California Current System. The data assimilation component is a version of The Navy Coupled-Ocean Data Assimilation (NCODA) system. The following issues are investigated: impact of glider data assimilation and assimilation of other observational assets (data denial experiments) on surface and subsurface properties of the model predictions; impact of COAMPS atmospheric fluxes on model predictions of upwelling/relaxation events; use of sigma versus hybrid (sigma-z) vertical grid; and coupling with a larger-scale model on the open boundaries.

LOUISIANA WETLAND MONITORING USING SATELLITE ALTIMETRY AND SAR INTERFEROMETRY

At present, accurate monitoring of coastal estuaries and wetland water level changes and its changes relative to the shoreline presents a challenge to the contemporary spaceborne active remote-sensing tools, including the pulsed-limited nadir radar altimeters and the repeat-pass synthetic aperture radar interferometry (InSAR). While the Ku-band radar altimeters and the innovative use of the dual-bounce SAR interferometers, etc., have been demonstrated to be feasible to observe water level changes in vegetated wetlands, the establishment of absolute and high-resolution (e.g., up to 40 m) water level change time series remain difficult. Here we present a study using retracked Ku-band radar altimetry (TOPEX, ENVISAT) water level change time series (up to decadal), and high-resolution waves. This conversion is clearly defined using the integrated wave vorticity as a diagnostic, and the observed transient point agrees well with predictions based on weakly non-linear theory using the background stratification and shear. Microstructure and velocity measurements were carried out for the first few waves of each train, providing estimates of kinetic energy, available potential energy and dissipative loss in the waves. The energy of individual waves often changed rapidly; factors controlling this alteration included dispersion, wave interactions and intense mixing events.

AN ASSESSMENT OF GEOCHEMICAL MOBILITY OF METALS IN SURFACE SEDIMENTS OF THE SANTA ROSALIA MINING REGION, WESTERN GULF OF CALIFORNIA

The sediments near Santa Rosalía are polluted by metals, produced by ancient copper smelting. However high metal enrichments were not observed in the brown seaweeds collected in the ‘pollution hot spot’, suggesting low bioavailability of the metals. To check this hypothesis, a sequential chemical leaching was applied to the sediment samples with different levels of pollution, and relative abundances of Cd, Cu, Fe, Mn, Ni, Pb and Zn were measured in each fraction. Most of metals of the sediments of the ‘pollution hot spot’ were found mainly in a residual (refractory) fraction. For example, the copper abundances in the highly polluted surface sediments with concentrations of this metal ranging from 2895 mg kg⁻¹ to 4818 mg kg⁻¹ followed the next sequence: residual fraction (79.5 ± 4.6 %) > adsorbed form (14.0 ± 4.6 %) > Fe and Mn oxyhydroxides (5.7 ± 1.5 %) > associated with organic matter and sulphides (4.3 ± 3.6 %). The mobile (exchangeable form and carbonates) fraction abundance was the highest for Cu, Zn, Mn and Cd in non-polluted or slightly polluted sediments.

IRON/LIGHT CO-LIMITATION OF THE DEEP CHLOROPHYLL MAXIMUM IN THE WESTERN PACIFIC OCEAN

The deep-chlorophyll maximum (DCM) is a ubiquitous feature of oligotrophic open ocean waters, with different mechanisms proposed to explain its formation and maintenance. The depth of this feature is in part determined by the tradeoff between light from above and nutrients supplied from below. Here we describe six amendment grow-out experiments at four stations in the equatorial Pacific Ocean (between 140W and 150E) and 2 stations in Western Pacific Warm Pool designed to test iron and light co-limitation. Photosynthetic efficiency (Fv/Fm) and biomass responses to different amendments, including planktonic community structure (planktonic diatoms, photosynthetic picociakaryotes, Synechococcus, Prochlorococcus, and major Prochlorococcus ecotypes) were assessed. Except for some ecotypes of Prochlorococcus (eMT9313 and eNAT27A), all populations were light-limited in the DCM; only planktonic diatoms showed a significant increase with the addition of iron, and no populations were limited by iron alone. These responses were relatively consistent across the equatorial Pacific Ocean and in the Warm Pool, and suggest that light is the primary limiting factor of the DCM in spite of the variability in iron flux across this vast ocean region.

MODELING THE SUPPLY OF NUTRIENTS TO THE COASTAL OCEAN: THE ROLE OF A SHELF BREAK FRONT

The coastal ocean off the East Coast of the United States is not an upwelling regime, but has an open ocean source for nutrients via a mechanism referred to as “shelf break upwelling”. Shelf break upwelling occurs along isopycnals of a shelf break front and so the dynamics of the front influence the source waters for the upwelling, which in turn determine the flux of nutrients supplied to the shelf. It is unclear, however, where the water comes from, and what influence the winds have on the source waters. A three-dimensional, nonhydrostatic, high-resolution model with idealized bathymetry is used to simulate the shelf and shelf break front circulations of an archetypical passive margin off the eastern coast of the United States. The model is adapted for the coastal setting from a model developed for open ocean fronts (Madhevan et al, 1996a; Madhevan et al, 1996b). Data collected from the Mid-Atlantic Bight is used to ground-truth the model. A series of tracers are introduced that will be used to demonstrate dependence of the source waters on the winds. We find that where the front resides, the outer shelf/upper slope region dominates the supply of nutrients to the shelf. Madhevan, A., J. Oliger, and R. Street, Physical Oceanogr. 26, (9), 1168-1880, 1996a; Madhevan, A. J., Oliger, J. and R. Street, Physical Oceanogr. 26, (9),1881-1900, 1996b.

A TIME SERIES ASSESSMENT OF SEDIMENT PLUMES AND PHYTOPLANKTON BLOOMS IN THE SANTA BARBARA CHANNEL, CALIFORNIA

The ocean waters of the Santa Barbara Channel (SBC) are affected by plumes of suspended sediment and intensive blooms of phytoplankton driven mostly by storm runoff and the upwelling of new nutrients. Here, a decade of in situ and satellite observations from the Plumes and Blooms program are used to assess the scales and sources of variability of SBC physical, chemical and biological properties. Fair correspondence is found between ship and satellite indices of sea surface temperature, chlorophyll and suspended sediment concentrations. Large interannual variations in water properties are observed in connection with El Niño events. Empirical orthogonal function analyses show four dominant modes which explain ~90% of the variance among a suite of hydrographic and biological variables. These modes represent four associated water types, each with a high lithogenic particle concentrations and low salinity (12.6%) and a mode with high lithogenic particle concentrations and high salinity (11.3%). The attribution of statistical modes with physical processes provides a way of assessing the importance of plumes and blooms to SBC water properties.

APPLICATION OF MISST L4P ANALYSES PRODUCT FOR OPERATIONAL MARINE FORECASTING AT NOAA OCEAN PREDICTION CENTER

The NOAA Ocean Prediction Center issues operational marine weather warnings and forecasts of winds and waves for high seas area in North Pacific and North Atlantic oceans and off shore regions adjacent to the US. High resolution sea surface temperature analysis is an important tool for forecasters to determine factors such as location and strength of the Gulf Stream. Frequent heavy cloud cover associated with large winter ocean storms over the extratropical ocean results in lost of SST observations by IR and microwave sensors. Techniques using a combination of IR and microwave SST observations have demonstrated a superior capability to produce much improved SST coverage. OPC introduced a L4p analysis product (Reynolds, et al., 2007) into marine forecast operations in Fall, 2007. We will present an initial assessment on using the new SST analysis in making operational marine weather warnings and forecasts.

OBSERVATIONS OF NORTH ATLANTIC INFLOW BY DUAL USE OF A TRANS-ATLANTIC FIBRE-OPTIC CABLE

The northern branch of the Atlantic-water inflow to the Nordic Seas was monitored using a technique based on the novel employment of a fiber-optic cable. Induced voltages, caused by the motion of saline water across the earth’s magnetic field, were measured over a branch-line of the transatlantic (CANTAT3) cable, extending 110 km northwards from Tjärnö on the northern coast of the Faroe Islands. To ensure the quality of the complete electric circuit of the monitoring system and of possible thermal influences...
on the voltage signal. This inquiry showed that the obtained voltage time series could be used for oceanographic purposes. The results from a spectral analysis of the data demonstrated that the signal is dominated by tides, which is reasonable since the observational technique is known to yield estimates related to the barotropic flow across the section. Comparisons were made with ADCP data from nearby moorings and correlation analyses gave at hand that the voltage measurements provide estimates of the flow immediately north of the Faroe Islands.

SOURCE, DEGRADATION, AND FATE OF SEDIMENTARY ORGANIC MATTER IN A COASTAL MARINE ENVIRONMENT: EVIDENCE FROM THE HAURAKI GULF, NEW ZEALAND

Molecular level analysis of amino acids, n-alkanes and the distribution of their δ13C composition quantify the relative marine and terrestrial inputs to sedimentary organic matter (OM) in the Hauraki Gulf, northeastern New Zealand. Levels of recalcitrant biomarkers (alkanes) indicate marine inputs to the organic matter are constant across the Hauraki Gulf with terrestrial OM levels equaling or exceeding marine inputs by up to 5-fold, proximal to point sources. Microbial biomarkers (D-amino acids) indicate preferential microbial utilization of terrestrial material in the inner gulf (proximal to delivery). Preferential microbial utilization of marine organic matter occurs in the outer gulf, however, terrestrial contributions to microbial synthesis there are comparable to marine. Total OM accumulation rates (3.2 to 10.7 mg cm⁻² yr⁻¹) vary with sedimentation rates and alkane accumulation rates (less than 15 µg cm⁻² yr⁻¹). This approach is used in a rural school in Georgia. We will share our experiences (and the thrill) of having students fall in love with the diversity and complexity of the oceans though through inquiry-based learning. Using hands-on activities from the COSEE-System Ocean model. Time series of depth-dependent and depth-integrated near-inertial kinetic energy are calculated from available mooring data after filtering to isolate near-inertial frequency motions. Observational results document a pronounced seasonal cycle featuring a wintertime maximum in results from depth-integrated near-inertial kinetic energy derived chiefly from variability in the upper 500 m of the water column. A simple depth-integrated near-inertial kinetic energy model consisting of a wind forcing term and a dissipation term is proposed. The kinetic energy model captures the overall order of magnitude of the observed near-inertial kinetic energy, as well as the winter enhancement, though agreement on the time scale of individual wind stress events is poor.

CHARACTERIZATION AND REMEDIATION OF ENERGETIC COMPOUNDS IN SEDIMENT AND WATER ON VIEQUES ISLAND, PUERTO RICO

In Vieques, Puerto Rico, former naval sites were used for weapons training and housed several disposal sites. The Atlantic Fleet Weapons Training Area consists of areas and nearby waters that have become contaminated primarily by United States Department of Defense (DoD) activities. Known areas of concern include waters influenced by target practice off the eastern shores of Vieques, areas where ships were anchored north of Vieques, and waters near the western side of Vieques, including Mosquito Pier. It is not fully understood whether the Navy’s operations on Vieques expose residents to unhealthy levels of environmental contamination. Detection and remediation of energetic compounds, such as TNT, RDX, and HMX in these areas are necessary to protect the health and well-being of the present and future Vieques residents and visitors. Our research focuses on the characterization of energetic compounds, such as TNT, RDX, and HMX on the island of Vieques. In addition, the remediation of energetic compounds with an innovative embolized zero-valent iron (EZVI) system is explored.

DYNAMIC MODELING OF NONLINEAR INTERNAL WAVES IN THE SOUTH CHINA SEA

Tidal flow through the Luzon Straits generates internal tides which are routinely observed in the South China Sea (SCS) as diurnally modulated large-amplitude nonlinear internal waves (NLIW). Predictive and hindcast first-principles calculations of these waves are presented. Unique aspects of the simulations are simplified hydrostatic and isopycnal physics (with concurrent computational efficiency) but realistic geometries and boundary conditions. In spite of these simplifications, the model shows skill in predicting the presence and location of NLIW when compared to in-situ and remote-sensing observations. The model allows for a detailed energy analysis of baroclinic generation, modal conversion, and evolution. It is found that NLW formation results from a mid-basin nonlinear internal wave amplification of a K1 tide, leading to steepening of the internal tide as it approaches the continental shelf. It is also found that semidiurnal modulation of K1 internal tidal generation occurs, predominantly in the Southern Luzon Strait, and thus the simulations broaden our current understanding of the source regions for SCS NLWs.

SEASONAL SEDIMENT ERODIBILITY AND TIDAL EFFECTS IN AN IDEALIZED NUMERICAL MODEL OF THE YORK RIVER ESTUARY

A quasi-one-dimensional model was used to study sediment transport in the York River estuary, Virginia. This ROMS (Regional Ocean Modeling System) model used semidiurnal tidal forcing and radiation boundary conditions to generate uniform bed shear stresses. Specificity to the site was obtained through the input of erodibility profiles of critical shear stress for the sediment bed. Erodibility profiles were generated through microcosm erosion tests on sediment cores taken in September 2006 and May 2007. Representing fall and spring, these months show seasonal differences in erodibility profiles. After running for 30 days (60 tidal cycles), the model was analyzed through spatial variation, time series plots, and erodibility profiles. Suspended sediment concentrations were maximized during peak ebb and flood tides, and minimized during slack tide, the period of maximum deposition. Spring suspended sediment concentrations were three times greater than those estimated for fall. Spring sediment also eroded at lower critical shear stresses for the entire duration of the model run.

TOTAL AND EXTRACTED PHOSPHORUS IN SEDIMENT CORES COLLECTED BEFORE AND AFTER ONSET OF AN APHANIZEMONEN FLOS AQUAE BLOOM IN UPPER KLAMATH LAKE, OR, USA

Bottom sediments in Upper Klamath Lake (UKL) are a potential source of phosphorus (P) for Aphanielmomnium flos-aquae (AFA) blooms in the water column. To test this hypothesis we collected duplicate sediment cores at 4 sites in April, 2005, before onset of an AFA bloom.

TOWARDS RAPID ENVIRONMENTAL ASSESSMENT AND COASTAL FORECASTING IN THE NORTHERN ADRIATIC

A high resolution coastal ocean forecast system in the Northern Adriatic is developed to respond to operational assessment requests on a rapid way. This work aims to establish a Rapid Environmental Assessment system based on three coastal monitoring networks and the large scale operational forecasting system of the Adriatic Basin investigating different modeling issues. FOM model is implemented in the Northern Adriatic and nested in the Adriatic Regional model. Model validation is performed with Satellite Sea Surface Temperature observations and coastal CTDs. A multi-scale optimal interpolation technique is applied to blend coastal data and large scale fields in the model initialization owing to a forecast skills improvement. The spin up time, necessary to develop the new scales circulation features, is investigated in order to reach the minimum time required with the maximum accuracy in the model forecasts. A spin-up period of two weeks is required for kinetic energy to settle to the new values allowed by the higher resolution nested model. This is possible through energetic evaluation and comparison with coastal observations too.

**THE PUZZLE OF MIXING IN THE SEASONAL THERMOCLINE OF THE SHELF SEAS**

**Turbulent kinetic energy inputs, arising from stresses at the two boundaries, drive stirring which competes with surface buoyancy exchange to control the seasonal stratification in shelf seas. After the spring bloom, which exhausts the nutrients in the surface layer, subsequent new biological production is determined by the transfer of nutrients from the bottom layers into and through the pycnocline and into the surface mixed layer where levels are frequently undetectable. A maximum in phytoplankton concentration, indicated by a peak in Chlorophyll concentration, is frequently observed in the pycnocline suggesting that nutrient uptake is such that diffusive fluxes of nutrients are taken up as soon as it reaches a level where adequate light and stability are available. Production in this region is postulated to be the dominant contribution during the summer and a major part of the total annual carbon fixation. The key questions are: (i) what mechanisms drive the mixing responsible for the crucial fluxes in the pycnocline? and (ii) can we determine the magnitude of the fluxes involved? Here we report the result of a four-week experiment with water column concentration interpolated technique is applied to blend coastal data and large scale fields in the model initialization owing to a forecast skills improvement. The spin up time, necessary to develop the new scales circulation features, is investigated in order to reach the minimum time required with the maximum accuracy in the model forecasts. A spin-up period of two weeks is required for kinetic energy to settle to the new values allowed by the higher resolution nested model. This is possible through energetic evaluation and comparison with coastal observations too.**

**SURFACE NUTRIENTS IN RELATION TO PHYTOPLANKTON COMPOSITION IN THE SEA ICE ZONE WEST OF THE ANTARCTIC PENINSULA**

**Abundant macronutrients characterize shelf waters west of the Antarctic Peninsula. We present results from a 13-year time series (1995–2007) from the Palmer LTER project in order to characterize patterns in nutrient distribution in surface waters. The establishment of a steeper, mixed layer in late spring isolates surface waters from winter waters (0-150 m). The growth of phytoplankton is able to reduce nutrient concentrations from winter values and the rate of reduction differs depending on dominant phytoplankton assemblages. Diatoms are more abundant in coastal waters where the Silicate:Nitrate ratio can exceed 4.5 and least abundant in slope waters where Silicate:Nitrate averages 1.5. Large accumulation of cryptophytes increase Silicate:Nitrate due to differential uptake of nitrate. The resultant nutrient distribution is a mosaic combining onshore–offshore nutrient gradients superimposed on nutrient uptake in response to phytoplankton biomass. Additionally, local differences in nutrient ratios respond to phytoplankton composition. We discuss the influence of water masses, topography, nutrient concentration at depth (250-500 m) and differential biological uptake on nutrient concentrations and nutrient ratios.**

**COMPARISON OF THE PERFORMANCE OF A COMPLEX OCEAN ECOSYSTEM MODEL WHEN COUPLED TO TWO DIFFERENT GENERAL CIRCULATION MODELS**

**We present results from simulations using the PLANKTOM5.0 ecosystem model, which includes five plankton functional types or PFTs (corresponding to diatoms, mixed phytoplankton, coccolithophorids, micro- and mesozooplankton), and biogeochemical cycling of four elements (carbon, phosphate, silicate and iron). Experiments were performed where the same ecosystem model, with identical parameterizations, was embedded in two contrasting physical models, namely OCCAM and OPA. The two physical models have comparable horizontal resolution and external forcing, but different numerical grids, vertical resolution and mixing parameterizations. We compare predictions of bulk ecosystem properties (primary production, export, biomass), as well as partitioning among the different PFTs, between the two simulations. The stability of the model solutions to changes in parameter values is also assessed. Results indicate considerable sensitivity to choice of both physical model and ecosystem parameterizations.**
Molecular microbial water quality assessment and bacterial source tracking for the Florida area coastal environment (FACE program)

The Florida Area Coastal Environment Program (FACE) at NOAA/AOML was developed to assess whether municipal infrastructure impacts the health of Florida coastal ecosystems by providing an integrated analysis of the physical, chemical, and biological oceanography of coastal areas near wastewater outfalls, septic systems, inlets, and canals. With the FACE program, we have utilized both traditional culture-based and molecular-based detection methods to assess microbial water quality for a variety of fecal indicator bacteria, alternative indicators, bacterial source-tracking markers, and selected bacterial, viral, and protozoan pathogens. Analysis of surface soil water from six wastewater outfalls along the SE Florida coast demonstrated presence of both pathogenic viruses and protozoan cysts, but essentially no presence of bacterial fecal indicators or bacterial pathogens. In contrast, certain SE Florida coastal inlets and several canal and near-shore coastal areas of the Florida Keys demonstrated elevated levels of fecal indicator bacteria, presence of source tracking markers for both human-source and domestic animal fecal contamination, and the presence of viral and protozoan pathogens. These continuing studies aim to assess the efficacy of on-going sanitation improvement programs in the region.

The effects of brevetoxin on natural microbial populations

Brevetoxin is a potent neurotoxin that has been linked to fish kills, marine mammal kills, sea bird deaths and adverse human health affects. Brevetoxin producing Karenia brevis has also been shown to have toxicological effects on several phytoplankton species. The effects of brevetoxin on the natural microbial communities, however, remains understudied. To assess the effects of brevetoxin on natural microbial communities, synthesized brevetoxin was added to bacterial communities from three different bay locations along the east coast and Florida. Each location represents a system with varying historical brevetoxin exposure. Brevetoxin additions, ranging from 0-200 μg/L, elicited distinct responses in the microbial populations. Significant differences were observed in the total bacterial cell number and the proportion living versus dead bacteria after 24hr incubations. These results suggest that microbial populations that have previously been exposed to brevetoxin may be less susceptible to it effects than those populations that have limited or no exposure.

A comparison of Arctic and Antarctic faunas: A case study of the Laptev and Weddell seas

We compare macrobenthic species diversity of the Arctic Laptev Sea (LS) and the Antarctic Weddell Sea (WS). There are 1414 macrobenthic species in the LS and 1448 in the WS. The LS has fewer species than the WS in Periuridae (75/159), Arctozoa (27/48), Pycnogonida (22/85), Myidea (17/32), Gastropoda (137/274), Cephalopoda (7/12), Brachiopoda (2/7), Holothuroidea (11/34), Echinoida (2/19), Asteroidea (17/50), Ophiuroidea (13/56), Pterobranchia (0/5), Ascidiacea (26/51). These taxa are epifaunal and most are stenon-feeders, carnivores or carion-feeders. The LS has more species than the WS in Hydrozoa (85/41), Nemertea (41/10), Polychaeta (228/60), Amphipoda (308/120), Pogonophora (6/1), Bivalvia (78/64). Four of these taxa are infaunal and two are epifaunal. In conclusion, Antarctic benthic communities are dominated by epifauna, mainly sessile suspension-feeders, whereas Arctic bottom communities are dominated by infauna, mainly deposit-feeders. Essential differences in bottom-sediments (muddy sand with gravel/boulders in WS versus clay/silt in LS) and functional histories may explain these differences. The recent Antarctic glacial fauna originated from the ancient Antarctic fauna putting Antarctic epifauna at an advantage over infauna early on. Recent Arctic shelf fauna in contrast evolved on shallow bottom.

Controlling the air-sea fluxes in a global oceanic model by assimilation of SST and SSS data

Bulk formulation parameterizing turbulent air-sea fluxes remain a major source of error in present model, which strongly affect the ability to provide a realistic short term forecast. The recent Antarctic glacial fauna originated from the ancient Antarctic fauna putting Antarctic epifauna at an advantage over infauna early on. Recent Arctic shelf fauna in contrast evolved on shallow bottom. (End of text)
Chemical characteristics of marine aggregates are largely unknown. We investigated neutral aldehydes (NA)(absorbing and scattering components of marine aggregates and other organic matter size fractions in the field. NA yield increased with increasing particle size for all fractions except marine snow. The NA yield indicated that marine snow could have been diagnostically derived from particulate and HMW-fractions, i.e. marine snow aggregates. NA included both monomeric and colloidal material. There was no clear correlation between marine-snow aggregate size and NA yield, i.e. there appears to be no general age difference between small and large marine-snow aggregates. NA composition was similar among different marine-snow size-fractions collected during the same day, indicating that aggregation/disaggregation reactions resulted in homogenizing NA composition in marine-snow aggregates of all sizes. This leads us to believe that the major component, sourced from lignin, is surviving transport from the river to the ocean. We use GC-IR-MS to establish the isotopic signatures of specific DOM components, especially the lignin. It is possible that lignin-derived compounds have previously evaded detection by lignin-phenol methods due to the structural re-workings that occur during microbial or photochemical processes. Overall, our preliminary results indicate that we have identified an abundance of lignin-derived compounds in marine water.

EVIDENCE OF A LIGNIN SOURCE FOR PREVIOUSLY UNCHARACTERIZED COMPONENTS OF DISSOLVED ORGANIC MATTER (DOM) IN MARINE WATERS

We utilize Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR-MS) and high performance liquid chromatography isotope ratio mass spectrometry (GC-IR-MS) to characterize the lignin contribution to dissolved organic matter (DOM) isolated from terrestrial and marine waters in the Chesapeake Bay and offshore coastal sites. Molecular formula assignments and structural assignments for the individual constituents of DOM, based on FTICR-MS results, indicate that there is a great similarity in the DOM from terrestrial and marine sites. One possibility is that the major component, sourced from lignin, is surviving transport from the river to the ocean. We use GC-IR-MS to establish the isotopic signatures of specific DOM components, especially the lignin. It is possible that lignin-derived compounds have previously evaded detection by lignin-phenol methods due to the structural re-workings that occur during microbial or photochemical processes. Overall, our preliminary results indicate that we have identified an abundance of lignin-derived compounds in marine water.
a success, we are striving to ensure adoption into classroom curriculum by conducting follow-up workshops that will take place in October and providing the necessary equipment and support to each participating schools. We will present dissemination methods, related to the Kentucky Department of Education's Core Content, lessons learned from our initial summer workshop, services that will benefit teachers and curriculum adoption, student outcomes, survey results of the fall 2007 follow-up workshop. We strongly feel that our methods will lead to the integration of stream ecology concepts in the classroom as well as raise overall environmental awareness.

OCEANIC HEAT TRANSPORT AND ARCTIC SEA ICE COVER

Effects of variation in the poleward advection of oceanic heat on the Arctic ice cover is explored. The oceanic heat transport is specified at a boundary of a simple column model that has a vertical 1m resolution and resolves the sea-ice distribution with more than 40 ice classes. The column model (1Dice) is horizontally integrated, uses monthly mean atmospheric forcing, and reproduce the Arctic sea-ice thickness distribution and most of the thinning onwards from the 1970s (Söderqvist and Björk 2004). The effects of increased oceanic heat transport is sensitive to the depth at which advection is specified and the model mixing, in addition to the obvious heat transport estimate. Many different scenarios are fully explored until they reach a steady state, usually within 20-50 years. Results presented include the Arctic Ocean and the area that receives the largest oceanic heat transport of any seasonally ice cover in the Arctic - the Barents Sea.

USING SYNTHETIC PROFILES TO IMPROVE SOUND SPEED PREDICTION IN OPERATIONAL GLOBAL OCEAN MODELS

Accurate representation of sound speed is a major objective for operational naval ocean models. The Modular Ocean Data Assimilation System (MODAS) uses climatologically-determined regression coefficients to project satellite measurements of sea surface height and sea surface temperature into synthetic profiles of temperature (T) and salinity (S). Sound speed derived from these standard profiles has a climatological average vertical structure. Mixed-layer depth (MLD) forecasts from the NRL Layered Ocean Model are used to modify MODAS synthetics to better represent sound speed inflection points. The standard and MLD-modified synthetics are assimilated into the global Navy Coastal Ocean Model to produce dynamically-balanced T and S forecasts. While the adequacy of any particular sound speed estimate can be highly dependent upon depth and frequency of the sound source, accuracy of ocean characteristics such as MLD, sonic layer depth and below-layer gradient are good indicators of a product's overall suitability for many acoustic applications. Evaluating the various products related to unassimilated in situ observations, we produce global maps of system performance to identify preferred products for calculating acoustic transmission.

THE 1/12 DEGREE REAL TIME HYCOM NOWCAST/FORECAST SYSTEM

The 1/12 degree global HYCOM nowcast/forecast system has been running in near real time since 22 December 2006 and in real time since 16 February 2007. With ~7km longitude resolution (3-4km near the poles), the system will depict the location of meso-scale features such as oceanic eddies and fronts and provide the three dimensional ocean temperature, salinity and current structure. The Navy Coupled Ocean Data Assimilation (NCODA) system is used to assimilate available observations. NCODA is a multivariate optimal interpolation scheme (MOVD) that assimilates surface observations from satellite altimeter tracks and available CMSSST data. NCODA also assimilates in situ observations, including profile data from BT's and ARGO floats. The different components of the system will be described and the latest results including comparisons with independent observations will be shown. The prediction system will provide boundary conditions for higher resolution coastal models. An accurate representation of the oceanographic fields at the open boundaries of a coastal model is important for a successful coastal ocean prediction system. Results from the global system can be viewed on the HYCOM web page http://www.hycom.org/. The model output can also be accessed through this web page.

Since the fall of 2003, a line of stations extending from Cape Cod about half way to Bermuda has been occupied twice a year as part of an investigation of interannual variation of the Deep Western Boundary Current (DWBC). Prior to the near shelf part of the line was sampled a number of times during the Primor and other projects in the 1990s and early 2000s. The line begins as a total of 38 locations occupied between 1994 and 2007. The water property cores for Labrador Sea Water (LSW) and Denmark Strait Overflow Water (DSOW) in the DWBC were identified as maxima in chlorofluorocarbon concentration and average properties for these extrema were calculated for each crossing of the DWBC. Two vintages of well-ventilated low salinity LSW passed through the section in 1994-1996 and in 2005, corresponding to periods of deep convection in the Labrador Sea in 1989-1993 and 2000 respectively. DSOW salinity increased between 1994-1996 as LSW freshened, but then freshened after 2000. Changes in other properties will also be presented.

COASTAL-TRAPPED WAVE PROPAGATION IN THE PRESENCE OF SUBMARINE TOPOGRAPHY

CTW propagation along the continental slope and its subsequent interaction with the submarine canyon was investigated experimentally. Our observations demonstrated that CTW propagates along the continental slope with the strongest currents being concentrated near the shelf break. The topographic irregularity was strong enough to promote wave scattering. Flow characteristics in the canyon were found to be sensitive to the relative value of the Burger number. When the latter was very large (strong stratification), no variations in the wave spatial structure were observed in the canyon region. The scattering effect becomes significant at moderate values of the Burger number (of the order of unity). It was shown that stratification can eliminate backward propagating modes and limit the number of transmitted modes, forcing the flow to generate highly-energetic evanescent modes in order to adjust to the variations of the topography. Eventually strong mesoscale flows are generated in the form of a cycloidal eddy trapped inside the canyon region influencing the transport of nutrients and pollutants in the coastal region.

SEDIMENT WATER INTERACTIONS IN THE SWAN RIVER ESTUARY (AUSTRALIA), 2000-2006

Geoscience Australia has conducted four surveys to the Swan River Estuary, Western Australia, between 2000 and 2006 to determine the importance of sediments as a source of nutrients. Extreme seasonality of river flow causes the estuary to alternate between fully marine (summer) and almost fresh (winter). Catchment derived nutrients and internal recycling, combined with stratified conditions, drive temporary algal blooms within the waterway. Between 2000 and 2006 there has been a significant increase in the amount of organic matter being degraded, and therefore, nutrient release from the sediments of the upper Swan River. Fluxes of TCO₃⁻, NH₄⁺, PO₄³⁻ and SiO₄⁴⁻ have been among the highest we have recorded in any Australian estuary. The increase in organic matter is also limiting the phosphorus binding capacity and adversely affecting the denitrification efficiency of the sediments. It is possible that reduced flows as a result of global climate change are responsible for the increased organic matter degradation.

MICROORGANISMS LIVING DEEP WITHIN MARINE SEDIMENTS

Recent investigations have led to the discovery that much of the life on Earth resides below its surface. This has resulted in a substantial revision of our understanding of the physical extent of Earth’s biosphere. Cores retrieved by the Integrated Ocean Drilling Program have yielded evidence that microorganisms exist in sediments hundreds of meters below the seafloor. Data from multiple sites have been used to estimate that up to 10% of the extent of Earth’s biosphere. Cores retrieved by the Integrated Ocean Drilling Program have yielded evidence that microorganisms exist in sediments hundreds of meters below the seafloor. Data from multiple sites have been used to estimate that up to 10% of the extent of Earth’s biosphere.
Since the early 1990s ESA has flown Along Track Scanning Radiometer (ATSR) instruments on its ERS-1 and -2 satellites and is currently flying the Advanced ATSR instrument (AATSR) on its very successful Envisat mission; each successive sensor has been an incremental improvement over the last. The sensors have been specifically designed to provide the information urgently needed for the debate on climate change and global warming, as well as to produce properly calibrated image data sets for use in a wide range of EO studies. Each ATSR exploits the multi-channel method pioneered in AVHRR but also uses new technology to improve instrument stability and calibration, detector signal to noise, and to provide observations of the same surface scene at two different angles. The novel feature of each ATSR, from which the sensor is derives its name, is its use of along-track scanning to reduce the effects of the atmosphere on surface measurements. This method obtains two observations of the scene through differing amounts of atmosphere; the

AMIS EDUCATION PROGRAMS FOR THE OCEAN SCIENCES: A PARTNERSHIP OF A PROFESSIONAL SOCIETY, GOVERNMENT AGENCIES, UNIVERSITIES, AND THE K-12 COMMUNITY

The American Meteorological Society has been involved with teacher enhancement programs for over 15 years in the atmospheric, oceanic and related sciences. A key to the success of its programs is the partnerships it has forged. This paper will focus on two programs that promote ocean science education and the groups that form the partnerships. In 1994, the Maury Project was established in partnership with the United States Naval Academy and SUNY College at Brockport, with support from the National Science Foundation, the Navy and NOAA. This program is directed towards improving teacher effectiveness in generating interest and understandings in oceanography. In 2003, AMS initiated a distance learning course called DataStream Ocean. The partners include AMS, graduates of the Maury Project, and subject matter experts who assist as members of local implementation teams to facilitate teaching ocean science topics to precocious teachers. Funding for this program is primarily provided by NOAA. This course is delivered by the AMS education program and taught in a decentralized fashion at nearly 30 sites nationwide. This paper will describe these two programs and how the partners contribute to accomplishing their goals in training teachers on aspects of the ocean sciences.

VIRTUAL STOWAWAY ON AN OCEANOGRAPHIC CRUISE: AN INTERACTIVE EDUCATIONAL WEBSITE EMPLOYING LINKED SHIPBOARD PAM AMAS

An oceanographic cruise is a part of scientific research few can experience firsthand. We are developing an informal education website, Virtual Stowaway on an Oceanographic Cruise, that uses linked QuickTime panoramas to offer a broad public a virtually first-hand look at scientific research and exploration aboard a dedicated research vessel on the open ocean. Clicking on hotspots within these panoramas may lead to explanatory text, video or audio clips. Underwater shots showing the "jelly animals" that are targets of study on these cruises will be linked to descriptions of the animals depicted. Other hotspots within the panoramas will allow visitors to the site to "move" from one space to another on the ship, seeing the activities that typically take place in each. By showing scientists, crew, and study animals in their respective places at sea, we hope to illustrate how the ship's spaces, functions, and people fit together to help researchers learn about the ocean around them. We will present the latest version of this "Stowaway" site, welcoming suggestions on how it may be made more functional, attractive and interactive.

RECONSTRUCTION OF THE ATLANTIC MERIDIONAL OVERTURNING CIRCULATION USING A PHYSICALLY-BASED DATA ASSIMILATION METHOD

Our main aim is to produce a high-resolution reconstruction of the global ocean over the last 50 years suitable for the study of ocean climate signals and in particular the Atlantic meridional overturning circulation (AMOC). The relative abundance of colocated temperature and salinity observations provided by Argo are used to develop an assimilation scheme whereby temperature and salinity profiles are assimilated on isotherms and isopycnals. This allows us to exploit the larger spatial and temporal decorrelations of these quantities, compared with assimilation on geopotential surfaces, allowing flow dependent assimilation and recovery of water mass information. The ¼ degree NEMO ice-ocean model developed by DRAKKAR is used to perform a series of experiments over the Argo period, assimilating on depth, temperature and density surfaces. These experiments are evaluated in terms of the ability of the different methods to capture observed water mass properties, and the effect of the Argo data on the AMOC. A 20% spin-up will also be made with estimates of the AMOC from the RAPID Array at 26N. If completed, results from a 50 year reanalysis using this model-data synthesis method will also be shown.

FLUSHING THE NEAR SHORE

Waves exert a strong influence near shore, notably driving alongshore flows that sometimes exceed 1 m/s. How do these wave-driven flows interact with other dynamics in the nearshore region? Here we consider observations of a fresh water density flow propagating down-coast along the barrier islands past Duck, NC. The primary data set discussed here is a time-series of 2-D horizontal surface velocities estimated over an area several hundred meters on a side of a pair of

129 TRANSPORT IN THE DEEP WESTERN BOUNDARY CURRENT IN THE NORTH ATLANTIC OCEAN

During the early 1990s, discharges of 129I from European nuclear fuel reprocessing plants increased by 500% resulting in a well resolved, tracer "front" whose spreading beyond the Nordic Seas is presently being observed by 129I-time-series measurements on the WOCE (World Ocean Circulation Experiment) Line W Section in the Labrador Sea. In addition, the 129I tracer in 241Pu levels in the Labrador Sea at depths greater than 3000 m in Denmark Strait Overflow Water (DSOW) increased by about 200% between 1997 and 2001 and by only about 15% since that time, indicating that the 129I tracer front had fully entered the North Atlantic Deep Waters (NADW) by 2001. By May 2007 the 129I concentration and 241Pu-11 ratio in the DWBC on Line W had increased by 20% compared to levels measured between 2004 and 2006 suggesting that the leading edge of the 129I tracer front had arrived. These results indicate that the transit time in the DWBC to Line W is about 8-10 years from the Labrador Sea and 10-12 years from the Nordic Seas.

PATTERNS OF POTENTIAL TEMPERATURE RISK DURING INTERTIDAL EMERGENCE IN DIFFERENT TIDE REGIMES

Organisms living in marine intertidal zones are exposed to terrestrial conditions during a portion of each day. When low tide occurs during midday in summer, organisms may reach high body temperatures that are physiologically harmful. Therefore timing of the low tide is important for determining thermally risky areas. Past studies have shown variability in the timing low tide across regions and continents using predictions from individual tide stations. However, individual tide stations do not provide the spatial information necessary for determining large-scale patterns in the timing of the low tide. We used the USJ Tidal Inversion Software which is based on TOPEX POSEIDON and Jason 1 altitude data to predict the timing of low tide and the NASA JPL Horizons software for solar elevations to model potential temperature risk. While this method does not account for wind, waves, and local topography, it does provide a useful baseline to select potentially interesting areas for more localized studies on the effects of thermal stress.

DETRITAL AGGREGATE COVERAGE ON THE DEEP-SEA FLOOR IN THE NORTHEAST PACIFIC OVER A 17-YEAR PERIOD

Long-term monitoring of an abyssal site (Sta. M) in the northeast Pacific has found seasonal and interannual variation in the flux of particulate organic carbon to the seafloor, as measured by sediment traps. A portion of these organic carbon inputs to the benthos occurs in the form of discrete detrital aggregates, which may not be characterized adequately by sediment trap collections. The spatial and temporal coverage of detrital aggregates on the seafloor at this abyssal site were examined with time-lapse photography. These aggregates have chemical compositions similar to sediment trap material at the study site. Seafloor coverage of these aggregates as well as their sizes and densities were compared to particulate fluxes measured synoptically by sediment traps. The temporal relationship between sediment trap flux measurements and seafloor aggregate occurrence and coverage were examined. Surface conditions, including major climatic phenomena such as the El Niño-Southern Oscillation and patterns in primary production, also were compared with sinking particle fluxes and detrital aggregate coverage on the seafloor at this site.
THE VERTICAL STRUCTURE OF PV MIXING ACROSS THE ACC

Satellite observations show that Rossby wave phase speeds in the core of the Antarctic Circumpolar Current (ACC) are at least as fast as the mean current by about 25%, implying a strong shear instability at significant depth. Detailed linear stability calculations from hydromechanical theory reveal a strong unstable mode with maximum amplitude and phase at a similar depth, near the base of the jet, implying preferential eddy generation at the level of the jet. Calculations using a nonlinear model forced by the mean shear and stratification at a series of locations spanning the ACC, confirm this picture. Despite that the instability structure is broadband and complex, the mixing level is dominated by a particular growing mode --- this is the mode that can lead to the most efficient conversion of available potential to eddy kinetic energy. The resulting structure of the PV eddy flux is consistent with an eddy velocity that acts to flatten tilted isopycnals. An important result of this study is that the vertical structure of the PV diffusivity is strongly depth-dependent, and so the diffusivities of eddy PV and eddy buoyancy are not the same.

PARAMETER ESTIMATION USING AN ENSEMBLE SMOOTHER: THE EFFECT OF THE CIRCULATION IN BIOLOGICAL ESTIMATION

An ensemble smoother is used to estimate the initial conditions and mortality rate for a spatially explicit model of the toxic dinoflagellate Alexandrium fundyense. The skill of this ensemble is assessed through the hindcast of the enzyme analysis carried out with three different representations of circulation: no circulation, climatology and a data assimilative hindcast. While the hindcast to the assimilated data is minimized with no flow, the hindcast of the biological hindcast is better with the hindcast and climatological velocity fields.

RESPONSE FOR SCIENTIFIC INQUIRY: PROFESSIONAL DEVELOPMENT FOR SCIENTISTS TO SUPPORT THEIR WORK WITH EDUCATION

Funders are asking scientists to become more involved in communicating the "broader impacts" of their work. In addition, scientists wish to contribute to public science literacy and high-quality science education in schools. The ReSciPE Project---Resources for Scientists to Partner with Education---provides professional development workshops and other resources to scientists who are involved in education and public outreach. As of fall 2007, we have reached roughly 400 scientists through our workshops on "Scientific Inquiry in the K-12 Classroom" at professional meetings, laboratories, and universities. The project goals and our model for helping scientists to become more effective in working with students and teachers will be described. Evaluation results from pre- and post-workshop surveys of participants demonstrate that the workshops are effective in broadening participants' ideas of their potential role in education. However, they also have ongoing needs for both knowledge and support. We argue that working with education or other public audiences is an increasingly important professional skill for scientists and offer this project as one experiment in providing appropriate professional development for this work.

ON THE EFFICIENCY OF A DISTRIBUTED FORECAST SYSTEM FOR THE SIMULATION OF TROPICAL STORM DRIVEN WAVES AND STORM SURGE

The SURA Coastal Ocean and Prediction (SCOOP) program is developing a prototype distributed coastal laboratory linking sensors, software and computational resources. SURA (Southeastern Universities Research Association) researchers are creating an IOOS to improve forecasts of tropical storm driven waves and storm surge with the eventual goals of improving emergency planning, safe maritime operations, and support of coastal security. As part of the system, ensemble forecasts from atmospheric wind models are distributed to a network of computers where they are then used to drive storm surge and wave models. For initial system prototyping, SCOOP is focusing on the use of an ensemble of 30+ analytical wind and pressure fields which are based on a probabilistic analysis of historical hurricane force events. Results are then cross validated. The atmospheric products are distributed to a series of nodes which are responsible for archiving, cataloging and eventual visualization of the products for use by emergency managers. We will examine the speed, latency and efficiency of the distributed data transport in this overall system with emphasis on its response during real hurricane events.

THE TRI-SPAR: A POSSIBLE OOI GLOBAL-SCALE NODE FOR HIGH-LATITUDE SITES

The OOI Global Network design envisions nodes providing power to seafloor instruments and communications to the shore. Of particular importance are nodes at high-latitudes. Environmental conditions in such locations will make installation and reliable long-term operations challenging. Compared with Alex buoy systems, spar buoy systems provide superior motion characteristics and have been used successfully in the oil industry and for scientific research (FLIP). A modification of the conventional spar design is the Tri-Spar, which comprises three cylindrical columns spaced about three diameters apart, connected by a horizontal spar. As part of the system, ensemble forecasts from atmospheric wind models are used to improve forecasts of tropical storm driven waves and storm surge with the eventual aim of reducing risk to the ocean observing network. SURA (Southeastern Universities Research Association) researchers are creating an IOOS to improve forecasts of tropical storm driven waves and storm surge with the eventual aim of reducing risk to the ocean observing network.

A COMPARISON OF LIGNIN-PHENOLS AND BRANCHED/ISOPRENOID TETRAETHERS (BIT INDEX) AS INDICES OF TERRITAL ORGANIC MATTER IN SURFACE SEDIMENTS

Recent work has shown that the branched versus isoprenoid tetratera (BIT) index is a useful proxy for determining the fluvial inputs of terrestrial organic matter in the marine environment (Hopmans et al., 2004). To compare this new approach with the long-standing CuO method, first introduced by Hedges and Ertel (1982), sediments collected as part of the pre-Antarctic Sea of Meso acid Benthos (DeGOMB) Project were analyzed using both methods, as well as surface sediments obtained from estuarine fords in southwestern New Zealand. The DeGOMB and Fiordland samples represented sediments with expect low and high inputs of terrestrial-derivative organic matter, respectively. The unusually high inputs of terrestrial-derivative organic matter in Fiordland are primarily due to land-slip and steep fiord slopes that mostly occur during high rainfall events; rainfall typically averages 7 m per year in this region.

USE OF POP-UP SATELLITE TAGS TO REFINE KNOWLEDGE OF SWORDFISH FEEDING ECOLOGY ON GEORGES BANK, AN AREA OF FISHERY AND RESOURCE CONCENTRATION.

A three year program to tag North Atlantic swordfish on the northeast peak of Georges Bank, off Nova Scotia, Canada has provided depth profile data of swordfish while feeding. The data indicate that swordfish spend much of their time foraging at depths of between 300 and 600 meters. Stomach samples collected in the same waters have shown that swordfish in this area were feeding on several species of meso-pelagic fish and cephalopods and generally exhibited high feeding success. The homing behaviour clearly demonstrated by satellite-tagged swordfish on Georges Bank indicates that this area is used consistently from year to year, and forms an important feeding site for North Atlantic swordfish. The implications of these observations for management of the stock are discussed.

MULTI-ELEMENT ECOSYSTEM DYNAMICS IN THE SERIES IRON-ENRICHMENT EXPERIMENT: COMPARING FIXED- AND VARIABLE-COMPOSITION VERSIONS OF THE NEMURO ECOSYSTEM MODEL

We model the dynamics of Fe, N and Si during SERIES, comparing a Fixed-Composition (FC) and a Variable-Composition (VC) planktonic ecosystem model and focusing on variations in drawdown ratios and diatom composition. Because nutrient uptake kinetics are key to these two models, we compare the newly developed Upalma Uptake (UY) kinetics to the classic Michaelis-Menten (MM) kinetics. OU kinetics, based on the aclimation of phytoplankton physiology to ambient nutrient concentrations, is similar to the MM equation, but with maximum uptake rate and half-saturation "constant" that both increase with nutrient concentration. When fit to the data, all model versions reproduced well the nutrient and chlorophyll data, but with different patterns of nutrient limitation.
and material flows. Comparing fits started with different initial guesses, the VC model reproduced the observed changes more accurately than the FC model. The different uptake kinetics yielded significantly different biomass of zooplankton (through effects of food quality). In the VC model, MM and OU kinetics yielded very different elemental compositions for phytoplankton. Field data for such changes in composition are needed to clarify multi-element dynamics in the ocean.

AN ANALYSIS/FORECAST SYSTEM BASED ON THE 4DVAR CYCLING REPRESENTER DATA ASSIMILATION METHOD AND THE NAVY COASTAL OCEAN MODEL

This presentation will overview an ocean analysis/forecast system that is being developed at the Naval Research Laboratory (NRL) that employs 4DVAR assimilation to combine ocean observations with the Navy Coastal Ocean Model (NCOM) to obtain an optimal solution that minimizes a cost function containing the weighted squared errors of data, initial conditions, boundary conditions, forcing, and model dynamics. In order to converge to a global minimum, the ocean model (and its adjoint) must be linear. Since NCOM is highly nonlinear, its model dynamics and adjoint are linearized using tangent linearization. The accuracy and stability of this tangent linearized model (TLM) is a very sensitive function of the background accuracy, the level of nonlinearity of the model, complexity of the bathymetry, and the complexity of the flow field. Therefore, in high-resolution coastal domains, which this assimilation system is designed for, the TLM is only going to be stable for a relatively short period of time. To overcome this problem, the cycling representor method is employed to solve the 4DVAR problem by splitting the time period into short cycles that are within the time frame of TLM stability. This cycling assimilation system will be validated for a Mississippi Bight domain assimilating velocity measurements from an array of ADCP moorings.

QUANTITATIVE VERIFICATION OF VIABILITY STAIN PERFORMANCE AND PHOTOSYNTHETIC ACTIVITY IN PHYTOPLANKTON

Recent recognition of the sources and magnitude of phytoplankton cell death have heightened awareness of the importance of measuring algal viability. Fluorochrome stains have the potential to streamline viability measurements for incorporation into ecological studies, toxicological studies, and applied problems such as testing the effectiveness of ballast water treatment, but the performance of these stains under variable conditions remains relatively untested. This study tested the effectiveness of some common viability stains under both controlled laboratory and complex environmental conditions. Flow cytometry was used to detect viability in laboratory algal cultures and a field populations of estuarine cryptophyte algae against a known measure of photosynthetic activity determined from 14C-uptake. Controlled laboratory experiments indicate that fluorochrome methods can be remarkably consistent with side-by-side determinations of photosynthetic activity. However, direct transfer of methods to field samples is not necessarily straightforward. These results suggest that increasingly common fluorochrome methods available for measuring viability should continue to be tested for efficacy before incorporation into studies of phytoplankton dynamics, and that the use of other non-fluorochrome assays should be explored for use in complex natural samples.

THE SHIPBOARD AUTOMATED METEOROLOGICAL AND OCEANOGRAPHIC SYSTEM (SAMOS) INITIATIVE

The status of the shipboard automated meteorological and oceanographic system (SAMOS) initiative will be described. The SAMOS initiative focuses on improving the accuracy and access to quality-assured, high-resolution (sampling rates ~ 1 min.) meteorological and near-surface oceanographic observations collected on research vessels. The SAMOS data assembly center (DAC) and its partners in NOAA and UNOLS have implemented a series of daily data transmission from ship-to-shore using an email protocol. All data arrive at the DAC soon after 0000 UTC and undergo automated quality evaluation. The data review and responses to data demands at sea when problems are identified. All quality evaluated data are freely available to the user community (via http://samos.coaps.fsu.edu). Currently, 12 research vessels are providing routine data transfers. The authors will describe ongoing activities and outline plans to recruit additional vessels, including potential collaboration with voluntary observing ships equipped with automated weather systems. Methods will be discussed to improve metadata retrievals from vessels, expand data distribution, and advance data quality evaluation.

RESPONSES OF BENTHIC MACROFAUNA TO ENVIRONMENTAL STRESSORS: IS THERE A CHARACTERISTIC STRESSOR RESPONSE?

Benthic macroinvertebrates are frequently used as indicators of ecological health and condition in estuaries. Several tools, such as the multimetric Chesapeake Bay Benthic Index (CBI) and the Marine Biotic Index (AMBI) have been developed to assess the condition of estuarine systems based on generalized responses of benthic macroinvertebrates to environmental stress. One of the component metrics of the CBI classifies individual species into pollution tolerance groups based primarily on expert opinion. An implicit assumption in this approach is that tolerance responses are not strongly species-specific and this classification is intended to reduce potential misclassification. For this study, we evaluated Chesapeake Bay benthic macroinvertebrate community composition, water quality, and sediment contaminant data in order to identify relationships between species abundance and specific stressors such as low dissolved oxygens, contaminated sediments and organic enrichment. Identification of stressor-specific responses will lead to more accurate and refined assessments of Chesapeake Bay benthic condition that can be used by resource managers to more effectively identify and remediate disturbed habitat.

BLEACHING DURING UNPRECEDENTED WARM WATER IN THE US VIRGIN ISLANDS AND DEGRADATION WITHIN POTENTIAL REFUGIA

The NE Antilles suffered the worst warm water event on record in 2005. Intensive and extensive monitoring of corals around the US Virgin Islands showed that bleaching was severe; during the peak of the event (Sep-Nov), most corals were bleached (73%, N = 1671) with high severity (50-90%) of the colony surface. During the recovery phase (Jan-May), both the prevalence (33%, N = 1881) and severity (10% - 50%) of bleaching decreased, reaching near pre-bleaching prevalence (20%, N = 1363) and severity (<10%) by June 2006. The prevalence of diseases increased during recovery, from 1% to 7%, due largely to an unprecedented, outbreak of white syndrome, with prevalence increasing from less than 1% to 4%. The combination of these disturbances caused recent partial and whole colony mortality to nearly quadruple in prevalence from 7% (prior to and during the bleaching) to 25% (during recovery). The net effect was a 38% reduction of coral cover over all monitored reefs. As predicted, potential coral reef refugia in deep water (~90 m) adjacent to cooler ocean water did not suffer substantial bleaching (27% prevalence). However, they did experience high prevalence of white syndrome (7%) and loss of coral cover (~22%). This suggests strong, but unobvious, stress on potentially naïve corals or the possibility of the spread of disease from shallow coral populations. Deep reefs may only be a partial refuge from the escalating impacts of increasing tropical SST.

SOUTHERN OCEAN PIGMENTS AND PRIMARY PRODUCTIVITY IN THE SEAWIFS AGE

Sea ice in the Southern Ocean is a major influence on phytoplankton productivity and growth. We used SeaWIFS phytoplankton biomass, PAR and cloud cover data, SIM1 and AATSR sea-ice surface temperature data, in combination with a vertically integrated model, to estimate primary productivity south of 60°S. We found substantial interannual variability in productivity from 1997 - 2005, and this appeared to be driven in part by ice dynamics. The most productive regions of Antarctic waters were the continental shelves, and no large, sustained blooms occurred in waters > 1.000 m. We suggest that this is due to the slightly greater mixed layer depths found in waters off the continental shelf, and that the interactive effects of iron and irradiance result in the limitation of phytoplankton. Annual productivity south of 60°S averaged 23.7 g C m-2 y-1, but yearly means between 1998 and 2004 ranged from 22.1 - 25.5 g C m-2 d-1. Annual primary productivity over the entire Southern Ocean has increased since 1998, and was driven by changes in January and February. Causes for this trend are unclear.

SLENDER SOLE AS BENTHIC ECOSYSTEM ENGINEERS IN SAAINCH INLET, BRITISH COLUMBIA, CANADA

The muddy seafloor at the VENUS Cabled Observatory in Saanich Inlet, British Columbia, supports high densities of the flatfish known as the Slender Sole. In this study, we tested the hypothesis that Slender Sole are potential agents of disturbance for sedimentary fauna. To test their role as ecosystem engineers, we deployed replicate fish exclusion cages (1-m diameter, 15-cm high) at 92 m depth, and sampled macrofauna inside and outside of cages during deployment in May and ~7 months later. Partial cages were also deployed to test for caging artifacts. Macrofaunal composition and abundance of sediment were similar during both sampling periods, however, faunal composition differed and abundances were significantly higher in full exclusion cages than in ambient sediments or partial cages. Nearby VENUS video records reveal continual sediment disrup-

SATELLITE OCEAN DATA VISUALIZATION AND MODELS FOR CLASSROOM EXPLORATION

The NASA-sponsored Ocean Motion website (http://www.oceanmotion.org) documents human kind’s experiences, observations and investigations of ocean surface currents. In addition to the information, resources posted on the website, there are also investigations that lead high school teachers and students to explore patterns and relationships through ocean observation data products with an emphasis on OSCAR (ocean surface current analysis - real time). These data products include color-coded maps, time series graphs and data tables. The investigations are done through an interactive browser interface that provides easy access to a wealth of ocean data. This talk focuses on the use of ocean surface current data and models in classroom tested student investigations. The formal education classroom ready investigations are integrated with existing science curriculum and provide application of basic science principles. Video interviews with oceanographers are positioned in the investigations to illustrate their research and the science topic under investigation. Themes of exploration and adventure tie investigations of patterns in ocean data to human endeavors of the past and future. This connection enriches the content and engages students.

PATTERNS OF PCB DISTRIBUTION IN BIOTA OF PENSACOLA BAY, FL

A spill of Polychlorinated biphenyls (PCBs) was discovered in 1969 in the Escambia River leading to Escambia Bay, Pensacola Bay system, FL. Sediment analyses in 1990’s demonstrated the persistence of these compounds in the Bay. Other areas of known PCB contamination exist in the urban bayous of the system. We have conducted a multiyear screening study for PCBs in harvested biota in the Bay area, including oysters, crabs, croaker, spotted seatrout, red drum, striped mullet, and other finfish. The goal of the study was to assess the safety of these harvested species for human consumption. Results of the work have prompted the State of Florida Department of Health to issue a fish consumption advisory for largemouth bass and mullet from the Escambia River, where muscle tissue samples exceeded 50 Åg kg-1 PCBs. The data also provide some interesting insights into ecological aspects of some of these species, especially with regard to spatial patterns of biota contamination, age and contaminant accumulation models, and accumulation as a function of trophic status. Some species like mullet may have relatively high site fidelity in the estuary, despite an extensive annual spawning migration, and accumulate high levels of PCBs despite a relatively low trophic status. For spotted seatrout, accumulation of PCBs and mercury follow different trends, suggesting contamination dynamics may be species and contaminant specific.

MONITORING THE STORM TIDE OF HURRICANE WILMA IN SOUTHWESTERN FLORIDA, OCTOBER 2005

Temporary monitoring stations employing non-vented pressure transducers were used to augment an existing U.S. Geological Survey coastal monitoring network to document the storm tide of Hurricane Wilma. On October 22, 2005, an experimental network consisting of 30 temporary stations was deployed over 145 kilometers of coastline to record the magnitude, extent, and timing of hurricane storm tide and coastal flooding. Sensors were programmed to record time, temperature, and barometric or water pressure. Water pressure was adjusted for changes in barometric pressure and salinity, and then converted to depth of water above the sensor. Elevation surveys using optical levels were conducted to reference storm tide water-level data to the North American Vertical Datum of 1988 (NAVD 88). Storm tide water levels more than 1.5 meters above NAVD 88 were recorded by sensors at several locations along the southwestern Florida coast. Temporary storm tide monitoring stations have demonstrated their value by allowing the U.S. Geological Survey to extend the scope of data collection beyond that of existing networks, and serving as backup data collection to existing monitoring stations.

NITROGEN FIXATION IN THE NORTH PACIFIC OCEAN: RATE MEASUREMENTS AND SPATIAL VARIATION IN SPECIES SPECIFIC ACTIVITY

Nitrogen fixation is an important contributor to export production in the North Pacific Ocean, as evidenced by seasonally low d15N of sinking organic nitrogen at the Hawaii Time-series station. However, relatively few nitrogen fixation measurements exist in the North Pacific. On two cruises there in fall 2002 and summer 2003, the abundance and nitrogen fixation rate of Trichodesmium spp. and bulk water sampled were measured. Trichodesmium spp. was only detected by our methods in the area near the Hawaiian Islands, in similar densities on both cruises. Despite similar densities, the areal nitrogen fixation rate of Trichodesmium spp. in fall 2002 was nearly four times greater than in summer 2003 at stations it occurred. Near the dateline, where Trichodesmium spp. was not present, the areal water nitrogen fixation rates were relatively high (≈100 micromol N m-2 d-1). Presumably uncellular diazotrophs were responsible for activity there. We hypothesize that higher dissolved iron concentrations near the Hawaiian Islands allow Trichodesmium spp. to grow there, whereas uncellular diazotrophs can be active in the central North Pacific at d15N concentrations as low as 0.1 nm.

INTERMEDIATE CIRCULATION IN THE NORWEGIAN SEA

To study the movement of Arctic Intermediate Waters (AIW) around the Norwegian Sea we deployed 26 isobaric RAFOS floats across the northern slope of the Iceland-Faeroe Ridge. In recent times these waters have increasingly been replacing the Greenland Water in the central Norwegian Sea, to the point where it may be possible to study this water mass in situ to a depth of 3000m. AIW are characterized by lower salinity, higher temperature, low oxygen content, high pH and high heat content. A unique feature of AIW is their high chlorinity, an unprecedented characteristic for a deep water mass. The deep chlorinity is created in the Norwegian Sea by the meridional heat transport through the Denmark Strait Overflow Water (DSONW) and the Arctic Intermediate Water (AIW). The floats moved passively with the current, but did not move along isopycnals. Most of the floats were moved north. The floats were programmed to record time, temperature, and barometric or water pressure. Water pressure was adjusted for changes in barometric pressure and salinity, and then converted to depth of water above the sensor. Elevation surveys using optical levels were conducted to reference storm tide water-level data to the North American Vertical Datum of 1988 (NAVD 88). Storm tide water levels more than 1.5 meters above NAVD 88 were recorded by sensors at several locations along the southwestern Florida coast. Temporary storm tide monitoring stations have demonstrated their value by allowing the U.S. Geological Survey to extend the scope of data collection beyond that of existing networks, and serving as backup data collection to existing monitoring stations.

STUDY OF POTENTIAL EFFECTS OF CLIMATE CHANGE ON THE ECOSYSTEMS OF TEMPERATE SEAS: THE ALBORAN SEA CASE

We study the inter-annual variability of the circulation in the Alboran Sea and its exchanges with surrounding sub-basins from the Western Mediterranean in the frame of SESAME project. We use ROMS forced by a 40 years re-analysis and MFS boundary conditions to identify global change scenarios and for each one, we study the adjustment processes between Modified Atlantic Water (MAW, S < 36) and denser Mediterranean Water (MW, S>37), in particular in the Eastern Alboran area where the Almeria-Oran front is a major dynamical boundary (1.5 sigma + difference) also characterised by a sig- nificant variability. We analyze the dynamical relevance of mesoscale and sub-mesoscale eddies in the different sub-basins, their relation to enhancing or blocking the north/south energy exchanges between sub-basins and the effects on the ecosystem variability using ROMS NPZD model. We also present first results obtained on the impacts of this variability on fisheries using NEMURO coupled to ROMS.

CETACEAN HABITAT MODELING IN THE CALIFORNIA CURRENT SYSTEM

Cetaceans, as top predators in the oceans, can be viewed as indicators of changing oceanographic conditions over annual and decadal time-scales. The physical, chemical and biological environment of the California Current System is spatially and temporally heterogeneous and cetaceans respond to these variations. Cetacean spatial and temporal presence suggests the presence of specific environmental conditions required for their survival which are often related to prey availability, predator avoidance or reproductive needs. Using autonomous High-frequency Acoustic Recording Packages (HARPs), we monitor occurrence of cetacean species at a variety of locations throughout the Southern California Bight with high temporal resolution. Incorporating frontal and near-surface oceanic glider and satellite data collected under CCE-LETTER, we developed generalized likelihood models of dolphin occurrence with respect to oceanographic variables to test hypotheses about the environmental conditions that are important for describing their habitat and likelihood of occurrence. Knowledge of preferred dolphin habitat conditions can be used to predict dolphin occurrence over a heterogeneous oceanic system and conversely presence or absence of dolphins at a given time and location may be used to describe the changing oceanographic environment.

variable fractal dimension instead of fixed one adopted previously is utilized here. For breakup, similar concept is adopted in a more empirical manner because breakup is too abrupt to entirely apply variable fractal dimension. New flocculation model using variable fractal dimension shows a reasonable agreement with experiment results in terms of equilibrium floc size. However, the prediction on temporal evolution of floc size requires further investigation. The flocculation model is coupled into a numerical model for fluid mud transport (Hsu et al. 2007, J. Geophys. Res., 112). The numerical model calculates turbulence quantities with a k-epsilon closure, which are then used to calculate flocculation process. Preliminary results for the effects of flocculation on fluid mud transport in tidal/wave boundary layer are presented.

REMOTE SENSING FOR TSUNAMI RESEARCH AND EARLY WARNING

The key to successful tsunami prediction for saving lives and property during tsunami emergencies lies in the early detection of tsunami generation and its propagation patterns. According to the conventional theory, tsunamis are formed by the vertical deformation of the seafloor during undersea earthquakes. However, numerous false alarms and historical failures in predicting tsunami height indicate that this ubiquitous theory has yet to function effectively. In this talk, I will first show evidence—based on radar altimeter data, GPS displacement measurements and satellite-inferred gravity changes—that the momentum transferred by the horizontal motions of continental slopes is likely the missing force in the conventional tsunami theory. The tsunami propagation patterns are apparently controlled by the horizontal slope motions with asymmetric features with both leading elevation waves and depression waves, and are best explained by the horizontally-forced mechanism. I will then demonstrate how remote sensing in conjunction with the modified theory can be used to detect tsunami genesis and scales for operationally warnings.

THE ESTABLISHMENT OF THE ATMOSPHERE-WAVE-OCEAN CIRCULATION COUPLED NUMERICAL MODEL BASED ON CCSM3

There are several common problems of the coupled ocean-atmosphere general circulation models (CGCMs) without flux correction, such as too cold tongue, reversed zonal SST gradient in equatorial Atlantic, semi-annual cycle in the eastern tropical Pacific. The causes are not well understood yet. One possible reason maybe is the inaccurate reconfi guration of the lower layer and thermocline structure due to the insufficiency of lateral mixing in the OGCM. It is believed that the wave-induced vertical mixing can greatly improve the simulation of the MLD and thermocline. Based on the surface wave-circulation coupled theory, an atmosphere-wave-ocean circulation coupled numerical model was established, which incorporates the MAXNUM wave number spectral model and the coupled ocean-atmosphere general circulation model, CCSM3. The model reveals that the model with wave-induced mixing could simulate the climate system much better than the original CCSM3, such as the improvements on too cold tongue in tropical Pacific, SST deviation in tropical Atlantic and annual cycle in eastern tropical Pacific. The analysis shows that the wave plays a key role in the climate systems. It is suggested that wave-induced mixing improve the performance of climate models on tropical bias. The wave-induced mixing is critically important for climate research and the improvement of the climate system coupled model.

OBSERVATIONS OF WINDabile FLOW CYTOMETRY FOR TIME SERIES OBSERVATIONS OF PHYTOPLANKTON COMMUNITY DYNAMICS

Better understanding of many aspects of plankton ecology requires long term, high frequency observations of community structure, which traditional sampling techniques cannot provide. To meet this challenge, we have developed a series of automated submersible flow cytometers for analysis of phytoplankton. The newest development, Imaging FlowCytobot, includes cell imaging capabilities for microplankton. When combined with automated image analysis and classifi cation, this instrument provides unprecedented time series of community structure with taxonomic resolution (often to genus or even species level). Like its predecessors, Imaging FlowCytobot carries out automated standard analysis and anti-fouling procedures, and it has proven capable of 6-month uninterrupted deployment at the Martha’s Vineyard Coastal Observatory, a cable facility on the New England shelf. We document these capabilities with detailed observations of wintertime diatom blooms measured in 2007. The bloom dynamics are complex with multiple event scales fluctuations in diatom abundance and taxonomic composition over several months. Shifts in dominant genus are evident as the season progresses. Multi-year time series of this type will be key to understanding the regulation of these fluctuations and their response to environmental change.

LAND-REEF AND REEF-REEF CONNECTIVITY IN MESO-AMERICA INFERRED FROM SATELLITE OCEAN COLOR OBSERVATIONS DURING 1998-2006

Weekly time series of Sea-viewing Wide Field-of-view Sensor satellite ocean color images acquired from 1998 to 2006 were used to determine connectivity patterns between land and reefs, and among reefs in the Mesoamerican Barrier Reef System (MBRS). A connectivity matrix was constructed for seventeen domains that cover major reefs in the MBRS and islands off the north coast of Honduras and Nicaragua. Ocean color images were carefully examined, and spatial connections between domains were recorded. The weekly time series of 466 images provided not only a clear view of seasonal distributions of the connectivity patterns, but also evolutions of estuarine plumes and transitions in the aftermaths of major perturbations like hurricanes in the MBRS. For example, river plumes from eastern Honduras reached as far as Chinchorro and Cozumel in Mexico. These results bring new products to be used in quantitatively reassessing long term connectivity in the region and validating fields produced by other modern approaches based on numerical modeling.

WIND WAVES AND SEDIMENT DYNAMICS IN THE INTERTIDAL MUFLATS OF THE ARACOHN LAGOON (FRENCH ATLANTIC COAST)

In intertidal areas protected from oceanic swell, wind waves can play a key role on sedi ment dynamics, as they can be the only forcing able to generate significant erosion. The Arcachon lagoon is a mesotidal lagoon of the french atlantic coast. 74% of its total area is occupied by intertidal flats. There is little knowledge on the effect of wind on local waves. There is also poor evidence on sedimentary balance, excepted for bathymetric charts showing secular trends of accretion of the order of 10 cm/century. Field experiments were carried out in the Arcachon lagoon in order to characterize wind waves and subsequent sediment transport. Ultrasonic altimeters, ADV velocimeters and OBS turbidimeters were deployed over two months during the winter of 2007. Collected data showed that the surface winds higher than 8 ms^{-1} can generate wind waves of more than 10 cm high. They also gave evidence of an increase of the wave height when tidal currents and wind are in the same direction. In terms of sedimentary forcing, bottom shear stress generated by wind waves is 10 times higher than shear stress generated by tidal currents. Altimeters recorded an erosion of the muddy bed of 1 cm caused by wind waves of a significant height of 40 cm. In the absence of wind, stabilisation occurs and the mudflat tends to recover its initial altitude. These results confirm that in these sheltered mudflats, erosive action of wind waves is effective as an opposite factor to the tidal action.

CO-OCCURRENCE OF PHOTOSYNTHETIC AND NITRIFYING COMMUNITIES IN CARIBBEAN SPONGES: IMPLICATIONS FOR MICROBIAL INTERACTIONS AND NUTRIENT CYCLING

We investigated the occurrence of nitrifying and photosynthetic microbial communities in sponges on Conch Reef, Florida, USA. Results from DIN flux measurements, chemical inhibition, and 15N tracer experiments with Caribbean sponges show that 12 of 18 species tested hosted nitrification. Of those 12 species, 9 also contained elevated photosynthetic pigments in their outer tissue, indicating photosynthetic microbial associates. Profiles of oxygen concentrations indicated extremely hypoxic tissues in many of the 12 species, a condition that could limit nitrification. Under hypoxic conditions photosynthesis in the outer tissue may partially alleviate oxygen limitation and enhance nitrification rates. Conversely, if ammonia is limiting, then ammonium assimilation by photoautotrophs may decrease nitrification rates. The number of sponge species hosting nitrification and photosynthesis suggest that these processes are important aspects of sponge metabolism. However, little is known about nitrifiers regarding the metabolic exchanges with the host, or with other members of the microbial community. These interactions may be important for sponge nutrition, and they may also mediate the considerable flux of dissolved inorganic nitrogen released by sponges.

UV-B TOLERANCE OF TWO ANTARCTIC HETEROTROPHIC PROTISTS, THE CILIATE URONEMA MARINUM AND NANOFLAGELLATE PARAPHYSOMONAS IMPERFORATA

Biologically harmful ultraviolet-B (UVB) radiation is increasing during austral spring in Antarctic waters due to seasonal ozone loss. Many organisms have known photoenzymat-

ic repair (PER) ability that offsets UV-B induced DNA damage in the presence of a photo-
terapire view (PBR), 320-700 nm). Photosynthetic, which are important links in aquatic food webs, have varying PER abilities and sensitivity to UV radiation. We determined the UVB tolerance of the ciliate, Uronema marinum, and the heterotrophic nanoflagellate, Paraphysomonas imperforata. Paraphysomonas imperforata with and without UV acclimation and in the presence and absence of PBR. Both species, isolated from the Ross Sea, were sensitive to UVB radiation as demonstrated by decreasing abundance after UVB exposure. Acclimation to low levels of UVB and UVA radiation increased resistance of both species to higher levels of UVB exposure. However, removal of PBR did not significantly alter maximum abundances with or without acclimation, indicating that neither species uses PER to repair UV-B induced DNA damage. We suggest that sensitivity to UV radiation may, in part, prevent these species from reaching high abundance during austral spring, which has implications for microbial trophic interactions.

QUANTIFYING PARTICLE TRANSPORT IN THE COLUMBIA RIVER PLUME

Vessel data collected by the RISE (River Influences on Shelf Ecosystems) project, which sampled the Columbia River plume, have been used to analyze plume-related particle transport. High resolution data show a source of particles in addition to that discharged with the river. Specifically, we find that tidally forced particle resuspension occurs and can be a dominant source of particles during summer low flow river conditions. This resus-

pension can provide a pathway for nutrients and contaminants to be brought up to the surface and thereby impact the coastal ecosystem. A combination of acoustic and optical backscatter (ABS and OBS, respectively) instruments along with bottle samples and in-situ particle size and volume concentration data has been used to derive information about the particle field. ABS is more sensitive to larger particles, whereas the OBS is more sensitive to smaller particles. By using bottle samples and particle size and volume concent-

TURBULENCE PROCESSES IN A MACROTIDAL ESTUARY.

Turbulence processes are important for the vertical transport in estuaries and shelf seas; they control the exchange of momentum, density and SPM. We have deployed a third gen-

eration Sediments Transport And Boundary Layer Equipment (STABLE III) at the mouth of the Dee Estuary, a macrotidal estuary in the Irish Sea with tidal range of the order of 10 m, where quarter-diurnal tidal TKE production is evident; there is also indirect evidence that forced convection from the converging part of tidal straining might be important. STABLE III is equipped amongst other things with 3 ADVs and three fast Sampling CT systems, which will allow us for the first time to calculate the full evolution of Turbulent Kinetic Energy (TKE) in the bottom one meter of the water column, e.g. total TKE, pro-
duction, dissipation and buoyancy turbulent fluxes. These in conjunction with an ADCP which measures the production and dissipation for the rest of the water column will allow us to understand how turbulence behaves in estuaries and discern any the effects from tidal straining convection and forced convection.

ASLO/AQUATOS/ERF
an important role near the main fronts of the ACC. The new estimate of kapa allow us to also revisit the estimate of the eddy induced advection through the parametrization of Gent and McWilliam (1990). Below the mixed layer, we find a convergence of the 2-d upper cell centered on the Polar Front. However, we have also shown that one can get a large range of results when working within the 2-d framework. Eddy diffusivity in the Southern Ocean has been estimated from several approaches in order to quantify the role of eddies on mixed layer heat and mass budgets, and to get the role of eddies on the upper cell of the meridional overturning circulation. Estimates were made with surface drifters. The pattern and the order of magnitude of kapa is compared to other studies. We consider the upper cell in a 3-d framework, unveiling strong inhomogeneities of the upper cell convergence. We estimate a proxy of the convergence by computing a budget of transport in the mixed layer based on observational data and mixed layer parameterizations.

MORE THAN A PIPELINE: COLLABORATIVE STRATEGIES KEY FOR A MORE DIVERSE WORKFORCE

The ocean sciences community is challenged to achieve a diverse and highly trained workforce for the future. Programs that target youth, teachers, science educators, and scientific writers need to go beyond the end-of-the-loop—not a pipeline, which reinforcing research and documents on diversity and science. Support for research in the ocean sciences demands an ocean literate public. The Centers for Ocean Sciences Education Excellence, funded in large part by the NSF, is charged with providing and promoting model programs leading to increased diversity in the ocean sciences workforce. This proposal focuses on how COSEE England and COSEE New England used an aquarium to attract, convert, and retain students from underrepresented populations to ocean themes and careers. The goal is to develop a model for other informal institutions. COSEE Southeast has integrated multicultural pedagogical methods into professional development programs designed for teachers with ethnically diverse student populations. Key strategies include inclusive strategies in planning and partnerships, program design, recruitment, and retention.

REDUCTION OF DIMETHYL SULFOXIDE BY MARINE PHYTOPLANKTON

Dimethyl sulfoxide (DMSO) is a trace gas produced by marine algae that comprises nearly the entire ocean to atmosphere flux of reduced sulfur. Despite this large flux, the production and removal pathways of DMSO are poorly understood. The primary loss pathways of DMS in the ocean are often photolysis or microbial uptake to form, in part, dimethyl sulfide (DMSO), a potential antioxidant compound. A potential pathway for DMSO removal is biogenic reduction to DMS, which has been documented in a number of organisms, most notably bacteria. We present the first detailed study of DMSO reduction by marine phytoplankton in axenic cultures. Reduction of DMSO was observed in three algal classes, with in vivo rates ranging from 0.256-3.85 fmol/cell/day at 1 mM DMSO. Michaels-Menten kinetic parameters (K_m and V_max) were estimated for three species, and the time course of DMSO reduction activity monitored. Enzyme affinities (K_I) for DMSO reduction were low with values between 0.373-2.36 mM. The ability of marine phytoplankton to reduce DMSO to DMS has implications for how algae utilize cellular DMS, particularly as part of an antioxidant system.

RESOURCE AVAILABILITY, BIODIVERSITY, AND TROPIC STRUCTURE AFFECT NUTRIENT DYNAMICS IN AN EXPERIMENTAL SEAGRASS ECOSYSTEM

Coastal habitats are influenced by fluctuations in resource availability and biodiversity that affect ecosystem processes, such as productivity and nutrient cycling. Using eelgrass (Zostera marina) habitat as a model system, we assessed the influence of two common disturbances, eutrophication and predator removal, on nutrient dynamics. We manipulate food chain length (i.e. predator presence), invertebrate grazer richness and trophic levels to influence nutrient dynamics in marine sedimentary ecosystems. Spilster, K. D., Oregon State University, Corvallis, USA, kspilster@coas.oregonstate.edu; Holman, R. A., Oregon State University, Corvallis, USA, holman@coas.oregonstate.edu

The RELATIONSHIP BETWEEN 2D CIRCULATION AND SEDIMENT TRANSPORT DURING ONSHORE SANDBAR MIGRATION EVENTS

Sandbars, which act as natural buffers to the beach against wave action, move onshore and offshore in response to changing wave conditions. The transport processes associated with sandbar migration are complex and involve feedback mechanisms between the bar and the fluid forcing [Plant, et al., 2001]. Understanding the relationship between an existing sandbar and sediment transport of California that are induced by that bar is key to being able to predict the natural cycles of sandbar evolution. Plant et al. [2001] were able to invert changes in the alongshore averaged bathymetry to determine unique relationships between the existing bathymetry and sediment transport based on the cross-shore integration of the 1D continuity equation. Sandbars, however, are rarely 1D [Lippmann and Holman, 1994] and the extension of the bathymetry inversion method to 2D is not simple. The technique has two unknown variables (Qx, Qy) and one observable (depth change). A further constraint is needed in order to uniquely invert bathymetry into sediment transport patterns. Plant et al. [2006] found a strong link between alongshore variability of the bar and it’s position, suggesting 2DH circulation may be an important factor in sandbar migration. A 2DH wave-phase-averaged circulation model is used to examine the relationship between current velocities and local bathymetry gradients in order to define the relationship between Qx and Qy in the bathymetry inversion technique.

EVALUATION OF THE REAL-TIME OCEAN FORECAST SYSTEM IN FLORIDA ATLANTIC COASTAL WATERS

The Real-Time Ocean Forecast System (RTOFS) is validated for the nearshore Atlantic coastal waters of southeast Florida. In situ data were collected as part of a summer undergraduate ocean cruise project conducted by the Florida Institute of Technology (FIT) Department of Marine and Environmental Systems (DMES) and includes ocean temperature, salinity, and current speed and direction. Data were collected in the vicinity of the western boundary of the Gulf Stream during early June 2007. RTOFS forecasts are compared to these data as well as buoy data provided by the National Data Buoy Center (NDBC). Insight from these comparisons provided a basis for further evaluation of RTOFS during Fall 2007 in terms of spatial and temporal biases.

ENVIRONMENTAL INFLUENCES ON EARLY LIFE HISTORY TRAITS AND POPULATION CONNECTIVITY

Population connectivity of benthic marine organisms depends on larval transit through the ocean as well as successful settlement and survival of young recruits. Thus environmental and oceanographic processes have the potential to play a significant role in population connectivity through their influence on early life history traits such as larval and juvenile growth, pelagic larval duration (PLD), and size and condition at settlement. Examination of these traits in the common coral reef fish Thalassoma bifasciatum at two geographic locations reveals how contrasting oceanic conditions (periodic passage of low-salinity North Brazil Current rings near Barbados, West Indies, and seasonal water temperature variation in the Florida Keys) can lead to differences in early life history traits. Not only can such environmental conditions determine the length of time larvae have to disperse to suitable settlement habitats, but by influencing larval condition at settlement, the hydrodynamic environment experienced by larvae can also affect early survival of recruits.

A NESTED MODEL OF THE OREGON COASTAL TRANSITION ZONE: SIMULATIONS AND COMPARISONS WITH OBSERVATIONS DURING THE 2001 UPWELLING SEASON

The Oregon Coastal Transition Zone (CTZ) extends several hundred kilometers offshore where shelf flows interact with the California Current. A limited-area model based on ROMS has been developed to study coastal circulation processes over the shelf and in the CTZ. The ~3 km resolution CTZ model obtains its initial and boundary conditions from a lower resolution (~9 km) regional circulation model of the California Current System (NCOM-CCS) and obtains its forcing from a regional atmospheric model (COAMPS). Nested model solutions during May through October 2001 are compared with extensive
in situ and remotely sensed observational data, primarily from the COAST program, to evaluate the impact of boundary and initial conditions. The best model solution skillfully hindcasts variability in shelf flows near 45N due to coastal trapped waves because the CTZ and atmospheric models resolve the strong wind forcing region south of Cape Blanco (43N). Also in that vicinity, the coastal jet separates and forms eddies which move westward, enhancing kinetic energy in a region extending 300 km offshore. The effect of this separation process on shelf/open ocean exchange is quantified.

THE INDOONESIAN THROUGHFLOW IN THE OUTFLOW PASSAGES AS MEASURED BY INSTANT

A 3-year time series of flow through the 3 major outflow passages between the Indonesian Seas and the Indian Ocean is described based on direct moored measurements as part of the INSTANT program. The mean flow along the sill in all passages is towards the Indian Ocean except for a weak near-bottom inflow into the deep Timor Trench. Each passage has a distinct vertical shear profile and carries different components of the total Throughflow. While Lombok and Ombai Passes share similar variability at the intra-seasonal and seasonal timescales, Timor Passage is very different. The seasonal variability shows complex vertical phasing in all passages, likely reflecting the competing effects of local and remote forcing. Our preliminary record-long averaged transports for Lombok are 2.2 Sverdrups and for Ombai 3.3 Sverdrups and Timor 7.6 Sverdrups, giving a total 3-year outflow average of about 13 Sverdrups into the Indian Ocean.

SUREZONE DRIFTER DISPERSION DURING THE HB06 EXPERIMENT

Nearshore waves and currents transport and mix runoff pollution that often drains directly into the surfzone. However, tracer dispersion in the surfzone is poorly understood. Rates of horizontal dispersion in the nearshore (within a few 100m of the shoreline, depths less than about 5m) are estimated using drifter observations obtained during the HB06 field experiment (Fall 2006) at Huntington Beach CA. A cross-shore transect of current meters and pressure sensors provide wave and current measurements. The bathymetry was surveyed repeatedly. GPS-tracked drifters released for several days on each of 5 days with different waves, currents and wind. Drifter trajectories and numerical simulations suggest that complex circulation features, including long-lived surfzone eddies and transient rip currents, contribute to mixing on spatial scales of 10-100m. Drifter dispersion statistics within and seawards of the surfzone, and on different days, will be compared and contrasted. The dependence of eddy diffusivities on waves and currents, and the mechanisms of dispersion (e.g. individual bores, shear waves) will be discussed. This work is supported by ONR, CA Seagrant, CA Coastal Conservancy, NOAA, and NSF.

DEMONSTRATION AND COMPARISON OF SEQUENTIAL APPROACHES FOR ALTImETER DATA ASSIMILATION IN HYCOM

Several sequential assimilation schemes have been developed for HYCOM as part of the NOPP-sponsored HYCOM-GODAE project. These schemes differ primarily in their specification of the background error covariance matrices which is either prescribed empirically as in the multivariate optimal interpolation or generated from statistical analysis of model output as in the Ensemble Optimal Interpolation, Reduced Order Singular Evolutive Filter and the Reduced Order Information Filter. In these schemes, the downward projection of surface information depends on the nature of the background error covariance matrices and is either dynamical or statistical. In this work, the above mentioned data assimilation approaches are compared and evaluated by performing twin experiments assimilating synthetic altimeter data into a 1/12 degree resolution HYCOM configured for the Gulf of Mexico. The evaluation is performed by analyzing forecast and nowcast skill at two times of innovations and residuals and the general consistency of assimilative model solutions.

THE RAPID CLIMATE CHANGE PROGRAMME (RAPID) – LATEST RESULTS AND FUTURE PLANS

In order to determine whether changes in the North Atlantic meridional overturning circulation (MOC – and so the thermohaline circulation, THC) are occurring, ring-dated deep water is being carried out to global warming, in 2004 the UK RAPID programme (working with US scientists) deployed observational arrays across 26.5E to and along the western margin of the basin. The continuous monitoring of the MOC allows its variability to be measured for the first time and possible changes to be determined. The data from the first year of deployment of the 26.5E array indicate that the MOC is highly variable. The initial results from the array along the western margin show the propagation of signals in the deep western boundary current (DWBC). The DWBC is part of the lower limb of the MOC / THC and the means by which changes further north in the Atlantic propagate south. In conjunction with these observational studies, modelling and analysis of satellite data is being carried out to improve understanding of the processes and mechanisms by which the MOC / THC may be changing. This paper describes latest results that have been obtained by the RAPID programme and describes plans for future work.

SCIENCE MADE ACCESSIBLE - AN OVERVIEW OF THE SCHOOL OF ROCK

In 2005, teachers experienced a pilot professional development program at sea in the successful JORC School of Rock (SOR) expedition led by a team of research scientists and education specialists. In 2006 the vehicles and audiences are more diverse; this program has evolved to include more professional development at institutions and as part of a competitive NSF-funded program for enhancing undergraduate education. The success of the evolving SOR program stems from synergy which results when research scientists and educators pool their combined skills and resources to make scientific data accessible to classrooms from middle to graduate school levels. This synergy is mutually important to researchers and educators, such as climate change, tectonics, evolution, and geologic time, and the international and interdisciplinary nature of scientific investigation are developed into educational units by team leaders and participants. Exercises are anchored in fundamental practices and discoveries of scientific ocean drilling research programs. This authentic data approach teaches the classroom to original scientific research in a high impact way. An overview of the program evolution, pedagogy, and the products of the SOR will be presented.

ENERGY DISSIPATION OF LARGE AMPLITUDE NONLINEAR WAVES IN THE SOUTH CHINA SEA

Data collected during recent field deployments in the South China Sea has been preliminarily analyzed, and reveals previously undocumented turbulence and dissipative properties of the large-amplitude internal waves generated in the Luzon passage. As previously documented in many studies, these waves propagate westward towards the continental shelves of China and Vietnam. In deep water, these waves are soliton-like depression anomalies in the thermocline, with vertical displacement amplitudes of order 100 m. The waves propagate with a coherent structure across most of the basin, breaking into trains of depression waves only after considerable shoaling, typically shoreward of the shelf break. However, our microstructure surveys found that turbulent kinetic energy dissipation rates were enhanced throughout the continental slope region, extending from the 1000-m isobath to the shelf break. Surprisingly, dissipation levels occurring in relatively deep water on the continental shelf were larger than those on the continental shelf. This is in contrast to coastal regions, such as the New Jersey shelf and Massachusetts Bay, where nonlinear waves are typically most dissipative in the shallow waters of the coastal zone. Our measurements suggest that the first-order closure of the energy budget for Luzon generated waves occurs primarily in water deeper than 100 m.

CONTRIBUTION OF CALCIFICATION TO THE CARBON BUDGET IN THE GULF OF Maine

Ocean acidification is a global concern the effects of which will likely impact calcifying ecosystems in this region. In this work we examine the degree to which calcification and calcite dissolution are a control on the dissolved inorganic carbon (DIC) in Gulf of Maine surface waters. A knowledge base is needed against which to measure the impact of acidification on pelagic productivity. Estimates of DIC and calcium carbonate production are compared to primary production data. Such knowledge is necessary for a baseline against which we can measure the impacts of ocean acidification on ecosystems in this region. In this work we examine the degree to which calcification and calcite dissolution are a control on the dissolved inorganic carbon (DIC) in Gulf of Maine surface waters. A knowledge base is needed against which to measure the impact of acidification on pelagic productivity. Estimates of DIC in the Gulf of Maine have been inferred using a suite of TA and pCO2, Ca2+ and Sr2+ measurements. Assuming changes in TA are attributable to Ca2+ dynamics only, we estimate the contribution of calcite production and/or dissolution to the carbon budget. Our methods are applied to a Gulf of Maine dataset (2004-2007) to demonstrate seasonal variations that calcite dynamics impose on DIC2- stocks. Data from the NOAA-GOMECG cruise (2007) provides a broad-scale synopsis of spatial variations of DIC2-.
Finally, we use the basic framework to argue that the spatial variability of the divergence mediating vertical mixing is greater than that of the convergences, so that spatial variation in layer thickness or intensity will be governed by inhomogeneous mixing events created by local instabilities and turbulent patches.

SPATIAL AND TEMPORAL INPUTS OF FRESHWATER AND SUBMARINE GROUNDWATER DISCHARGE TO A SUBTROPICAL ESTUARY USING GEOCHEMICAL TRACERS, BISCAYNE BAY, SOUTH FLORIDA

Biscayne Bay is a coastal estuary in Southeast Florida that historically has received significant quantities of fresh submarine groundwater discharge. Water management practices in the region have reduced these inputs. In an effort to differentiate the freshwater inputs to the bay, samples of precipitation, canal water, groundwater, and bay surface water, were collected from July 2004 to July 2006 and analyzed for salinity, stable isotopes of O, and H and Sr2+/Ca2+ ratios. These tracers were used in three mixing models and then combined to trace the magnitude and timing of the fresh water inputs to the estuary. The modeling results indicate rainfall dominating freshwater inputs in the wet season with the ratio of canal-precipitation-groundwater inputs of 30%-60%-10%, respectively. In the dry season canal inputs almost equal precipitation with the ratio of canal-precipitation-groundwater inputs changing to 40%-45%-15%, respectively. For a bay wide water budget that includes saltwater and freshwater mixing, fresh groundwater accounts for 2% of the total input. However, most groundwater inputs occur along the western shoreline of the bay, while precipitation dominates in the eastern portion of the bay.

DETERMINING THE GEOSTROPHIC OCEAN CURRENTS AND EDDIES FROM NEXT GENERATION ALTIMETER MISSIONS.

Knowing ocean surface currents with high space-time resolution is of importance for many oceanographic applications. In the past, however, the direct determination of surface geostrophic currents from space-borne data was hampered since only along-track sea surface height data are available from a single satellite at its nadir foot print. This situation will potentially change with the advent of a wide-swath altimeter. This paper will discuss the need for velocity observations on space scale of the order of 10 km, will discuss necessary sampling scenarios and will review potential future applications of next-generation wide-swath altimeter data. The mission will be guided by understanding surface geostrophic currents as they emerge from the tandem TOPEX/JASON altimeter mission from which geostrophic surface velocities are available simultaneously in horizontal and meridional direction and with 10 km along-track resolution. Highlighted application will range from the seasonal and interannual variation of eddy kinetic energy, to seasonal changes of the flow field to statistical evaluations of the resulting flow field.

A TIME-SERIES OF FIVE NOBLE GASES AND TRITIgenic HELIUM-3 AS TRACERS FOR BIOGEOCHEMICAL CYCLES

The five noble gases are biologically and chemically inert, have a wide range of solubilities and diffusivities, and thus respond differently to physical forcing. We present a time-series of the five noble gases and the isotope 3He, measured in the Sargasso Sea with monthly resolution at the Bermuda Atlantic Time-series Site (BATS). We combine the noble gas time-series data, hydrographic data, and a one-dimensional vertical mixed layer model (a modified Price-Weller-Pinkel model) in order to quantify air-sea gas exchange processes. We constrain the magnitude of diffusive gas exchange to ±6% and air injection processes to order ±15%. Additionally, the time-series of 3He, tritium, oxygen, argon, and nutrients is used to constrain upper ocean biological production. Specifically, we use the helium flux-gauge technique to estimate new production, apparent oxygen utilization rates to quantify export production, and euphotic zone oxygen cycles to determine net community production. The concurrent use of these three methods allows examination of the relationship between the types of production and begins to address some apparent inconsistencies in the elemental budgets of carbon, oxygen, and nitrogen.

FIELD OBSERVATIONS OF A WAVE-FORCED, SUSPENDED MUD LUCITOLINE ON THE INNER SHELF

During the last week of a bottom boundary layer experiment at the Monterey Inner Shelf Observatory late in the 2006 summer, a suspended mud layer moved across the 12m deep observation site. Continuous 16 Hz sampled, 1cm vertical resolution measurements of the three component velocity field were made with a Biotaic Coherent Doppler Velocity and Sediment Profiler during the experiment, capturing the turbulent, wave and mean velocity structure spanning the suspended mud layer. A spectral analysis of the velocity structure up from the sandy bed during the advection of the mud layer reveals a deep, highly dissipative boundary layer across the 0(1cm) height of the lutocline. Enhanced
vertical velocities at the dominant surface gravity wave frequency with a phase lag of up to 60 degrees were observed on top of the mud layer relative to the free stream velocity. Comparisons with force-rafted luteline models will be made.

NUMERICAL AND EXPERIMENTAL MODELLING OF THE INTERNAL TIDE NEAR A CONTINENTAL SLOPE

We have investigated the generation and nonlinear dynamics of the internal wave field resulting from the interaction of the barotropic tide with a continental slope (the so-called internal tide). A joint experimental and numerical approach is used for this purpose. Laboratory experiments were carried out on the Coriolis platform in Grenoble, France, while the finite-volume non-hydrostatic numerical code developed at MIT was used to closely model the experimental set-up. The configuration addressed in the present paper is that of a uniformly stratified fluid in a two-dimensional geometry (i.e. the fields do not depend upon the along-slope direction). In this simplified situation, the internal wave field organizes as a rectilinear wave beam with tidal frequency. We shall address the generation mechanism and structure of the wave beam, relying on theoretical modelling of internal wave emission by an oscillating cylinder. We shall also investigate the nonlinear dynamics of the tide, when harmonics are generated. Energy balance will eventually be considered along with the quantification of mixing induced by the internal tide.

CONSERVATION GENETICS OF REEF CORALS AND GIANT CLAMS AT THE CENTER OF MARINE BIODIVERSITY

Climate change mediated sea surface temperature fluctuations can devastate coral reef communities by breaking down the delicate symbiosis between marine invertebrates and their endosymbiotic algae, Symbiossion. Recovery from this disassociation, or bleaching, depends on the adaptation or acclimatisation of surviving adults, in essence their ability to harbor more heat tolerant symbionts. Recovery is also dependent on the successful settlement of juveniles from unaffected reefs. We have undertaken genetic surveys in two highly endangered invertebrate taxa, specifically: Pocillopora sp. and giant clams (Tridacna), in one of the world's most biodiverse marine regions, West Papua, Indonesia. Significant variation exists in the spatial distribution of Symbiodinium communities among reefs. There are also significant differences between the genetic patterns of coral populations, which are highly connected by gene flow, and clams which show significant regional genetic structure. These data allow us to assess the impact of climate change on connectivity and coral reef recovery and give insight into the long term stability of coral reef populations in West Papua. These information are currently being applied to conservation management in the region.

THE OSTIA MULTI-SENSOR, HIGH RESOLUTION SEA SURFACE TEMPERATURE ANALYSIS

The increased availability of high quality satellite measurements of sea surface temperature (SST) has made it feasible to create a near real time analysis combining multiple sensors. The Operational SST and Sea Ice Analysis (OSTIA) system has been developed at the Met Office to take advantage of these observations and is described in detail here. The output is a daily analysis with a resolution of 1/20° (~6km) combining an SST and sea ice concentration product, which is generated in near-real time. The analysis has been designed to meet the needs of applications requiring high-resolution space-time scales including global numerical weather prediction (NWP) and operational ocean models and to prepare for future high-resolution global and regional forecast systems. The analysis is now being used within the operational weather forecast model at the Met Office. Quality control, data filtering and dynamic bias correction within the OSTIA system allow the various contributing sensors to be combined into a homogeneous analysis. Results of validation and intercomparison will be presented, showing the accuracy of the OSTIA product.

NATURAL ISLAND IRON FERTILISATION IN THE SOUTHERN OCEAN: COMPARISON OF IRON SOURCES AT CROZET AND KERGUÉLEN

The Kerguelen (KEOPS) and Crozet (CROZEX) studies collected data on Fe supply to surface waters around these islands and the resulting blooms. The KEOPS work focuses on vertical diffusion and advective supply from an isolated shallow plateau to the bloom zone above, whilst CROZEX considers the horizontal advection of iron away from the island system source as well as upwelling and atmospheric terms. Both studies show a significant supply of Fe to the upper water column and when light and macro nutrients allow, the observed bloom can develop. The underlying iron-delivery processes will be compared. Whilst overall a similar story emerges from both studies, many details in the processes involved are unclear (e.g. over winter build up of Fe, cycling of Fe and C in the upper water column and possible decoupling), and the potential impacts of these mechanisms are explored here.

NOAA'S OPERATIONAL OCEAN COLOR PRODUCTS FROM THE COASTWATCH OKEANOS SYSTEM

NOAA generates near real-time operational ocean color products using the CoastWatch Okeanos system. CoastWatch ocean color products are used to determine the location, extent, and potential for development or movement of harmful algal blooms, and are accessed via the web or FTP. CoastWatch operational ocean color products are derived from the Okeanos system include daily mean chlorophyll a concentrations, remote sensing reflectances (Rrs) at 670 or 667 nm, and chl_a and Rrs anomalies from a 61-day mean. These products are generated in CoastWatch hierarchical data format (CW HDF) for continental U.S. coastal regions covering about one third of the globe. Okeanos processes ocean color data daily from a primary data source, SeaWiFS (Sea-Viewing Wide Field-of-View Sensor)/OrbView-2, and a backup data source, MODIS (Moderate Resolution Imaging Spectroradiometer)/Aqua. Ocean color data from MODIS/Terra are no longer processed, because ocean color products from this data source were not of sufficient quality to generate operationally. In 2008, NOAA plans to add the capability to process data daily from another ocean color sensor, MERIS (Medium Resolution Imaging Spectrometer)/Envisat, to mitigate the risk of losing either operational data source.

DETERMINATION OF SUSPENDED QUARTZ AND AMORPHOUS SILICATE CONCENTRATIONS NON-DESTRUCTIVELY BY X-RAY DIFFRACTION

Determination of the silicon budget in the oceanic system involves accounting for particulate silicon dioxide: both quartz (crystalline) components from river input or sediment reus-}
and for parameterizing turbulence along the equator will be discussed. Equatorial stations of the TAO/TRITON array. Results will be compared with direct estimates of eddy viscosity of the EUC using an inverse model based on linear dynamics. The method is first which are an important driver of climate. The dynamics of the EUC are strongly constrained by current system. It feeds equatorial upwelling and affects variations in sea surface temperature, the Pacific Equatorial Undercurrent (EUC) is a key component of the complex equatorial

**ECOLOGICAL RELATIONSHIPS OF MARINE MICROBES DESCRIBED THROUGH INTERACTION NETWORKS AT THE SAN PEDRO CHANNEL, CALIFORNIA.**

Microorganisms are central to all global biogeochemical processes, but determining the ecological relationships among microbes in natural complex systems, like the sea, is a daunting task that has not been realized despite remarkable advances in this field. A systems biology approach was applied to data collected on community composition (genetic cultivation independent) of Bacteria, Archaea, Protists, and environmental parameters monthly over 3 years at the San Pedro Ocean Time Series, to show mathematical relationships among the microbes. Correlations lagged in time were found by a procedure called local similarity analysis. The resulting interaction network showed, for example, which organisms co-occurred with and without time lags, resembling a succession of microbial guilds that included different members of important groups like the SAR11 cluster and marine cyanobacteria. Negative correlations, perhaps suggesting competition or predation, were common. The networks we observed shared many features with other studied biological networks. Overall, this is a promising new approach that will not only facilitate inclusion of complex microbial assemblages in community ecology studies, but may also assist in determining biogeochemical roles of otherwise unknown microorganisms.

**DEGRADATION RATES OF EXTRACELLULAR ENZYMES IN POLAR AND SUBTROPICAL SEAWATER: IMPLICATIONS FOR BIOAVAILABILITY OF HIGH MOLECULAR WEIGHT ORGANIC CARBON**

Heterotrophic microbes rely on extracellular enzymes to access high molecular weight organic matter. Degradation rates of these enzymes help to determine the amount of substrate a microbe can receive from the production of such an enzyme. We have assessed degradation rates of xylanase, alkaline phosphatase, and leucine aminopeptidase in arctic seawater (Kongsfjord, Svalbard), coastal subtropical seawater (coastal Gulf of Mexico), and open-ocean subtropical seawater (offshore Gulf of Mexico). We have also assessed the relative importance of photochemical reactions, thermal degradation, and hydrolysis of extracellular enzymes by microbial proteases in setting those degradation rates. Production of extracellular enzymes requires a substantial "investment" in carbon, energy and nutrients. Even when an enzyme substrate is present in the environment, enzyme degradation rates may determine whether that substrate can be "profitably" hydrolyzed using extracellular enzymes. Degradation rates of extracellular enzymes may therefore help explain the presence of semi-labile high molecular weight dissolved organic carbon, which may appear bioavailable based on chemical structure but nevertheless remain unconsumed by heterotrophs over a timescale of months to years.

**ESTIMATING VERTICAL EDDY VISCOSETY IN THE PACIFIC EQUATORIAL UNDERCURRENT**

The Pacific Equatorial Undercurrent (EUC) is a key component of the complex equatorial current system. It feeds equatorial upwelling and affects variations in sea surface temperature, which are an important driver of climate. The dynamics of the EUC are strongly constrained by vertical turbulent mixing, for which there are few direct measurements in the equatorial Pacific. The goal of this study is to estimate seasonal to interannual time scale changes in the vertical eddy viscosity of the EUC using an inverse model based on linear dynamics. The method is first tested by comparing estimated and actual viscosity from an ocean general circulation model. These tests indicate that reasonably accurate estimates can be obtained in the high vertical shear zone above the EUC core. The method is then applied to long time series measurements at 4 equatorial stations of the TAO/TRITON array. Results will be compared with direct estimates of vertical viscosity from previous field programs. Implications for understanding EUC variability and for parameterizing turbulence along the equator will be discussed.

Steeghs, A. L. MD, CNRS, Paris, France, steegner@lmd.fr

**CYCLONE-ANTICYCLONE ASYMMETRY OF LARGE-SCALE ISLAND WAKE**

Large-scale flows are known to present a predominance of anticyclonic vortices. For oceanic island wake such asymmetry could occurs when the typical island size L becomes larger than an eddy deformation radius. We have found by means of laboratory experiments performed in a rotating shallow-water layer, that a large-scale wake could strongly differ from the classical Karman street. Indeed, in a frontal geostrophic regime, the Strouhal number strongly increases and could reach a value up to 0.6. Moreover, for some extreme cases, coherent cyclones do not emerge at all, and only an anticyclonic vortex street appears several wavelengths behind the cylinder. The reason is that when linear stability calculations and non-linear numerical simulations we have found a drastic change in the nature of the wake instability when the island size increase. In the classical quasi-geostrophic regime the wake flow is absolutely unstable while in the frontal regime (Re<<1 and R=Di the wake flow becomes convectively unstable. This changing nature of the wake instability explains both the evolution of the eddy-shedding frequency and the asymmetric vortex street pattern.

**Ocean Acidification in the Arctic Over the 21st Century**

About a quarter of the anthropogenic CO2 emitted into the atmosphere is currently taken up by the ocean and modifies ocean pH and saturation states of sea water with respect to calcium carbonate minerals. We investigate the natural variability and projected future changes in pH and in the saturation state of the mineral aragonite using the NCAR carbon-bon-cyle climate model CM2.5-carbon and high (A2) and low (B1) CO2 SRES emission scenarios. The simulated seasonal variability of the aragonite saturation state is small at high latitudes and in the tropics. Deviations from the annual mean in the mid-latitudes of the Northern Hemisphere are as large as 15 to 20% of the mean. The annual mean global surface pH drops from 8.17 to 7.77 by year 2100 in the A2 scenario, with the largest changes found in the Arctic Ocean (reduction of up to 0.50 pH units). Surface waters in the Arctic are projected to become undersaturated with respect to aragonite by year 2040 AD. The impact of climate change on ocean acidification is small in most regions, except for the Arctic Ocean and parts of the North Atlantic.

**A LONG-TERM INCREASE IN ZOOPLANKTON BIOMASS AT THE BERMUDA ATLANTIC TIME-SERIES STUDY (BATS) SITE IN THE SARGASSO SEA**

Changes in zooplankton biomass and species composition over long time scales can have dramatic effects on biogeochemical cycling and transfer of energy to higher trophic levels. We analyzed size-fractionated biomass of mesozooplankton (>200µm) from monthly day and night tows taken in the top 200 m at the Bermuda Atlantic Time-series Study (BATS) site in the oligotrophic North Atlantic subtropical gyre. Total mesozooplankton biomass has doubled over a 12-y period (1994-2006), with higher increases in some...
larger size fractions, and in the nighttime compared to daytime biomass. From 1990-2005 integration of zooplankton cladoceran and copepod biomass and primary productivity ~20%—both significant increases. The mechanisms driving the zooplankton biomass increase are not entirely clear; however, phytoplankton biomass increased most in fall and winter during periods of highest nutrient inputs. The increase in phytoplankton biomass is associated with increased pelagophyte nanoplanckton which may be a better food source for zooplankton than phytoplankton. We discuss these results in the context of long-term changes reported from other zooplankton time series, and the implications of these changes for biogeochemical cycling and food web dynamics.

OBSERVATIONS OF A PLANKTONIC LAYER IN ITS PHYSICAL ENVIRONMENT
The vertical structure and evolution of a planktonic layer observed via in vivo fluorescence in the Gulf of Aqaba, Red Sea, is investigated in the context of local physical conditions: density stratification, shear, and turbulent mixing. The layer is located at approximately 30 m depth (in a 400 m water column), typically spans 5 - 15 m in vertical extent, and has a fluorescence signal as much as two times background levels. The layer feature persists for more than 10 hours in a 24 hour record. Preliminary analysis shows that the layer is located in a region of relatively strong density stratification (buoyancy frequencies of $10^{-5}$ s$^{-1}$) and low turbulence (diffusivity $(10^{-6}$ m$^2$ s$^{-1}$) inferred from coincident temperature microstructure measurements. Elevated diffusivity $(10^{-4}$ m$^2$ s$^{-1}$) associated with the deepening of the surface mixed layer may be tied to the dissipation of the layer. We consider the potential role of various mechanisms (including shear-induced straining and particle buoyancy) in maintaining the layer structure.

CHARACTERISTICS OF CDOM ABSORPTION IN UV AND THEIR APPLICATION FOR THE ADVANCED IOP RETRIEVAL ALGORITHMS
Separation of CDOM and phytoplankton absorptions could be significantly improved if UV data are added to existing VIS - NIR satellite measurements. While current Ocean Color satellites like MODIS and MERIS have no UV bands, relationships connecting the UV reflectance together with VIS reflectance to IOPs can be used to construct useful inversion models. We therefore compare and relate field measurements of CDOM VIS absorption spectra in Georgia waters, Long Island Sound, Peconic Bay and NY Harbor using a WET Labs AC-S instrument with 0.2 nm filter with both VIS and UV absorption of collocated water samples measured using a spectrophotometer. Together with measurements of collocated reflectance spectra (in the VIS and UV) as well as measurements of VIS extinction and absorption spectra, [CHL] concentrations, organic and inorganic TSS components, these results are used to explore the impact of including UV data on the retrieval of IOPs and [CHL]. CDOM fluorescence excitation - emission matrices are also developed and compared for some Metropolitan NYC waters to variability and impact on reflectance spectra. Field results are complemented and supported by Hydrodynamics simulations using synthetic datasets for coastal waters.

TAXON-SPECIFIC BIOGEOCHEMISTRY: THE SINGLE CELL APPROACH
The identification of predominant microbial taxa with specific metabolic capabilities remains one of the major challenges in environmental microbiology, due to the limits of current metagenomic and cell culturing methods. We used an alternative approach to address this problem, by direct analysis of multiple genes in individual microbial cells. Our protocol employs high-speed fluorescence-activated sorting of single cells, their whole genome multiple displacement amplification and subsequent PCR screening as well as genomic shotgun sequencing. We applied this methodology to generate single amplified genomes (SAGs) from individual prokaryote and protist cells collected from oceanic, coastal, and freshwater environments. Prokaryote SAGs were screened for phylogenetic markers (SSU rDNA) and for genes encoding biogeochemically significant enzymes (proteorhodopsins, bacteriochlorophylls, assimilative nitrate reductases, and nitrogenases). Prokaryote SAGs were analyzed for eukaryote and prokaryote SSU rDNA, providing information on taxa-specific protist feeding preferences. Partial genome assembly and annotation were performed on selected proteorhodopsin-containing Flavobacteria. Thus, single cell DNA analyses open possibilities for a wide range of taxon-specific and cultivability-unbiased microbial ecology and biogeochemistry studies.

HIGH-MOLECULAR WEIGHT DOM CHARACTERISTICS ALONG THE CONTINUUM FROM RIVER TO RESERVOIR: A COMPARISON OF CHESAPEAKE BAY AND LAKE SUPERIOR TRANSACTS
Attempts to pin down the overarching characteristics of aquatic dissolved organic matter (DOM) often arrive at mere glimpses into its complex nature due to its inherent chemical heterogeneity and difficulties in isolating sufficient material. Still, sampling several locations along a continuum can infer how DOM changes throughout a watershed. Here we compare two transects traveling from terrestrially-dominated upper-river regions to reservo (a large lake and an ocean) characterized by more autochthonous DOM. The natural DOM samples from surface waters are separated into high and low molecular weight (HMW & LMW) classes using ultrafiltration. Mass balances of both classes using DOC and UV-Visible spectroscopic (UV-Vis) measurements indicate good recovery for sampled and freshwaters systems. The HMW fraction is further characterized using DOC, analysis, UV-Vis, Fourier Transform Infrared spectroscopy and Electro spray Ionization Mass Spectrometry. Data illustrate a shift from terrestrially dominated OM in riverine systems to compositionally different material in open waters. Freshwater and saline transect data indicate common underlying trends to OM characteristics as one moves from waters containing primarily terrestrial DOM toward those with more aquatic DOM sources.

CONNECTIVITY AMONG RESTORED CRASSOSTREA VIRGINICA BARS IN THE SEVERN RIVER ESTUARY: IMPLICATIONS FOR OYSTER RECOVERY EFFORTS
In an effort to improve water quality and enhance the Crassostrea virginica fishery, many oyster restoration bars have been placed in Chesapeake Bay tributaries. Nevertheless, bars containing primarily terrestrial DOM toward those with more aquatic DOM sources.
Successful attachment of macrofuge propagules in the rocky intertidal zone requires that propagules actually arrive at the substrate (settlement). The analysis first considers the small-scale processes occurring at the propagule scale then places these results in the context of long timescale variability in wave forcing due to weather and climate. The non-dimensional scale, developed in terms of a particle Reynolds Number, Reₚ, that depends on both flow and particle scales. Scaling for size, inertia and buoyancy are described in terms of the Reₚ. Settlement mechanisms of several macrofuge species (Dorvillea antarctica, Hormosira banksii and Cystophora torulosa) are compared using direct velocity measurements and placed in context using a twenty year wave hindcast. The forcing is shown to be more closely linked to wave orbital speeds rather than breaker-driven phase speeds, and (negative) buoyancy has the greatest influence, identified through a Buoyancy Travel Ratio (BTR). Differences in these physical scales between the species are only moderate, suggesting supply, mucous and stickiness effects must be considered to fully resolve difference in success.

COASTAL MONITORING: DEVELOPMENTS AND INSIGHTS ON PROJECT DESIGN
Coastal processes occur on a range of time and spatial scales. Monitoring programs that seek to understand those processes must be designed in a manner to capture those signals. Methods for monitoring coastal change have evolved from time-tested observational to automated and remote sensing. However, there are very few long-term data sets of any one site. Emery first described his profiling method in 1961, nearly 50 years ago, and it remains in practice for its simplicity, minimal gear expense and repeatability. Recent studies have correlated profiles with video and other modern techniques to ensure precision and account for weaknesses in the methods. Using examples from the literature and ten years of daily data from the Gold Coast, Queensland, Australia, this paper provides guidance on temporal resolution in coastal monitoring. Analysis indicates that measurements taken monthly are generally sufficient to capture the changes of interest for management concerns regarding seasonal and inter-annual cycles. Extreme changes such as those resulting from storm events will not be adequately covered by this scheme, but must be accounted for in any development or management plan.

THE CELLULAR DISTRIBUTION OF PHYTOPLANKTON 210PO AND 210PB AND MARINE ORGANIC CARBON TRACERS
Polonium-210 and lead-210 were measured on phytoplankton cells rinsed with an oxalate solution to remove surface-bound metals (Tovar-Sanchez et al., 2003). Previous laboratory studies suggest that approximately 50% of the 210Po associated with phytoplankton cells is found inside the cytoplasm (Stewart and Fisher, 2003). Our field experiments indicated that this result may also hold true in wild populations as only 20-30% of the 210Po associated with phytoplankton was removed by the rinse. In addition, vertical profiles of zooplankton were compared with phytoplankton concentrations to determine whether zooplankton grazing on phytoplankton was significant. Remarkably, the concentration per gram of sediment ranged from as much as 1.0E+07 to 4.1E+05 for every gram of sediment. Final results are high performance liquid chromatography (HPLC) found a well-dechlorinating community.

ENHANCED POREWATER DISPERSAL IN SANDY SEDIMENTS SUBJECT TO PHYSICAL FORCING AT KILO NALU OBSERVATORY, OAHU, HAWAI'I
A remotely operated five-channel fiber-optic spectrometer array was used to determine two-dimensional dispersion rates of injected fluorescein tracer under a range of oceanographic conditions and small-scale bedform changes. Experiments were conducted at a water depth of ~10m, and at a sediment depth of 5-10cm during July-October 2007 at Kilo Nalu, a cabled ocean observatory offshore of Honolulu, Oahu, Hawaii. Surface waves during the experiments had significant wave height of 0.4-1.4 m, and periods of 1.9-10 s. Preliminary analyses indicate substantial variability in dye dispersion rates and directions with changes in the prevailing hydrodynamic conditions and the position of sand ripples above the point of dye injection. Hydrodynamic conditions that were monitored included significant wave height, wave period, near-bed current velocity and turbulence. Our results are consistent with those of Hebert et al. (2007), who observed enhanced porewater mixing (as much as 2-3 orders of magnitude faster than sedimentary molecular diffusion) using a single-channel system at this site.

POST-GLACIAL REBOUND SIGNATURES ON LATTE HOLOCENE AND PRESENT DAY SEA-LEVEL CHANGES ALONG THE COASTS OF ITALY
Solving the sea-level equation for a spherically symmetric Maxwell Earth we investigate the effects of the melting of remote Pleistocene ice sheets on present day relative sea-level variations, vertical movements and geoid anomalies along the Italian coasts. For a suite of plausible viscosity profiles we compare predictions of different global ice chronologies that have been tested against various Mediterranean Holocene sea-level records. On the basis of the sensitivity of North African relative sea-level curves to the Holocene melting of the Antarctica, we study the effects of different assumptions regarding the time-history of this remote glacier. By considering the catastrophic melting of Antarctica at 8,000 years BP, a scenario supported by the relative sea-level data from Djerba (Tunisia), we compare the effects of a sudden declination to those due to a smooth and linear melting phase considered in previous works. Finally, we predict bounds on the glacial isotatic adjustment signal at different Italian tide-gauge and GPS stations and derive a mean value for the ongoing climate related eustatic sea-level rise in the Mediterranean.
ecosystems was evaluated. The basic model included a limiting nutrient, bacteria, two size classes of phytoplankton, two size classes of detritus and explicit microzooplankton and mesozooplankton compartments. Steady-state results in idealized mixed layers configured to represent observed conditions were used to identify parameters and mechanisms influencing each observed quantity. Values of critical parameters were adjusted within their uncertainties to maximize the fit to the observations, and the model results matched trends in ecosystem properties over the majority of observed conditions. Further, the steady-state experiments, unsteady simulations forced at storm-bend and seasonal frequencies were used to determine if unsteady processes can account for the remaining unexplained variance, and 2) identify systematic changes in mean ecosystem properties arising from unsteady dynamics that must be considered during model calibration.

GEOMORPHIC TRANSPORT LAWS TO GENERALIZE SEDIMENT LOADING TO THE REEFS OF MOLOKAI, HAWAII, USA

We hypothesize that historic conversion of steep Hawaiian watersheds from soil creep to overland flow caused significant changes in sediment magnitude and frequency of fine sediment flooding adjacent reefs. In Molokai’s semi-arid watersheds, transport-limited hillslope lowering rates approach 1.0 cm/a in bare soil. Low matrix hydraulic conductivities (~10-5 m/s) promote overland flow erosion of soils whose median and modal grain size is silt. LIDAR reveals that channel heads have locally migrated above background drainage-area values of ~104 m2 to rippled levees formed by overland flow. Process maps indicate sediment storage within catchment valleys. Cs-137 cores and shoreline progradation indicate most of this material has recently migrated out of catchments onto fans and reefs. To forecast sediment flux, we instrumented a small catchment with soil moisture sensors, overland flow meters, and sediment traps. The goal is to use monitoring with repeat 1-cm ground-based LIDAR to detect magnitudes and patterns of lowering. We will use these data to calibrate an overland-flow erosion law that can be generalized to the catchment by combining 1-m LIDAR with process maps.

PATCHINESS IN THE MICROBIAL WORLD: INSIGHTS FROM MICROFLUIDIC STUDIES

Marine microbes live in a world of patches, where localized, ephemeral pulses of organic matter can often represent the dominant nutrient resource. In this landscape, motility and chemotaxis allow microbes to exploit and accumulate within nutrient patches, resulting in intense bacterial hotspots that can attract predators and form microhabitats. When scaled up, these complex interactions can strongly affect biogeochemical rates in the ocean, yet elucidation of their dynamics has been hampered by experimental limitations. We report findings from a novel microfluidic platform to investigate microbial dynamics at relevant spatiotemporal scales. Experiments revealed that marine bacteria can be extremely proficient in exploiting nutrient patches, gaining up to a 10-fold advantage from chemotaxis. We present the first evidence that marine bacteria can colonize nutrient plumes behind settling marine particles for moderate settling speeds (50 m/day). Bacterial hotspots formed within tens of seconds, triggering equally rapid and intense aggregations from their predators. A new ecological model linking patch utilization with chemotactic abilities is developed to quantify the effect of this patchiness cascade sweeping through the microbial loop on rates of carbon transfer to the classic food web.

THE GLOBAL CENSUS OF MARINE LIFE ON SEAMOUNTS (CENSEAM)
The goal of CenSeam (http://censeam.niwa.co.nz/) is to foster global study of seamounts to determine their role in the biogeography, biodiversity, productivity, and evolution of marine organisms, and to evaluate the effects of human exploitation on these systems. Specifically, it is creating networking opportunities for existing and planned research programs, developing standards for sample collection and data sharing to make data more comparable across studies, supporting an online database of seamount biology (http://seamounts.sdsuc.edu), organizing large-scale synthesis review studies, and offering mini-grants to expand the scope of existing work. One example of recent CenSeam work is a report to the United Nations Environment Program predicting that suitable hard coral habitat on seamounts is most likely to coincide with future fishing pressure on large seamounts in the southeastern portion of the Mid-Atlantic Ridge in the South Atlantic, the central-eastern southern Indian Ocean, and some regions of the southern-central Pacific Ocean. Another recent activity, undertaken with the Marine Metadata Interoperability project, is developing MetaSEL, a draft metadata standard (http://marinemetadata.org/im-agemetadata) that will facilitate the finding and sharing of environmental images.

EMPLOYING SATELLITE-DERIVED SEA-ICE CONCENTRATION TO CONSTRAINT UPPER-OCEAN TEMPERATURE IN A GLOBAL OCEAN GCM

The Southern Ocean sea-ice simulations in a global ocean general circulation model (GCM) depends decisively on the simulated upper-ocean temperature. This is confirmed by assimilating satellite-derived sea-ice concentration to constrain the upper-ocean temperature of the ocean model. The resolution of the sea-ice model is about 22 km and thus comparable to the pixel resolution of the satellite data. The ocean GCM is coarse-resolution to afford long-term integrations for investigations of the deep-ocean equilibrium response. Besides improving the sea-ice-albedo feedback, simulations with constrained upper-ocean temperature yield much more realistic global deep-ocean properties, in particular when combined with glacial freshwater input. Both outcomes are relative insensitive to the passive-microwave algorithm used to retrieve the ice concentration being assimilated. The sensitivity of the long-term global deep-ocean properties and circulation to the possible freshwater input from ice shelves and to the parameterization of vertical mixing in the Southern Ocean is reevaluated under the new constraint.

PHYSICAL AND BIOLOGICAL HETEROGENEITY ON A FLORIDA KEYS REEF SLOPE: INTERACTIONS OF INTERNAL WAVES AND REEF TOPOGRAPHY

A dense spatial array of synchronized, fast response time, environmental sensors was deployed in two consecutive summers to study biological and physical coupling associated with the run-up of internal waves on the fore reef slope of Conch Reef, Florida Keys. Detailed surveys of the reef bathymetry and sampling of benthic microbial community composition and macroalgal isotopic signatures of carbon, nitrogen, and oxygen revealed strong physical and biological heterogeneity at scales of meters to tens of meters both across and within depths. Visualization through time of thermal anomalies mapped onto the reef bathymetry revealed persistent warm and cool patches associated with variability in the exposure to and duration of internal waves. The observed biological heterogeneity was not well explained by simple gradients in depth alone, but appeared to be related in many cases to within-depth physical patchiness resulting from the interaction of internal waves with the reef topography. These observations point to the importance of 3-dimensional structure even for a relatively low-relief reef slope, and emphasize the interacting and complex processes influencing biological heterogeneity on coral reefs in general.

SEASONAL OCCURREENCE OF COLLOIDAL BIOPOLYMERS CHANGING THE NANOSCALE SIZE DISTRIBUTION OF P, FE, CU, AG AND PB IN COASTAL SEAWATER

Seasonal variations in nanoscale size distributions of Fe, Cu, Pb and Ag associated to colloidal/macromolecular matter in coastal seawater, is presented. Samples were taken on a 0-40 m depth profile in the Gullmar Fjord (Sweden), during winter, spring bloom and summertime at 29 locations in the 0-50 m region (hydrodynamic elements) determined by Asymmetrical Flow Field-Flow Fractionation, coupled on-line to High Resolution ICP-MS. The colloidal/macromolecular matter was also analyzed for size and shape by Atomic Force Microscopy. Three populations of colloidal/macromolecular matter with different sizes, shapes and element binding properties, were distinguished. Spherical, ~0.5-2 nm CDOM, bound most elements, and was present throughout the sampling period at all
Conducting an evaluation of your education and interpretive programs is essential to assessing the effectiveness of your message delivery system. Explore with the NOAA National Marine Sanitaries staff the process for development and implementation of an evaluation system for a diverse offering of ocean literacy and conservation education programs. Topics include models for evaluating environmental education programs, integration of evaluation in the program planning process, structuring evaluation instruments and implementation challenges with broadly distributed program centers. This presentation is based on the culmination of a two year planning process for the newly developed evaluation toolbox for environmental learning designed in collaboration with the Institute for Learning Innovation.

SUPPLY PATHS OF AND TIME VARIATIONS IN THE OXYGEN MINIMUM ZONES OF THE EASTERN TROPICAL PACIFIC AND ATLANTIC OCEANS

The oxygen minimum zones (OMZs) in the eastern tropical Pacific and Atlantic Oceans extend from 200 to 800 m depth and are centered at about 10 degrees north and south of the equator. Model simulations of the future predict an overall dissolved oxygen decline and expansion of the OMZs. We describe the supply paths of oxygen to the OMZs by the eastward, tropical current bands through analyses of ADCP velocity observations combined with oxygen measurements. In the Pacific the Equatorial Undercurrent (EUC) provides the major oxygen supply to the OMZs, with smaller contributions from the Southern and Northern Subsurface Countercurrents. In the Atlantic the EUC and the North and South Equatorial Countercurrents provide oxygen to the OMZs. Time series of oxygen profiles from historical data extending beyond recent observations indicate an intensification of the OMZ in the tropical North Atlantic with a vertical extension of the low oxygen layer. A vertical widening of the low oxygen layer is observed in the equatorial regions of the tropical Pacific and the tropical Atlantic, suggesting a reduced oxygen supply.

PARTICLE FUNCTIONAL TYPES IN OCEAN OCEPITS: BEYOND BULK PARAMETERIZATION OF SUSPENDED PARTICULATE MATTER

Seawater is a complex optical medium consisting of a variety of particle types with different optical properties and biogeochemical functions. The traditional approach in ocean optics has been to use an overly simplified parameterization of seawater in terms of a few bulk particulate properties, such as chlorophyll or particle mass concentration. This approach has failed to explain the substantial optical variability in the ocean. I will present a concept referred to as a reductionist approach, in which the particulate matter is partitioned into a number of particle functional types that are optically and biogeochemically significant, such as inanimate colloids, viruses, heterotrophic bacteria, cyanobacteria, nanoplanckton and microplankton species or taxonomic groups, clay- and silt-sized minerogenic particles, and as inanimate colloids, viruses, heterotrophic bacteria, cyanobacteria, nanoplanckton and microplankton species or taxonomic groups, clay- and silt-sized minerogenic particles, and biogeochemical functions. The traditional approach in ocean optics

Why are the densest waters of the North Atlantic formed in the Subpolar Gyre? (and Labrador Sea, in particular)

The densest water mass formed in the Subpolar Gyre is Labrador Sea Water, the densest water mass formed in the Subpolar Gyre. This is counterintuitive given the accepted paradigm that the densest mode waters should be formed the farthest away from the warm water source. It is also counterintuitive given the large heat transport into the Nordic Seas compared to that into the Subpolar Gyre downstream of the bifurcation at the Greenland-Scotland Ridge. In general, no simple explanation for why the Nordic Seas’ densest waters should be deeper is found in the literature. In this study, the relative importance of factors, such as air-sea fluxes, topography, freshwater, sea-ice and ocean dynamics, in influencing the density of the waters formed in the Nordic Seas versus the Subpolar Gyre (and Labrador Sea, in particular) is examined using a combination of observations, idealized thermodynamic and dynamics models. The results presented are relevant not only to understanding our present climate but also to past climate scenarios when the location of connection in the North Atlantic was thought to be different.

Two approaches are described to improve fields of altimeter SSHA within 50km of the coast. One problem in this region occurs when the altimeter footprint hits land. A second class of problems involves the corrections applied to the radar travel time, especially the wet troposphere correction. One approach to overcoming problems with the corrections is to substitute mid-latitude corrections, usually based on models of the coastal atmosphere or ocean. Here we use model-based wet troposphere corrections, allowing us to retrieve along-track SSH data between ~60km to 20km from the coast, where land reflections begin. To produce SSHA fields that reach the coast, we simply ignore altimeter data within 40km of the coast, then interpolate between tide gauge SSH data at the coast and the offshore altimeter data to produce SSH fields that reach the coast. We simply ignore altimeter data within 40km of the coast, then interpolate between tide gauge SSH data at the coast and the offshore altimeter data. Examples of both approaches will be presented, with suggestions for improvements.

We demonstrate the potential for reconstructing sea surface temperatures along coastal British Columbia, Canada, using four chronologies developed from the growth increment widths of Pacific geoduck clams (Panopea abrupta). The four geoduck chronologies range from the southernmost to northernmost borders of British Columbia and were developed using standard tree-ring (dendrochronology) techniques, including cross-dating. Although each geoduck chronology significantly correlated with local records of sea surface temperatures (SST), correlations were unstable over time. In every chronology, the relationship with SST would occasionally dissolve for a period lasting approximately ten years. The timing of these climate-growth breakdowns was inconsistent and varied among the chronologies. For any one chronology, inconsistent climate-growth relationships represented a significant complication for developing accurate SST reconstructions. However, when geoduck chronologies were combined via multiple regression or simple averaging, irregularities in climate-growth relationships canceled out one another to yield strong and highly stable SST reconstructions. Final SST reconstructions captured more than 60% of the variance in the instrumental record and extended more than 120 years, capturing the historical range of variability and providing context for interpreting recent warming trends.
Several independent data sources suggest that there is a net upper-layer mass flux of order 3 \text{ Sv} to the west in the Gulf of Mexico, even in the western Gulf; it is a closed basin. Because the wind stress is convergent over most of the Gulf, we suggest that the net mass flux is removed from the upper layer by Ekman pumping, as is typical of all mid-latitude anticyclonic gyres. The downward flux can follow isopycnals to depths of order 500 m, and then be advected poleward by the Gulf Stream. More accurately, the mechanism for forcing deep water to the south through Yucatan Channel is provided by the intrusion and ring-shedding cycle of the Loop Current. Potential vorticity maps show that a deep flow from the western Gulf back to the Caribbean Sea, via Yucatan Channel is likely. This deep flow was observed by the long-term CICESE moorings. While almost all numerical models show the observed strong flow to the west in the southern part of the basin, none that we have examined show this observed net upper-layer flow to the west in the central Gulf.

**DEMONSTRATION OF A UHF RADAR IN AN INTEGRAL SALT MARSH**

In November 2005, a RiverSonde radar was deployed in North Inlet, South Carolina to examine the accuracy of UHF radar technology in measuring surface currents in an intertidal salt marsh. In order to validate the river-inspired surface current profiler (ADCP) was deployed in the radar’s footprint. Upon comparison, the radar yielded current measurements consistent with both the ADCP and known tidal variations in this region. The results further demonstrate that increased wind speed, up to a threshold, results in greater radar coverage. However, tidal currents are notable constraints on a UHF radar system in an intertidal salt marsh environment. For example, radar coverage fluctuates throughout the tide cycle as some areas become exposed during low tide, then flood again during high tide. The cordgrass Spartina alterniflora, which forms a thick canopy over the marsh surface, acts as an effective radar target causing energy peaks near zero Doppler shift. However, the peaks are a function of wind speed and are uncorrelated and likely can be filtered. Overall, this UHF radar system performed well in the subtidal channel. A promising future application involves a pair of overlapping radars to measure the total surface current vector field.

**THE FATE OF SEDIMENTS IN THE TAIWAN STRAIT: A REASSESSMENT**

Five of the 10 largest rivers in the world by discharge are tropical rivers and their plumes extend 100 to 1000s of km off continental shelves. It has been argued that the primary production associated with these river plumes is either due to nitrate introduced by the river or due to recycling of this nitrate. We have calculated a T/river ratio for several rivers and show that nitrate and recycling alone cannot account for the productivity of these plumes. Nitrogen fixation and organic nitrogen play a significant role in tropical river plumes. Only the sinking flux of new production associated with these allochthonous sources of nitrogen can be considered biologically mediated transport of CO2 from the ocean to the atmosphere. Echinoderm is an important carbon source in coastal zones and has been recently the focus of attention in the context of the effect of ocean acidification on the fate of these organisms. Few studies have explored how the changing chemistry caused by a decrease in pH affect physiological traits including calcification. Additionally, limited information at early stages of echinoderm development highlights the urgent need to address the question of how increasing CO2 partial pressure will impact upon echinoderm physiology and population adaptation to environmental change. We present results on the effects of changes in CO2 on the physiology of larvae during early developmental stages. The conditions used in this study represent present-day CO2 (385 p.p.m. V. CO2) and CO2 projections for two future scenarios (750 and 1200 p.p.m.V. CO2).

Sklar, F. H.; Cline, E.; Scinto, L. J.; Price, R. M.; application of the quasi-normal scale elimination theory to oceanic turbulence. Recently developed Quasi-Normal Scale Elimination (QNSE) theory of stably stratified turbulence has been applied to oceanic flows. QNSE is an analytical theory that fully accounts for the effects of flow anisotropy and internal waves. It yields vertical and horizontal scale-dependent eddy viscosities and eddy diffusivities and various one-dimensional spectra that roughly deviate from the Kolmogorov regime. It is shown that in the Oszmidov scale, the vertical spectrum of the horizontal velocity undergoes transition from the Kolmogorov -5/3 slope to the -3 slope. The numerical coefficients in the transition equation agree well with LES by Carnevale et al. (2001) and with the measurements of the vertical spectrum of the horizontal shear by Gargett et al. (1981) and Gregg et al. (1993). The theory provides a new theoretical basis for the observed collapse of the normalized data to a single curve and the universal scaling of the normalized shear spectrum first suggested by Gargett et al. (1981). A correction to the Kolmogorov-Oszmidov spectrum of temperature fluctuations due to the buoyancy effects is also analytically derived.

UNDERSTANDING AND PREDICTING CHANGES IN THE OCEAN SCIENCES, TECHNOLOGY, AND OPERATIONS WORKFORCE

Despite efforts of the U.S. Department of Labor to assess workforce status and trends, little is known about the ocean science, technology and operations (OSTO) workforce. Most ocean occupations are intertwined with other sectors of the economy, making it difficult to define, no less make projections about, many aspects of the ocean workforce. Understanding and Predicting Changes in the Ocean Sciences, Technology, and Operations Workforce is a study funded by the National Oceanographic Partnership Program and lead by the Marine Advanced Technology Education Program (MATE) Center and the Naval Postgraduate School that is designed to: produce a more complete description of the present state of the OSTO workforce; anticipate future developments in this workforce; and characterize the educational programs that will be needed to respond to those developments. Preliminary results of this study will be discussed including a description of the current workforce in support of ocean observing systems, positions that are the most difficult to fill, the knowledge and skill sets in highest demand, and general trends on the ocean workforce.

THREE YEARS OF THIN LAYER OBSERVATIONS IN MONTEREY BAY, CA USA

Fine-scale physical, biological and optical measurements within intense thin layers were made during three different years in Monterey Bay, CA (2002, 2005 and 2006). These measurements were made as part of the ONR sponsored DRI Layered Organization in the Coastal Ocean (LOCO). Vertical profiles of the water masses were made hourly over periods spanning 1 to 3 weeks using autonomous vertical profilers. In-situ measurements included CTD, oxygen, optical absorption and attenuation, (both particulate and dissolved), angular and spectral backscattering, chlorophyll and CDOM fluorescence, horizontal current intensity, shear, turbulence dissipation and phytoplankton species identifications within layers and the surrounding water column. Each of the three years had distinct thin layer formation mechanisms and characteristics. The unique properties of these thin layers and their comparative impacts to biology and optics will be discussed.

GROUNDWATER-SURFACE WATER INTERACTIONS IN TREE ISLANDS AT LOXAHATCHEE IMPOUND LANDSCAPE ASSESSMENT (LILA), FLORIDA

Tree islands are a natural component of the Everglades landscape, yet over the last century there has been a sixty percent reduction in tree island cover in some areas. This loss has been attributed to an alteration of the natural water level and flow patterns in the Everglades. To gain an understanding of tree island hydrology, a study was conducted on man-made tree islands at Loxahatchee Impound Landscape Assessment (LILA), a large replicated physical model of the Everglades located in at the Arthur R. Marshall Loxahatchee National Wildlife Refuge (LOX). Florida. LILA contains 8 tree islands constructed of either entirely peat or peat over limestone. Monitoring of groundwater levels and temperature in the tree islands relative to the surrounding surface water has provided insight into the tree island's hydro-dynamics. Groundwater levels in peat tree islands were elevated above the surrounding surface water year round, while groundwater levels in limestone islands were above surface water only during the wet season. A diurnal oscillation in groundwater level at times of low surface water level suggests that trees on the islands affect groundwater level via evapotranspiration.

NORTHWARD TRANSPORT OF PACIFIC WATER ALONG THE NORTHWIND RIDGE IN THE WESTERN ARCTIC OCEAN

A possible mechanism for northward transport of Pacific Summer Water (PSW) along the Northwind Ridge is presented. The recent sea-ice reduction in the Arctic Ocean is not spatially uniform, but is disproportionally large around the Northwind Ridge and Chukchi Plateau compared to elsewhere in the Canada basin. The PSW delivered from the Bering Sea is one of the likeliest candidates causing such disproportional sea-ice reduction. To understand mechanisms responsible for such sea-ice retreat, we examine the dynamics and timing of the delivery of the PSW into this region. A key mechanism is an interaction between the bottom topographies of the Northwind Ridge and annual cycle Rossby waves excited by sea-ice motion in the Canada basin. The analytical results show a quite different structure from those of mid-latitude basin due to the small value of beta effect. Incident barotropic waves cause strong baroclinic current over the topographies, and the current delivers warm PSW into the basin. The estimated timing of the PSW delivery is consistent with the sudden warming observed in the subsurface layer over the Northwind Ridge.

ENERGY TRANSFER BETWEEN THE SEMIDIURNAL TIDE AND NEAR-INERTIAL MOTIONS AT THE KAENA RIDGE

We investigate the nonlinear energy transfer from the semidiurnal tide to near-inertial frequency in a region of strong barotropic-to-baroclinic tidal conversion. The observations, comprising repeated velocity and density profiles in the nearfield of the Kaena Ridge, were part of the Research Team IIF in September-October 2002 as part of the Hawaii Ocean Mixing Experiment. Depth-integrated energy spectra suggest a fortnightly modulation of near-inertial energy, lagging the semidiurnal tides by 5-10 days. Guided by classical nonlinear interaction models, as well as more recent analytical and numerical studies, we find that triads consisting of an upward- and a downward-traveling near-inertial wave and their sum frequency in the semidiurnal band show a significant biocorrelation. When compared to statistical model trials for zero coupling with random phase, the observed biocorrelation values above the Ridge are significant at the 95% confidence level. The inference is that a semidiurnal to near-inertial energy transfer is indeed at work.

EFFECT OF INTERANNUAL TO INTERDECADAL CLIMATE VARIABILITY ON MARINE BIOGEOCHEMICAL CYCLE AND OCEANIC CARBON UPTAKE

The overall objective of this study is to improve our understanding of the influence of interannual to interdecadal climate variability on the marine biogeochemical cycle and oceanic carbon uptake using an ocean general circulation model (OEGCM) coupled with a marine biogeochemical cycle models. Studies that the interannual to interdecadal climate variability change the upwelling of nutrient-enriched waters and affect the biological productivity, and thus ocean carbon uptake. Moreover, oscillation on decadal time scales may be able to adjust the primary production of the marine ecosystem through changes in ocean mixing, wind stress, as well as atmospheric iron deposition. The phytoplankton growth and the marine biological pump can also change the temporal response of surface temperature and atmospheric CO2 concentration. In order to achieve our objective we integrate a marine biology model into a 3-D OEGCM. The marine biology model is a second-generation biogeochemical model Dynamic Green Ocean Model. The model includes three limiting nutrients, three phytoplankton state fractions, two zooplankton state fractions and three detritus. The ocean model is the POP general circulation model. The coupled modeling framework is used to conduct a set of sensitivity experiments to examine how the historical variability in factors such as surface heat flux, freshwater flux, sea-ice cover affect the ocean circulation and hence phytoplankton growth and ocean productivity.

POSITIVE FEEDBACK AND THE DEVELOPMENT OF ECOSYSTEM DISRUPTIVE ALGAL BLOOMS (EDABs), which severely alter or degrade ecosystem function, are occurring with increasing frequency. These blooms are often caused by toxic or unpalatable species that decrease herbivore grazing rates, and thereby disrupt the transfer of nutrients and energy to higher trophic levels, and decrease nutrient cycling. Many factors, such as nutrient availability and herbivore grazing have been proposed to separately influence EDAB dynamics, but interactions among these factors have less often been considered. Here we discuss positive feedback interactions among nutrient availabil- ity, herbivore grazing, and nutrient regeneration, which can substantially influence the dynamics of EDAB events. The positive feedbacks result from a reduction of grazing
rates on EDAB species caused by algal toxicity or unpalatability, which promotes the proliferation of the EDAB species, but also lowers grazer-mediated recycling of nutrients and thereby decreases nutrient availability. Since many EDAB species are well-adapted to nutrient-stressed environments and many exhibit increased toxic production and toxicity under nutrient limitation, positive feedbacks are established which can greatly increase the rate of bloom development and the adverse effects on the ecosystem.

ESTIMATING RESPONSE TIMES OF OCEANS TO MERCURY EMISSION REDUCTIONS AND IMPLICATIONS FOR EXPOSURE FROM MARINE FISH

We synthesize results from global-scale atmospheric and oceanic cycling models to assess anthropogenic mercury exposure from marine fish consumption. Modeling results suggest that anthropogenic mercury enrichment is greatest in the Atlantic Ocean and Mediterranean Sea, and that global emissions remain at present levels, mean concentrations will decrease in these areas. However, our results also indicate concentrations in the North Pacific Ocean may increase. These modeling scenario runs agree with data from 2006 North Pacific cruises which reveal increases in total mercury concentrations for comparable latitudes to stations sampled in 1987 and 2002. Data from the Mediterranean Sea, on the other hand, indicate decreasing concentrations in recent years. Since almost 40% of human mercury exposure in the US is from tuna harvested primarily from the Pacific Ocean, these data suggest that population wide decreases in mercury may not decline as rapidly as we propose with decreased domestic emissions. This analysis illustrates the complex anticipated response of oceanic fish mercury levels resulting from large-scale mercury emission reductions, and emphasizes the important role scientists have for informing policy makers and resource management agencies.

OBSERVATIONS OF UPPER OCEAN MIXING USING AIRBORNE LIDAR

We present results from dye release experiments conducted off the east coast of Florida in which airborne LIDAR was used to obtain 3-D maps of the dye patch on times scales of minutes to hours, and spatial scales of meters to 1 km horizontally and 0.5-10 m vertically. In particular, we examine the rapid formation of a banded structure in the dye distributions on scales of the mixed layer depth. In situ observations from an acoustic Doppler current profiler (ADCP) combined with conductivity, temperature, and depth measurements (CTD) show a strongly stratified shear layer overlying a weaker, more uniform flow. We investigate the hypothesis that the bands are the result of shear instability in the upper part of the water column (Langmuir circulation can be ruled out based on the observed wind speed, wave height and stratification). As part of our analysis, we estimate vertical diffusivity and horizontal dispersion coefficients from the rates of vertical and horizontal spreading of the dye layers, and further exploit the ability of the LIDAR observations to track individual features in the dye distributions to account for small-scale features, intermittency, wavenumber spectra, etc.

IMPACTS ON THE AMERICAS OF MULTIDECadal VARIABILITY IN ATLANTIC AND INDIAN OCEAN SEA SURFACE TEMPERATURES: A MULTIMODEL COMPARISON

Previous work has shown strong evidence that multidecadal variability in Atlantic Ocean conditions influences the climate of the North, South and Central America, affecting patterns of rainfall in particular. However, there is uncertainty as to the strength of these impacts, with notable contrasts between results from different studies. It is unclear to what extent these differences arise from the use of different models, or from differences in experimental setup. As part of an EU project, DYNAMITE, we have carried out controlled experiments in which 5 different atmospheric GCMs have been forced with the same pattern of multidecadal change in Atlantic SST. While there are similarities in the overall patterns of response, we find considerable differences between the model simulations of climate impacts over the Americas, especially with respect to the magnitude of rainfall anomalies. Further studies are providing insight into the causes of these differences and evaluation of which responses may be most realistic. Finally, we have carried out a similar set of experiments forced by the observed multidecadal change in Indian Ocean SST, and will report on these results also.

BATHYPLAGIC FISH DIVERSITY IN THE SARGASSO SEA, NORTHWESTERN ATLANTIC OCEAN

Of the various marine habitats, one of the (if not the) most daunting to quantify is the largest habitat on Earth. One project addressing this challenge is the Census of
Marine Zooplankton (CMarZ), whose goal is the assessment of biodiversity of animal plankton throughout the world's oceans. The 2006 CMarZ cruise in the Western North Atlantic provided an unprecedented opportunity to sample bathypelagic micronekton using a large midwater trawl (10-m³ MOGNESS) outfitted with fine (0.335-mm) mesh netting. This netting allowed non-destructive sampling of the fragile fish fauna to 5000 m depth, thus facilitating accurate identification and at-sea DNA extraction and sequence- ing. A total of 3,965 fish specimens were collected from at least 127 species (94 genera, 42 families), many rarely caught, and four of which may be undescribed. Of note were male anglerfishes from five families, which are poorly known. Tissue was taken from all males to match with females, thus enabling the construction of a key for the most diverse bathypelagic fish group.

BALANCED AND UNBALANCED VARIABILITY NEAR TOPOGRAPHY
Various physical mechanisms of topographically enhanced variability are discussed. Given that balanced motions are dynamically controlled by potential vorticity, topographic effects will be most pronounced in mesoscale features with strong potential vorticity anomalies. Analysis of intense vortices evolving near horizontal boundaries and tall sea-mounts is presented. Resonances between Rossby (vortical) and inertia–gravity modes result in unbalanced agostrophic instability which is shown to be related to violation of Ripa's sufficient stability condition.

UNDERSTANDING PROJECTIONS OF SEA LEVEL RISE IN A MODEL FOR INTERDISCIPLINARY RESEARCH ON CLIMATE VARIATION 3.2 (MIROC3.2)
Sea level changes resulting from CO2-induced climate changes have been investigated in a series of idealized experiments with medium-resolution version of MIROC3.2. Changes in wind stress have important role of the several pronounced local features, while heat flux changes affect sea level rise in the Atlantic Ocean and fresh water flux affect sea level rise in the Indian Ocean. The changes in wind stress and surface fluxes and the following sea level changes are also shown in the high-resolution version of MIROC3.2 with more detailed features. These local features are related to density changes mainly contributed from redistribution of ocean heat content. This work was supported by KAKENHI 18740305.

FROM BACTERIA TO BIRDS: THE IMPACT OF SULFIDE IRRUPTIONS ON MICROBIAL COMMUNITY STRUCTURE IN A HYPERSALINE LAKE
Numerous water quality problems plague California's largest lake, the Salton Sea. One of the main reasons for the presence of high concentrations of hydrogen sulfide (H2S) in the lake: The development of large phytoplankton blooms and high summertime water temperatures lead to anoxia and H2S formation. Frequent windstorms mix H2S-rich bottom waters into surface waters, causing mass mortality of plankton, macroinvertebrates, and fish. Although similar phenomena have been documented in other lakes and marine ecosys- tems, the extent to which these events affect microbial community structure has not been studied. A mixing event was captured in the Salton Sea in September 2005 by sam- pling along a transect passing through an H2S-rich plume. Physical and chemical water column properties were measured at 12 transect and two reference stations. Community fingerprinting (T-RFLP) was used to determine composition and structure of archaeal and bacterial communities. Archaeal community structure was strongly influenced by H2S concentration, whereas the bacterial community exhibited only minor changes. Aside from the immediate effects of mixing events on the biota, the resulting changes in micro- biological communities may also lead to biogeochemical changes.

PHOTOCHEMICAL CYCLING OF CHROMOPHIC DISOLVED ORGANIC MATTER (CDOM) IN THE OPEN SEA: COMPARISON OF PHOTOLOYTIC QUANTUM YIELD AMONG THE MAJOR OCEAN BASINS
Solar photolysis of chromophic dissolved organic matter (CDOM) drives the global open-ocean surface CDOM distribution seen from satellite. This process also leaves an imprint on CDOM absorption (in terms of magnitude and spectral shape) in regions of the ocean interior characterized by relatively frequent ventilation (e.g., subtropical mode waters of the North Atlantic and Pacific). Here we present preliminary experimental determinations of apparent quantum yield (AQY) for CDOM photolysis on open-ocean samples from ranging hydrographic provinces within the Pacific, Atlantic and Southern oceans (collected as part of both the CO2/CLIRAP Repeat Hydrography Survey and Bermuda Atlantic Time-series Study). CDOM photolysis rate is measured from a labora- tory-simulated solar irradiation time course and used to solve for parameters describing AQY. Geographic variation in AQYs will be assessed within the context of the oceanic vertical distribution of CDOM and related hydrographic data. We investigate whether variation in AQY can be ascribed to regional biogeography (specifically biological production characteristics) or the geochemical character of source water masses, each of which may influence the chemical composition thus photochemical potential of CDOM.

SOURCES AND FORCES: WHAT DRIVES VARIABILITY IN SUSPENDED SOLID CONCENTRATIONS AT THE KILO NALU OBSERVATORY
Concern for Hawaiian coastal water quality, especially on Oahu's economically vital south shore, has risen significantly in the past decade. In order to predict variability in water quality, it is necessary to understand the relative importance of the various forcing mecha- nisms and how their combined effects influence the area. The Kilo Nalu Observatory, located on the south shore of Oahu, is ideal for studying water quality variations and their underlying physical forcing mechanisms. Using ADCP acoustic intensity as a relative measure of suspended solid concentration, quantitative analysis of the variance attributed to the major forcing mechanisms (swells, currents, solar irradiance, and tidal cycles) has been carried out. Regression analyses identify the significance of wave forcing in driving low frequency variability, while spectral analyses reveal diurnal and tidal influences in the acoustic intensity time series. Spatial variability in acoustic intensity in the Kilo Nalu area is assessed using AUV surveys.

CLIMATE CHANGE, UPWELLING, AND ECOSYSTEM DYNAMICS IN THE GULF OF THE FARALLONES
In eastern boundary current systems, coastal upwelling is predicted to intensify as a result of increasing temperature gradients between land and sea. Along the U.S. west coast, atmospheric-oceanographic coupling in the past decade has been extremely variable, resulting in dramatic, unpredictable responses of the California Current large marine ecosystem. While global warming is predicted to cause increased upwelling in neritic environments, the potential effects on offshore regions is less clear. Herein, we investigate biogeographical change in neritic to offshore zones to test the hypothesis that global warming is differentially affecting these habitats. To test this hypothesis, we examine primary, secondary, and tertiary productivity by depth zone for the wide Gulf of the Farallones continental shelf ecosystem off central–northern California. We find trends in primary, secondary and tertiary productivity which are consistent with our hypothesis of differen- tial ecosystem changes in the Gulf of the Farallones depending on distance from the coast, and relate these to changes in coastal upwelling and offshore wind curl.

VIRUSES FOUND IN SEWAGE AND THEIR POTENTIAL TO INDICATE FECAL POLLUTION IN COASTAL WATERS
The presence of pathogenic viruses in coastal environments is potentially an important tool in evaluating water quality and human health risks. Millions of viruses are excreted in fecal matter and bacterial indicators do not correlate with the presence of pathogenic viruses. Enteroviruses have been used to identify fecal pollution in the environment; however, other viruses transmitted via the fecal–oral route could indicate fecal pollution.
The purpose of this research is to develop a baseline understanding of the diversity of viruses found in raw sewage, and to assess their presence in the environment. PCR was used to detect Adenoviridae, Herpesviridae, Papillomaviridae, Reoviridae, Hepadnaviridae, Caliciviridae, Paramyxoviridae, Tobamoviridae, and Human Poxviridae in viruses concentrated from raw sewage throughout the US and from five marine environments ranging in their exposure to human influence. Adenovirus, Norovirus, Pepper Mild Mottle Virus, and Human Poxviridae were detected in raw sewage but absent in the marine environment. This baseline understanding of viruses in raw sewage and the marine environment will enable educated decisions to be made regarding the use of viruses in water quality assessments.

DELTA S AT RISK

The long-term sustainability of deltas is more affected by large-scale engineering projects than eustatic sea level rise associated with global warming. This finding has crept up on scientists, as the subject is both complex and, highly variable around the world's coastlines. On deltas, relative eustatic sea level rise (~2 mm/y) is often smaller than the rate for iso-static-controlled subsidence (0.3 to 3.6 mm/y) on the Mississippi (and of the same order of magnitude: sediment compaction (0.7 to 2.2 mm/y). Accelerated compaction (25 to 125 mm/y) associated with petroleum and groundwater mining can greatly exceed natural subsidence rates (3 to 8 mm/y). The reduction in sediment delivery to deltas due to trapping behind dams, along with the human control on the routing of river discharge across delta plains, limits the aggravation of a delta surface from new sediment deposition. This perhaps is the reason for the world's sinking deltas. Delta from upstream sources is often mitigated through controlled water releases and diversions for irrigation; channels are stabilized to aid in this control. However flooding from the sea is now more common, as a deltas' surface subsides. Consequences include shoreline erosion, threatened mangroves and wetlands, increased salinization of cultivated land, and hundreds of millions of humans put at risk.

POTENTIAL EFFECTS OF CLIMATE CHANGE ON PARTICLE COAGULATION EFFICIENCY IN THE OCEAN

Marine particle formation and the subsequent export of organic carbon from the pelagic zone is an important mechanism for sequestering CO2. We studied the effect of increased CO2 concentrations and temperature on the coagulation efficiency of phytoplankton, a factor important for modeling aggregate formation. Dissolved and colloidal exudates derived from phytoplankton during blooms are enriched in acidic sugars and have recently been shown to be precursors for abiotically-formed gel particles operationally classified as transparent exopolymer particles (TEP). It has been suggested that TEP enhances aggregation by increasing effective particle size and colloid frequency of particles, and also by serving as organic glue between cells. TEP abundance, dissolved and colloidal neutral and acidic sugar composition, and cellular abundances were measured for diatoms grown in mesocosms at elevated temperatures and for coccolithophores grown in chemostats under different temperatures and pCO2 concentrations. Coagulation efficiency of cells undergoing collisions by shear was determined experimentally using horizontal Couette devices. Here we report our findings and discuss their implications for marine particle dynamics and the marine carbon cycle in the future.

FEEDING OF CARNIVOROUS ZOOPLANKTON IN WEST GREENLAND WATERS

The aim of the present study is to contribute to a better knowledge about carnivorous zooplankton, their trophic role in the arctic pelagic ecosystem, with emphasis on their predation on Calanus spp. The diet and vertical and horizontal distribution of the carnivorous copepods and chaetognaths were investigated in West Greenland waters during the Arctic spring. Feeding by the carnivorous copepod Paraeuchaeta norvegica was assessed by measuring egestion of faecal pellets and the chaetognaths were analysed for gut contents. Simultaneously, prey composition, prey production and vertical distribution were determined by measuring egestion of faecal pellets and the chaetognaths were analysed for gut contents. The feeding rate of P. norvegica ranged from 1.8 to 5.6 prey d-1. The impact on prey production was even higher. Our study shows that invertebrate predators is an important population regulating factor in West Greenland waters.

DO GLOBAL OCEAN BIOGEOCHEMICAL MODELS NEED TO ACCOUNT FOR IRON SPECIATION AND ABISTIC CYCLING?

Global ocean biogeochemical models (OBMs) are critical in appraising the response of the marine carbon cycle to changes in climate, but must balance mechanistic realism against computationally efficient model formulations. This is particularly true for iron, which despite exhibiting complex abiotic cycling and speciation, is typically only a single pool in OBMs. However, iron limits phytoplankton productivity (PP) in a variety of important ocean regions (e.g. the Southern Ocean and Equatorial Pacific) and such shortcomings might prove important in governing regional PP and air-sea CO2 fluxes. To that end, we employ a complex iron cycle model to test iron speciation as a function of irradiance and temperature. Over a suite of sensitivity experiments, we find that increased irradiance promotes the conversion of Fe into bioavailable forms. The absence of such processes could be important in OBMs if the irradiance/mixing regime of the ocean were to change. We outline a method by which such effects can be accounted for in an OBM and find that predictions of PP are sensitive to the inclusion of chemical processes, even if we consider no changes in circulation.
data taken by Argo floats and the monthly mean objective data analysis of temperature and salinity (Levitus data). Our new method successfully estimates meso-scale three-dimensional thermal structures in near-real time. We validate the accuracy of the estimation, comparing the estimated isothermal depths with that of in-situ sea temperature taken independently from the data used in the method. We present three case studies. The comparisons show excellent agreement between the estimated isothermal depth and that of in-situ observations. We also developed a statistical technique to estimate the error bar for the isotherm surface. We discuss the conditions of successful cases and the limitation of our method.

UNDERWAY SAMPLING SYSTEM FOR DETERMINATION OF DISSOLVED AND PARTICULATE TRACE METALS IN OCEANIC SURFACE WATERS (GEOS/I BiOCARBON)

Recent findings on the role of trace metals as a factor controlling primary productivity and biogeochemical processes in the oceanic waters emphasized the need for better understandings of spatial-temporal variabilities in concentration and chemical speciation of trace metals in marine systems. Here, we present an underway-sampling system as a means of sample collection for near-real-time measurements of dissolved and particulate trace metals in surface waters. The underway-sampling system was designed using a Tellow bellows pump, Tellow tubing, and an epoxy-coated “fork” which is towed from a stainless steel wire attached to a winch. To stabilize the fish at a depth of 0.5–1.5 m even at ship speeds over 15 knots, its weight was increased to 75 kg with tungsten alloy rods. Surface seawater was pumped up at a speed of 7 liters per minute to the operation deck level. The system was successfully used during the R/V Hakuko-maru research cruise in the NW Pacific in July 2007. The results confirmed advantages of this method of underway sampling include a reduced risk of sample contamination and enhanced sampling frequencies.

TRACE ELEMENT COMPOSITIONS OF UPLAND AND SUMMER (2006) TRAPPED FLOOD SEEDBED, HANALEI BAY, KAUAI

Changes in the Hanalei River watershed on Kauai’s north shore have the potential to increase sediment delivery to Hanalei Bay, which in turn may adversely affect adjacent coral-reef communities. Summer floods in Hanalei Bay may pose a significant threat to reef health because residence times of flood sediment may be long when wave energy is low. Two time-series sediment traps (4.5-day intervals) and five tube traps were deployed in Hanalei Bay from June to September 2006 to characterize temporal and spatial variations in trapped sediment quantity and composition, particularly during a flood event. Total elemental ratios of the silt + clay fractions of upland and trap sediment were compared to identify geochemical fingerprints of lower watershed regions; to distinguish flood and non-flood sediments in traps; and to determine whether watershed sediment sources varied during the flood event. Trapped sediment delivery by Hanalei River flood in August 2006 had a distinct Ba/Al ratio, and sediment delivery as the flood ended had elevated Cu/Al ratios compared to early- and non-flood trap sediment and to Hanalei River suspended sediment.

CHARACTERIZING COHERENT STRUCTURES IN AN ESTUARY USING IN-SITU AND REMOTE MEASUREMENTS

As part of the COHerent STructures in Rivers and Estuaries eXperiment (COHSTREX), we investigate the structure of internal waves and coherent vortices behind a rocky sill using a combination of in-situ measurements and remote sensing techniques. Fluid shear and turbulent energy are estimated by bottom-mounted ADCP measurements, while high frequency (25 Hz) and high resolution (1.8 cm bin) acoustic backscatter from a Bioioscens sensor detects the propagation of internal waves and coherent vortices past the sill. Coherent vortices are simultaneously captured on the water surface using an aerially mounted infra-red camera which detects boils of cool, surface seawater impinging the warmer surface. The location, growth rate and frequency of the surface boils are related to the in-situ flow field, vertical mixing processes, and the coherent structures observed in the acoustic backscatter. The appearance of surface boils coincides with a local increase in turbulence production and the erosion of large stratification. The measured fluid properties are compared to the results of a Kappa-epidon turbulence model, and show that boils significantly alter the expected mixing field. The ultimate goal is to relate the surface signature of boils to fundamental properties of the flow, e.g., roughness, depth, mixing, and fluid velocity, and thus obtain information from rivers and estuaries remotely.

GLOBAL-SCALE, DECADEL CHANGES IN SALINITY AND OXYGEN BASED ON RECENT REPEAT HYDROGRAPHIC SECTIONS

Salinity and oxygen variations are examined from each ocean basin, using repeat hydrographic data, including chlorofluorocarbons that provide time-scale information. Results are considered with respect to basin-wide analyses of salinity and oxygen trends (Roy et al. and Garcia et al., 2005). Temporal changes in ocean fronts and the formation of water (high latitudes and Pacific Ocean), and became saltier in more saline regions (subtropical latitudes and Atlantic Ocean), suggesting a strengthening of the normal atmospheric water transport. Reported oxygen decreases in the northern hemisphere mid-latitude thermoclines suggest a widespread slowing of thermocline ventilation (Emerson et al., 2004; Deuser et al., 2005; Johnson and Gruber, 2006). However, the upper thermoclines of all three southern basin subtropical gyres show increased oxygen, suggesting a increase in southern hemisphere circulation that could be related to recent observations of increased dynamic height and strengthened southern hemisphere westerlies. These changes are shallower than the Antarctic Intermediate Water and within and above the Subantarctic Mode Water, which originate close to the Antarctic Circumpolar Current. Both the salinity and subtropical oxygen changes are consistent with anthropogenic change.

THE VARIATION OF WAVE SPECTRAL SHAPE UNDER TYPHOON WIND FORCING INCLUDING WAVE-CURRENT INTERACTION

For the improved estimation of the wave spectra, numerical treatment of the nonlinear transfer function (Snl) is crucial because it controls the evolution of the spectral shape. The Interactive Dispersion Approach has been widely used for the computation of Snl, despite it is not able to properly calculate the Snl. To overcome this discrepancy, we implemented the SRIAM method for efficient and accurate computation of the Snl. In this work, we will present case studies of wave evolution under typhoon wind forcing in the Kuroshio region. Associated with the changes of the strong surface wind, characteristic zonal distribution of wave steepness appears ahead of the typhoon. Moreover, quasi-unidirectional wave field can be seen outside the typhoon. From the perspective of wave-current interaction, the Kuroshio also exerts significant influence on the variation of spectral shape. The wave spectral difference between the cases with and without current indicated that the changes of frequency bandwidth and the directional spreading occur inside the countercurrent region. These results indicate that the spectral shape is highly sensitive to the surface wind and current structures.

EFFECTS OF NUTRIENT ENRICHMENT ON RELEASE OF DISSOLVED AND PARTICULATE ORGANIC MATTER FROM REEF-BUILDING CORALS

Coral branches of Acropora pulchra were incubated in nutrient-enriched seawater (5 µmol l⁻¹ nitrate, 0.3 µmol l⁻¹ phosphate) for 1-22 d, and effects of the nutrient enrichment on organic matter release from the corals have been investigated. Release rates of dissolved and particulate organic matter (DOM and POM) were measured by bottle incubations in gently stirred seawater for 5 h. The results have shown that the nutrient enrichment enhanced POM release rates per unit surface area of the corals at daytime, while the effect was not found for DOM. Symbiotic algal cells released from the host accounted for only 10% of the released POM, but release rates of chl a were significantly correlated with those of the bulk POM. These suggest that symbiotic algal and other POM such as coral mucus were simultaneously released as a result of the nutrient enrichment. Inorganic nutrients have been considered to enhance symbiotic algal photosynthesis and consequently reduce coral calcification. This study has suggested that the imbalance between the two processes could be alleviated by POM release to the ambient seawater, rather than DOM.

This low PV water in Malvinas Current encounters Brazil Current at the Brazil-Malvinas confluence and is injected into the Atlantic.
subtropical gyre by eddy-induced velocity. The downward residual-mean velocity, which is sum of the eddy-induced and usual Eulerian-mean velocity, exceeds 3.1 10^{-4} m/s at the Brazil-Malvinas confluence. This strong downward transport may explain the formation of AAIW in the Atlantic subtropical gyre.

INTERACTION OF FRONTOGENETIC AND WIND-FORCED INSTABILITIES AND THEIR EFFECT ON SUBMESOSCALE TRANSPORT AND MIXING

In the upper ocean, submesoscale, i.e. O(1) Rossby number, processes develop from wind-forced and frontal instabilities. We examine the dynamical characteristics of the flow and the submesoscale transport of tracers across fronts in numerical simulations where submesoscale processes are at play. We find a correspondence between the conditions for submesoscale processes, such as large Ro and small fRi numbers, and diapycnal transport and mixing. Frontal cups or frontogetic singularities are particularly where submesoscale conditions give rise to large geostrophic velocities and rapid diapycnal transport. Rapid restratification can lead to horizontal spreading. The process of upper ocean re- and de-stratification via frontal instabilities and wind stress are discussed in the context of cross-front exchange. Parameterizations should include both advective and diffusive effects to account for these processes.

SURFACE CURRENTS INDUCED BY THE WIND ON THE GRAND BANKS - A STUDY OF THE WAVE EFFECTS ON SURFACE CURRENTS

The effects of surface waves on surface currents are investigated using surface drifter data from the Grand Banks and a coupled current-wave drifter model. The theoretical basis of the study is Jenkins’ theory of wave-current interaction in which the surface currents are modified by wind-wave and wave-current momentum transfers. The total surface current is the sum of the wave modified current, the Stokes drift and the tidal current. Jenkins’ formulation was incorporated into the Princeton Ocean Model and applied to the Labrador Sea and the adjacent shelves. The wave energy spectrum from WAVEWATCH III was used to calculate wave transfer and the Stokes drift. A series of model experiments were conducted to simulate the drifter trajectories and examine the sensitivity of the simulations to model parameters. The results show that the Stokes drift is the dominant wave effect, which increases the surface drift speeds by 35% and veers the currents toward the wind directions. The net effect of wind-to-wave and wave-to-current momentum transfers reduces the surface speeds by a fraction. A statistical analysis of the model currents and drifter data shows that the inclusion of the wave effects improves the model simulations significantly. A sensitivity study shows the model surface currents are most sensitive to the surface eddy viscosity and the wave energy spectra.

IT’S GOOD TO BE BIG!!! - PHAEOCYSTIS ANTARCTICA COLONY SIZE UNDER THE INFLUENCE OF ZOOPLANKTON GRAZERS

The diaptomous Phaeocystis antarctica forms extremely dense accumulations in the Ross Sea, Antarctica, and can account for over 60% of the region’s seasonal primary production. As with the northern Phaeocystis species, P. antarctica exists as solitary cells and mucilaginous colonies that differ by several orders of magnitude in size. Recent experiments with P. globosa suggested that colony formation is a defense mechanism against small grazers. As part of the ESCAP project we conducted incubation experiments at McMurdo Station during the austral summer using natural P. antarctica and zooplankton assemblages. Dialysis bags were used to separate P. antarctica and zooplankton in the incubators but allow exchange of dissolved chemicals. Geometric mean colony size decreased by 35% in the control, but increased by 30% in the presence of grazers even without physical contact. P. antarctica growth rate in terms of chlorophyll a or POC was unaffected, and it ranged 0.26 to 0.28 per day. While our observations support the notion that colony formation is a defense mechanism against grazing, the cost of such mechanism, as predicted by defense theory, remains unknown.

THE ARCTIC OCEAN SINK FOR ANTHROPOGENIC CO2

The concentration and inventory of anthropogenic CO2 (Cant) in the Arctic Ocean is poorly known despite its relatively large volume of well ventilated waters. We use a synthesis of available CFC and SF6 measurements from close to ten thousand individual tracer samples to calculate the Arctic Ocean Cant inventory. For these calculations we have used the Transit Time Distribution (TTD) method, where the TTD is calculated from the tracer data, and then applied to the known atmospheric CO2 increase, assuming time-invariant air-sea exchange of CO2, to calculate the oceanic Cant content. The Cant field is then integrated over the Arctic Ocean and the inventory is calculated. For this we find that the Arctic Ocean holds about 2% of the total global oceanic Cant inventory. We will show horizontal distributions of Cant as well as depth integrated profiles from the individual basins.

SIZE SPECTRA OF EUKARYOTIC NANO- AND MICROPLANKTON IN THE CALIFORNIA CURRENT ECOSYSTEM

We examined the size spectra of nano- and microplankton as a function of environmental variability in the California Current system. Water samples were collected during May 2006 at eight depths in five distinct water parcels, varying from eutrophic coastal water to oligotrophic open ocean. For each assemblage, heterotrophic and autotrophic protists were quantified and sized using digital image epifluorescence microscopy, and size spectra were examined as continuous distributions of exceedence. Among the different waters examined, auto- and heterotrophs show similar size spectral patterns in the mixed layer, which may be a general system characteristic. The spectra, however, diverge at depth, with larger heterotrophs and smaller autotrophs becoming proportionally more abundant at the base of the euphotic zone. Predator-prey dynamics underlying these size relationships are being explored experimentally and in food web models.

EFFECTS OF SUBMARINE GROUNDWATER DISCHARGE ON SEASHELL ECOSYSTEM IN THE COASTAL ZONE

Submarine groundwater discharge (SGD) is recognized as an important pathway from land to ocean, not only for water and dissolved material transports but also for ecosystem in the coastal zone. Strontium isotope ratios of the shell (clam and oyster) in Omaehama and Edajima, Japan, were examined to evaluate the ratio of fresh water component of SGD. The relationships between the size/distribution numbers of the shell and Sr isotope ratio were examined. The seepage meters (for SGD flux), piezometers (for groundwater potential), optical fiber cable (for sea bottom temperature) and resistivity (fresh-salt water distribution) measurements had been also made to evaluate the flux and quality of the SGD. The distribution numbers of the clam in Omaehama agreed with the magnitude of the fresh component of SGD. The relationships between the size of the oyster and fresh water component of SGD have been examined. SGD may be one of the important geophysical and chemical factors for the seashell ecosystem in the coastal zone.

TAKING IT TO THE STREETS: SEAS MOBILE LABORATORY EXPOSES STUDENTS TO OCEAN SCIENCE RESEARCH

To support inquiry-based field activities in local K-12 schools, Florida Tech recently purchased and renovated a 35 ft recreational vehicle that serves as a mobile laboratory. SEAS Lab seeks to improve ocean literacy by exposing students to the tools and techniques used by marine scientists. The lab also gives schools access to equipment and resources they would otherwise be unable to afford. SEAS can accommodate up to 12 students and includes 22 ft of bench space, five computers, a GPS unit, filtered seawater, and a multi-sensor weather station. The lab also gives schools access to equipment and resources they would otherwise be unable to afford. SEAS Lab offers access to equipment and resources that would otherwise be unable to afford. SEAS Lab offers access to equipment and resources that would otherwise be unable to afford. SEAS Lab offers access to equipment and resources that would otherwise be unable to afford. SEAS Lab offers access to equipment and resources that would otherwise be unable to afford. SEAS Lab offers access to equipment and resources that would otherwise be unable to afford.
TEMPORAL VARIABILITY IN MICROBIAL COMMUNITIES AND ACTIVITIES WITHIN THE PHYSICO-CHEMICAL CONTEXT OF THE CARIACO BASIN

Monthly to semi-annual observations collected for over a decade at the CARIACO time series illustrate that microbial inventories and heterotrophic productivity in the upper 100 m vary to 20-fold annually, similar to primary production but out of phase. Microbial variables within the redoxcline (200-450 m) and in deeper anoxic waters vary over similar ranges, and appear uncoupled from surface processes. Recent phylogenetic analyses using 16s rRNA illustrate that bacterial community structure is also highly variable, suggesting that varying physico-chemical conditions favor different eukaryophytes, thereby altering relative contributions of identifiable ribotypes to the community. Through times series and non-parametric statistical analyses, we explore how microbiological variables relate to physical, chemical and other biological variables, including upwelling intensity, water mass intrusions, nutrient inventories, DO/CPOC, primary production, sources of mortality, and vertical fluxes of organic matter.

INVESTIGATING THE SOURCES AND TRANSPORT OF ORGANIC CARBON USING INTACT BACTERIAL HOPANOLYS

Intact bacteriohopanepolys (BHPs) are pentacyclic triterpenoids with poyfunctional sided chains found ubiquitously throughout the geosphere. These structurally diverse compounds have been isolated as cell membrane lipids from a range of prokaryotes, including methanotrophs, acetic acid bacteria, cyanobacteria, and purple non-sulfur bacteria. Their recalcitrance allows intact BHPs to be considered as ideal biomarkers for tracing the input and movement of microbial-derived organic carbon within estuarine and marine systems. The Chesapeake Bay and Arctic Ocean are differing sedimentary environments with varied carbon sources and significant amounts of both marine and terrestrial derived organic carbon. In transects of surface sediments from both systems, we determined the distribution of intact BHPs using atmospheric pressure chemical ionization liquid chromatography/multi-stage ion trap mass spectrometry (APCI-LC/MSn). This information is being integrated with a suite of lipid biomarkers to examine the carbon sources, transport and preservation in these two systems.

OBSERVED OCEANIC RESPONSE UNDER HURRICANE IVAN

Current moorings with wave/tide gauges were deployed on the outer shelf and slope in the northeastern Gulf of Mexico. Fortunately, Hurricane Ivan passed directly over these moorings. Currents greater than 20 cm/s were measured. Strongest currents were found to be to the left of the hurricane path on the shelf but were to the right of the track on the slope. During Ivan’s approach, shelf currents followed Ekman dynamics with overlapping surface and bottom layers. As Ivan passed over the moorings, the shelf currents transitioned to a deepening surface boundary layer. Bottom currents were wind driven near the surface at the onset of Ivan but deeper in the water column subinertial waves with characteristics of topographic Rosby waves and periods of 2-5 days were excited during Ivan’s passage. Near-inertial motion lasting for about 10 days was generated by the storm. A record wave height of 27.7 m and an extreme bottom scour of 0.36 m at 60 m water depth were measured. Surface momentum transfer was calculated from measured currents and peaked at winds of 32 m/s before decreasing.

ANOMALOUS FAST DRIFT OF A SURFACE-INTENSIFIED EDDY NEAR STEEP CONTINENTAL SLOPE

The first data sets of the EGYPT cruises in the eastern Mediterranean sea reveals a large meso-scale vortex traveling along the Libya-Egyptian shelf. Surface drifters trajectories combined with a CTD transect quantifies the horizontal and the vertical structure of this surface-intensified anticyclone. The observed westward drift speed is significantly faster than expected from the beta-effect only. To investigate the eddy dynamics we used a two-layer idealized model with steep continental slope and zonal boundary. An integral momentum balance for the upper layer is used to derive the vortex center velocity assuming a circular dome interface at the leading order. This approach reduces the problem to the

ocean models the sea-ice dynamics is modeled by a momentum balance, which includes a conservative law that relates the ice stress to the strain rate and sea-ice strength. This law requires a parameterization for the sea-ice thickness distribution and sea-ice strength. Most models use simple formulations with spatially constant empirical parameters, which is known to be insufficient in most cases. An improvement is to allow for spatially varying parameters and using data-assimilation to estimate these parameters from observations. We present results of an estimation of local values of a crucial parameter, p, using a local SAR filter to assimilate satellite observations and detailed in-situ observations of sea ice parameters into the high-resolution finite-element ocean model FEMO of the Arctic Ocean. The model is forced by high-resolution atmospheric variables. Furthermore, on a higher level, optimal parameterization formulations of the sea-ice thickness distribution and strength are determined using this highly-detailed observation set.

**OBSERVATIONS ON THE TRANSPORT AND STRUCTURE OF THE PANAY STRAIT OVERFLOW**
The Philippine Archipelago is composed of deep ocean basins, interconnected by a network of straits. The renewal of the deep waters of the Sulu Sea from the South China Sea by westward overflow with the Panay Strait measurement in June 2007 (Moore et al., 2008) ADCP and an array of lowered ADCP stations observed strong bottom intensified overflow into the Sulu Sea. The mean transport is estimated to be 0.31 Sv, with the maximum and minimum transports during the ~3 week deployment at 0.52 Sv and 0.11 Sv, respectively, and coinciding with spring tides. The estimated residence time of the sub-sill waters within the Sulu Sea is 10 years. Some of the overflow we observed flowed toward the shallower sill at a depth of ~600m, just below sill depth. This counter-current may be induced by entrainment of ambient water into the dense overflow. Substantial geothermal heating influences stratification within the deep Sulu Sea.

**PIECOLONKTON ABUNDANCE AND DIVERSITY IN A HYPER-EUTROPHIC LAGOON**
Picoplankton (cells with a diameter of 0.2-3 µm) is the dominant contributors to both primary production and biomass in the ocean. Most of the studies on picoplankton were conducted in the oligotrophic open sea but few in the eutrophic area. In this study, we investigated different picoplankton populations (Synechococcus, Prochlorococcus and picocyanobacteria) and their correlation with environmental factors (temperature, NO3, N2O, PO4, and total Chl a) in a hyper-eutrophic marine coastal lagoon (Dapeng Bay, Taiwan). We also used small subunit ribosomal RNA (18S rDNA) gene sequence to investigate the genetic diversity of picoeukaryotes in this area. The results show that all three picoplankton populations varied seasonally, and were significantly influenced by PO4 concentrations. Picoeukaryotes diversity included Alveolates, Stramenopiles, Haptophyceae, Viridiplanetae and Metazoa. Among them Stramenopiles and Metazoa were the dominant ones. Some of the sequences represented previously unknown marine species. Overall the study shows that picoplankton abundance in the eutrophic area was high, however the diversity was relatively low as compared to other parts of the world.

**A SEVERE NITROGEN DEFICIT IN THE LOWER ST. LAWRENCE ESTUARY: THE IMPORTANCE OF BENTHIC NITRATE ELIMINATION**
Water column nutrient concentration and benthic fluxes were measured in the LSLE and the Gulf of St. Lawrence in order to understand nutrient budgets in the SL system and their potential link to hypoxia the LSLE bottom waters. Using N2 as an integrative tracer of the balance between N inputs and losses, we observed a severe nitrogen deficit (i.e. low N) in and around the hypoxic zone, indicating active nitrate elimination in the deep LSLE. The St. Lawrence River is characterized by high N input from the watershed. Benthic N fluxes were calculated from water column gradients. Nitrate fluxes into the sediments were significantly higher in the LSLE (115-184 µmol.m-2.day-1) compared to the Gulf (84-95 µmol.m-2.day-1), suggesting that hypoxic bottom waters enhance benthic denitrification rates. Benthic O2 fluxes were measured using micro-electrodes, and could be used to estimate the rate of nitrate loss due to coupled nitrification-denitrification. Estimates of total denitrification rates were 4 to 5 times higher than diffusive nitrate fluxes, highlighting the important role of nitrification-denitrification coupling as major N elimination pathway in the LSLE sediments.

**WORMS AND GLOBAL CHANGE: WHY COULD CLIMATIC CHANGES ALTER MARINE POPULATION CONNECTIVITY AT DIFFERENT TEMPORAL SCALES?**
For most marine invertebrates, dispersal plays a significant role on populations/dynamics, biogeography and speciation. In this context, the present work highlights the influence of both past and present climatic changes on the connectivity of marine populations, focusing on the past demography and the actual distribution patterns of three polychaetes species in the NE Atlantic. First, molecular studies show a strong phyleogeographic break along the Lusitanian/Boreal biogeographic transition zone. Second, the actual impact of climatic changes on larval phenology (spawning period, planktonic larval duration) is assessed from the analysis of Continuous Plankton Recorder data in the English Channel and the Bay of Biscay over the last 4 decades. Third, a 3-dimensional bio-physical model of the study area is developed, including a Lagrangian dispersal procedure with specific larval behaviour; to explore how complex seasonal hydrodynamic features (e.g. gyres, upwellings) could alter larval dispersal and connectivity: dispersal kernels and connectivity matrices for several climatic scenarios are analyzed as a function of spawning release date and larval durations.

**LARGE, MOTILE EPIFAUNA INTERACT STRONGLY WITH HARPACTICOID COEPODE AND POLYCHAETE AT A BATHYAL SITE**
The strengths of interactions in deep-sea-sediment communities are poorly known. Large, motile-epifauna (~ 1 LME), such as sea cucumbers, occur in the deep sea and have the potential to interact strongly with the infauna. Off southern California at 780 m depth, we excluded the LME from five 75-cm by 75-cm plots with cages. After 143 days, we sampled these plots and five plots of the same size paired with them as controls. The abundances of harpacticoid copepods and polychaetes were significantly lower in cages than in controls. In three cages, the nematodes and kinorhynchus were dramatically less abundant than in paired controls. The results suggest that the LME ordinarily affects the infaunal assemblage in such a way that harpacticoiids and polychaetae (and perhaps nema todes and kinorhynchs) can maintain higher abundances than they can in the absence of LME, indicating that strong interactions can influence the organization of deep-sea sediment communities. In a multivariate analysis of environmental parameters, cage and control samples were intermixed, so how the LME transmit their effect is not clear.

**BIOGEOGRAPHY OF THE OCTOCORAL GENUS PARAMURICEA ON ATLANTIC SEAMOUNTS: EVIDENCE FOR MULTIPLE INVASIONS OF THE NORTHWESTERN ATLANTIC DEEP SEA?**
The Corner Rise and New England seamount chains extend north-westerly from the mid-Atlantic ridge to the North American continental margin. To understand the biogeography of the deep-sea fauna in this region, we collected 78 octocoral colonies (genus Paramuricea Kölliker, 1865) from depths between 220-2200 m spanning these seamounts and two locations on the continental margin (Oceanographer Canyon; Gulf of Maine). DNA sequencing of the mitochondrial msh1 gene reveals four haplotypes (denoted A-D) and suggests three or four species. Type C is the most geographically widespread, spanning the continental margin seamounts to the easternmost seamounts, and is the only haplotype observed on the isolated, off-shelf Mur Seamount. Type B has a similar distribution to C but does not extend as far west or south. Haplotype A & D, evolutionarily the most recently derived, are associated with continental margin habitats; all colonies sampled from the continental slope are type A. Haplotype A & D are more closely related to a haplotype from Hawaii than to B or C, suggesting possible multiple invasions of Paramuricea species into the western North Atlantic deep sea.

**COMPARISONS OF CHLOROPHYLL VARIABILITY BETWEEN THE CALIFORNIA AND HUMBOLDT CURRENT SYSTEMS: LINKAGES TO LOCAL VERSUS NON-LOCAL FORCING**
Ten years (Sept 1997 - Aug 2007) of SeaWiFS satellite data over the California and Humboldt Current Systems are used to quantify interannual variability of chlorophyll concentrations. Variability is characterized as both biomass anomalies and as shifts in underlying temporal variance structure quantified and isolated with wavelet analysis. Dominant patterns in each system are summarized first as EOF decompositions. As a function of latitude, concentrations averaged over the 100km closest to the coast capture the majority of upwelling and shelf-related chlorophyll biomass anomaly variability. Maximum negative anomalies are associated...
with the 97-98 El Nino, strongest off Peru, central Chile and the U.S. Pacific Northwest. Strongest positive anomalies are in 2001-2002 and in late 2005 in the California Current, and in 2002-2004 off Peru and 1998-2000 off central Chile. We isolate strongest temporal chlorophyll variance within specific frequency bands and as a function of cross-shelf distance. Dominant interannual signals of both biomass anomaly and temporal variance are compared first to each other and then to concurrent local wind forcing and basin-scale climate-related signals to gauge the importance of local versus non-local forcing.

FRICION, FRONTOGENSESIS AND THE STRATIFICATION OF THE OCEAN SURFACE MIXED LAYER
The generation and destruction of stratification in the surface mixed layer of the ocean is traditionally considered to result from vertical turbulent transport of buoyancy momentum driven by air-sea fluxes and stresses. However, the magnitude and penetration of vertical fluxes is strongly modified by horizontal gradients in buoyancy and momentum. A classical example is the strong restratification resulting from frontogenesis in regions of confluent flow. In this presentation it will be shown that frictional forces acting on a baroclinic current can also modify the stratification by driving Ekman flows that differentially advect density. Scales are constructed for the relative importance of friction versus frontogenesis in the restratification of the mixed layer. High resolution numerical simulations of mixed layer fronts forced by both wind-stress and confluence are performed to test the scalings. Both the simulations and scalings suggest that for wind-stress magnitudes, mixed layer depths, cross-front density gradients, and confluence typical of the ocean, wind-induced friction is as or more important as frontogenesis in the modification of the stratification of the upper ocean.

STABLE CARBON ISOTOPE DISCRIMINATION BY FORM IC RUBISCO FROM THE METABOLICALLY VERSATILE BACTERIUM RHODOBACTER SPHEROAREIDES
A major factor influencing δ13C values of autotrophic biomass is the degree to which the enzyme carbonic anhydrase contributes to the isotope discrimination factor δ13C. For autotrophs using the Calvin cycle, the primary carboxylase is Rubisco, of which six forms exist (IA-ID, II, and III). Despite the diversity of these enzymes, an ε value of ~25‰ is commonly assumed for modeling studies. ε values ({{\frac{1}{2}}\epsilon / \{k / 1\} × 1000}) have been published for form IA, IB, and II enzymes, but not form IC, which are particularly relevant to marine and aquatic habitats based on their presence in many algal or bacterial nitrifiers. A substrate depletion method was used to determine ε values for form IC Rubisco from Rhodobacter sphaeroides. The ε value was determined to be 22.9‰, which is within the low end of the range measured for form IA and IB enzymes (22-29‰) but greater than ID enzymes (12-19‰). Sampling the full phylogenetic breadth of Rubiscos for isotopic discrimination makes it possible to constrain the range of δ13C values of organisms fixing carbon using the Calvin cycle.

PRACTICAL APPLICATIONS FOR NUMERICAL MODELING IN SALT MARTH DESIGN, TEXAS GULF COAST
Numerical models can be applied in the design process to assess the function of designed salt marshes on the Texas Gulf Coast prior to construction. Although analysis of geo-morphology is often not rigorously modeled because of financial and/or time constraints, it is important in areas such as the Texas coast where relative sea level rise (RSLR) is greater than the average rate of sediment deposition. Circulation modeling of proposed marsh designs helps assess tidal exchange and flushing via tidal conveyances such as channels and ponds within the marsh complex, but only provides qualitative information about morphology. Morphologic predictions are inferred from circulation modeling but may not be accurate enough to predict survivability of the marsh against RSLR. This presentation will discuss analyses of designed salt marsh systems both before and after construction including methods to analyze circulation, sediment transport, and morphologic changes. Lessons learned about the practical value of numerical modeling of designed marsh systems on the Texas and Louisiana coast will conclude the presentation with emphasis on future research needs from the point of view of a practicing coastal engineer.

SURFACE DRIFTERS AND TOPOGRAPHY AT THE TIP OF THE ANTARCTIC PENINSULA
Near the tip of the Antarctic Peninsula, topographically-forced frontal jets are important in transporting nutrients and krill larvae from source regions on the continental shelf into the Antarctic Circumpolar Current. However, our understanding of the circulation in this region is limited due to the effects of complex topographical features, the confluence of the jets with the Antarctic Circumpolar Current and a scarcity of observational data. In February 2007, 40 surface drifters were deployed along a section extending from the tip of the Antarctic Peninsula across the continental shelf and slope into the deep Weddell Sea. The fine spacing of the drifters, ~5 km off the shelf break and ~10 km off the continental slope, has enabled the identification of previously unresolved features of the surface circulation including a series of narrow frontal currents, topographically-controlled standing eddies and regions of strong lateral shear. Through the use of simplified models of the flow field, we investigate how physical mechanisms such as potential vorticity conservation and tidal forcing influence tracer transport in this region, especially in governing cross-topography exchanges.

THE BIOGEOCHEMISTRY OF MODERN OODS: ASSESSING THE ROLE OF MICROBES IN OOID FORMATION
The origin of ooids remains elusive and controversial despite their geologic and economic significance. In this study drifters were deployed in 2007 and 2008 to examine the role of the Gulf Stream in lowering the transport and heat anomalies that we probe a model of ooid formation requiring a diverse redox-dependent microbial consortium at the site of calcification.

A., University of Washington, Seattle, USA, kellyapl@apl.washington.edu; McClean, J., Scripps Institution of Oceanography, La Jolla, USA, jmcclean@ucsd.edu; Greiner, E., Mercator Ocean, Toulouse, France, egreiner@mercator-ocean.fr

USING HIGH RESOLUTION PROGNOSTIC AND ASIMILATIVE MODELS OF THE NORTH ATLANTIC TO EXAMINE THE ROLE OF THE GULF STREAM IN INTERANNUAL CHANGES IN HEAT TRANSPORT
A 1/10th of a degree prognostic ocean model and a 1/3 of a degree assimilative model of the North Atlantic is used to evaluate the propagation of transport and heat anomalies from the subtropical gyre to the subpolar gyre through the Gulf Stream Extension and recirculation and around the Northwest Corner. The prognostic model (POF, Parallel Ocean Program) is run from 1800 to 1999 in the North Atlantic with daily forcing based on NCEP forecast winds (National Center for Environmental Prediction) with relaxation to observations at the Northern and Southern Boundary. The assimilative model (MERA11) is a reanalysis from 1992 to 2002 that assimilates a variety of observational data and is forced by ECMWF ERA 40 winds and was performed by the MERCATOR group. The assimilative model along with altimetry observations are used to evaluate the fidelity of the high resolution model. The reanalysis product shows evidence for warm anomalies propagating from the subtropical to subpolar gyre. Intertannual variability of the upper ocean heat content in the prognostic model does not reproduce that in the observation, but because the model physics are internally consistent, it can be used to evaluate whether and how anomalies of mass and heat enter the Gulf Stream extension and remain coherent into the subpolar gyre.

USING STABLE ISOTOPES TO QUANTIFY DIFFERENTIAL VITAL RATES AND AS A MEASURE OF HABITAT QUALITY
Habitat quality is a important measure for the determination of essential fish habitat. There is no standard measure, nor method, for the quantification of habitat quality.
The most often used measures are abundance, growth, and survival. Survival is the best measure yet also the most difficult to quantify. Therefore the use of growth as a proxy for survival is often the best alternative. Biotic factors, which regulate differential growth, can be divided into two major schools of thought: top-down (preyation) and bottom-up (food quality/quantity). We examined the growth of juvenile spotted seatrout on seagrass beds in Chesapeake Bay to determine whether observed differences in juvenile growth were related to bottom-up (diet) influences. We used stable isotopes and stomach contents to conduct a preliminary analysis of bottom-up control on juvenile spotted seatrout growth in the Bay. We found significant differences in carbon sources among the beds, and also provide evidence that in some beds fish may be feeding at different trophic levels. Preliminary stomach content analysis shows some differences in diet which may be reflected in the nitrogen isotope signatures.

REMOTE ESTIMATION AND VALIDATION OF WAVE BREAKING ENERGY DISSIPATION

Recent observations suggest that the strength of breaking surface waves can be quantified remotely. Specifically, simultaneous remote and in situ measurements of breaking waves are needed to test the Duncan-Phillips formulation for spectral energy dissipation. Visible and infrared images are used to calculate the distribution of whitecaps on Lake Washington, where swell and other motions can be neglected and in situ measurements are collocated for direct comparison. The images are processed using a new method in which the frequency-wavenumber spectrum is mapped to a distribution of crest speeds and energy biasing is avoided. Both the breaking rates and the dissipation rates measured remotely are consistent with in situ measurements. In addition to the passive imagery, active infrared measurements are used to demonstrate the importance of microbreakers, which do not generate foam but do contribute to the total dissipation.

ASSESSING ZOOPLANKTON PREY SELECTIVITY USING REAL TIME PCR QUANTIFICATION OF PREY DNA

Due to high predation pressure zooplankton prey selectivity is a major modulator of phytoplankton biodiversity. In the past, the general consensus has been that planktonic consumers are more passive filter-feeders or only in some cases able to switch between different feeding modes. Only recently have we turned our attention to prey selectivity and trophic niche differentiation in marine zooplankton. We have tested a method for measurements of prey selectivity by quantification of prey DNA in copepod guts by real-time PCR. Primers and fluorescent oligonucleotide probes targeting LSU ribosomal DNA have been generated and successfully tested for functionality and species specificity in different phytoplankton species regularly used in laboratory grazing experiments. These probes were then used in mixed grazing experiments using a protocol, which allows calculation of selectivity indices without absolute quantification of number of algal cells in the copepod guts. The protocol employs the concentration ratios of target DNA sequences in water and guts. The protocol is scalable for use in testing the response of individuals to different feeding modes. It is also possible to test the response of individuals to different feeding modes. It is also possible to test the response of individuals to different feeding modes.

SEASONALITY IN CARBON BIODECAY AND INFLUENCE OF NET ECOSYSTEM PRODUCTION ON CO2 SUPERSATURATION IN EUTROPHIC COCHIN ESTUARY, INDIA

The seasonality in carbon biodecay and the influence of net ecosystem production (NEP) on CO2 supersaturation was assessed in the eutrophic Cochin estuary on the southwest coast of India. Dissolved organic carbon dominated total organic carbon and their ratio to particulate organic carbon ranged between 1 and 5. Increase in the dissolved inorganic carbon (DIC) to organic carbon ratio with suspended particulate matter suggests that the maximum turbidity zones could be potential sites for respiration of organic carbon. The community respiration (R) was consistently higher than primary productivity (P), indicating a strong heterotrophic activity. Both the biochemical and biotic respiration contributed 20% of R, suggesting strong heterotrophy (NEP < 0). NEP increased sharply from pre-monsoon (~ 84 ± 91 mgCm-2d-1) to monsoon (~ 171 ± 147mgCm-2d-1), supporting production of excess CO2 (ECO). The increase in CO2 was correspondingly high (~ 10.9 ± 13.4 % of DIC. Strong relationship between P and apparent oxygen utilization (P < 0.001) indicates that respiration is a major factor for CO2 supersaturation (up to 19 times). Our studies suggest that Cochin estuary sustains net heterotrophy all the year round and hence, is a potential source of CO2 to the atmosphere.

HOW WILL CHANGES IN FRESHWATER INFLOW (FREQUENCY VERSUS MAGNITUDE) IMPACT THE ECOLOGICAL SYSTEM HEALTH OF GALVESTON BAY?

With a rapidly expanding urban population in Texas coastal regions, policy makers, water regulators and managers are faced with the challenge of meeting human needs, potentially by freshwater diversions, while maintaining critical freshwater inflows to estuaries to preserve their overall health. We used a flow-through boat-mounted Dataflow unit and a PHYTO-PAM (Phytoplankton Pulse Amplitude Modulated fluorometer) to map various primary productivity parameters and phytoplankton responses respectively across Galveston Bay throughout 2006. Tightly gridded transects took two days to complete. An integrated GPS allowed us to reference all measurements for each variable. Discrete water samples were collected for nutrient analysis and light/dark bottle primary productivity measurements. We found complex relationships between the freshwater inflow (frequency, magnitude), water quality (temperature, salinity, dissolved organic matter, chlorophyll, nutrients) and phytoplankton responses (productivity, community structure). Spatial and temporal patterns were deconvoluted with seasonality and the magnitude of a freshwater inflow event being the two principal driving factors regulating primary productivity. Understanding these relationships will provide scientists and regulators with information to assess estuary health in Galveston Bay as well as other estuaries along the Texas coast.

SILICON CYCLING IN THE CARACIO BASIN, VENEZUELA: SEASONAL VARIABILITY IN SILICATE AVAILABILITY AND THE SCN COMPOSITION OF SINKING PARTICLES

A nine-year time series of water column and sediment trap measurements was used to examine silicon cycling within the Caracibo Basin. Annual production rates as high as 9.8 mmol m-2 d-1 occur during winter-spring upwelling. However, even during upwelling, surface waters tend to be depleted in both Si(OH)4- and NO3- as a result of rapid utilization. Surface waters during the upwelling period are marked by Si(OH)4-=NO3- and Si* values less than one, conditions which may restrict diatom production. During non-upwelling conditions, Si(OH)4-=NO3- ratios in the upper 50 m exceed 10, implying that nitrate is limiting production. Particle collected at 150 m depth have average SiC and SiN values of 0.17 ± 0.01 and 1.14 ± 0.10, respectively. These ratios increase with depth to 400 m and then remain relatively constant. Similar depth-dependent changes in these ratios are seen in seasonal transects from the basin. Seasonally, particulate SiC and SiN values are highest when upwelling is most intense, while both ratios decrease to their lowest values during summer-fall. High SiN ratios (~3.0) during upwelling are similar to values observed in areas where Fe-limitation occurs.

OVERFLOW OBSERVATIONS ON THE MID-ATLANTIC RIDGE

Observational evidence suggests that there are tens of thousands of overflows located in canyons on the global mid-ocean ridge system. The high levels of diapycnal mixing associated with these overflows makes them important for the abyssal buoyancy budget and, hence, for the global overturning circulation and for the Earth’s climate. In recent years, a variety of physical oceanographic data have been collected at several such overflows on the Mid-Atlantic Ridge. Common characteristics include hydrographic evidence for “Bermoulli suction” upstream of the sills, gravity currents downstream of the sills, hydraulic transitions, as well as lee waves. While the kinetic energy near the sills is typically dominated by the (quasi-steady) overflow currents, there is significant variability, especially at tidal frequencies. At distances greater than a few kilometers from the sills, the tides usually dominate the kinetic energy. There are several well known processes associated with overflows that can account for the high levels of diapycnal mixing observed there, including interfacial shear instabilities, hydraulic jumps and breaking lee waves. However, the thickest layers of static instability in the water column near two different overflows extending over more than 100m were observed upstream of the sills, suggesting a hitherto undetected process probably associated with temporal variability.

OBSERVATIONS OF THE EFFECTS OF TURBULENCE ON PARTICLE SIZE DISTRIBUTIONS IN AN ESTUARINE BOTTOM LAYER BOUNDARY
Estuarine bottom boundary layers (bbls) are an area of intense interest to physical oceanographers. It is here that model levels of turbulence are found, due to high stress and shear rates. Sediment erosion and deposition also occurs in the bbl. The magnitude of turbulence is critical in determining the vertical flux of suspended particulate matter (SPM) and in the presence of cohesive particles the degree of flocculation as well. Here we present concurrent, concurrent observations of dynamics and SPM performed in the bbl of a macrotidal estuary during a 24-day period. The balance of turbulent kinetic energy is considered, in conjunction with variations in the concentration and size distribution of the SPM and its relationship with the turbulent shear rate. Both the turbulence and the SPM are found to vary over a number of tidal frequencies in addition to exhibiting a tidal asymmetry. Possible explanations for these findings are suggested and their implications considered.

PRIMARY PRODUCTION IN THE NORTHWESTERN SARGASSO SEA: 19 YEARS OF DATA FROM THE BERMUDA ATLANTIC TIME-SERIES STUDY.
Measurements of primary production using in situ 14C incubations have been carried out at the Bermuda Atlantic Time-series Study (BATS) site monthly since October 1988. Strong seasonal variations in depth integrated primary production (PP) values have been shown to exist, characterized by a marked increase in surface layer productivity from February to March, from 7.2×10^{-2} Wm^{-2} to 7.2×10^{-3} Wm^{-2} in the winter, and a gradual decrease to 7.2×10^{-5} Wm^{-2} in the spring and summer. These results are compared to PP values for the Sargasso Sea obtained from measurements off the Bermuda Rise (BRL). Both BATS and BRL show very high variability in PP values, especially in the surface layers, with seasonal variation and interannual trends. Additionally, we report continuing experiments comparing differences between sampling from CTD Niskin bottles and trace metal clean GoFlo deployments. Initial experiments have shown very high variability between the CTD and GoFlo methods (Ncv = -70), however more recent comparisons suggest a closer correlation (typical Ncv = -25).

MIXING ON CONTINENTAL SHELF AND SLOPE OF THE NORTHERN SOUTHERN CHINA SEA
A mixing experiment was performed from 20 April to 5 May 2004 on the continental shelf and slope of the northern SCS. The observation shows that the intensified turbulent mixing on the shelf is due to the internal wave breaking and the salt finger mixing on the slope, which is attributed to the intrusions of North Pacific Tropical Water and North Pacific Intermediate Water. The mixing is more intense on the shelf, with both the dissipation rate of TKE ε (7.2×10^{-6} Wm^{-2}) and of thermal variance χ_{θ} (1.1×10^{-5} Wm^{-2}) one order larger than that on the slope. The eddy diffusivity for density K_{θ} in doubly stable regions is 2.3×10^{-4} m^2 s^{-1}, almost equivalent to the eddy diffusivity for heat K_{θ} (2.3×10^{-4} m^2 s^{-1}). The study results demonstrate that turbulence also contributes to the mixing even in the finer-scale favorable regime. Furthermore, the mixing efficiency was estimated, giving 0.08-0.27 in doubly stable regions, and 0.7-1.5 in salt finger regions.

MODEL-BASED ANALYSES OF NUTRIENT AND CARBON CYCLING ON THE U.S. EASTERN CONTINENTAL SHELF
Continental shelf systems represent an important, but poorly quantified component of the global nitrogen and carbon cycles. In this study, simulations obtained from a one-dimensional biogeochemical model developed for the U.S. eastern continental shelf are analyzed to assess nitrogen and carbon cycling processes. The one-dimensional model includes lower trophic level interactions with and without explicit dissolved organic matter dynamics and is forced by advective fields obtained from a three-dimensional implementation of the same biogeochemical model. Taylor diagrams are used to compare simulation results from specific regions of the continental shelf with observations. These provide an evaluation of model skill as well as insights into adjustments that are needed for the rates and parameterizations used to simulate phytoplankton processes. Analyses of preliminary simulations suggest strong regional variability in the skill of the model to predict surface chlorophyll concentrations. However, for clarity, we focus on a few of these data assimilation studies, provide an approach for understanding regional differences in model skill.

USE OF REMOTE SENSING AND PROCESS-BASED MODELS TO EXAMINE THE DISTRIBUTION AND TRANSPORT OF DISSOLVED ORGANIC CARBON IN WATERSHEDS AND ADJACENT COASTAL WATERS
We introduce a GIS-based integrative modeling approach to examine the sources and transport mechanisms of dissolved organic carbon (DOC) from terrestrial ecosystems to coastal oceans. The modeling is based on a set of in situ measurements collected monthly from the last two years. A soil and water assessment tool (SWAT) was adopted as a framework to predicting DOC transport processes and linking them with terrestrial biophysical properties. First, the paper discusses a statistical analysis of in situ measurements of fresh-water DOC endmember samples and examines their spatial variability with precipitation, season, hydrological processes, and soil physical characteristics. Then we present a predictive model describing the seasonal and spatial patterns of terrestrial DOC sources as well as daily fluxes to coastal water. Our study shows that terrestrial sources of DOC can be associated with biophysical and climate conditions that are obtainable using GIS and remote sensing. The model has been tested in the Neponset and Hudson watersheds in the northeast USA.

ATMOSPHERIC FE DEPOSITION MODES AT BERMUDA AND THE ADJACENT SARGASSO SEA
Atmospheric fluxes of Fe were determined from bulk (wet + dry) and wet deposition, and aerosol concentrations at Bermuda from 1999 to 2001. Dry deposition dominates (>70%) total Fe deposition during this period from proximate continental dust sources and sausal pattern of precipitation. Longer Bermuda records show dry deposition positively correlates with the North Atlantic Oscillation (NAO) winter index. Conversely, wet Fe deposition dominates during negative NAO as the Bermuda high relaxes promoting wet deposition of summer. Dry Fe deposition velocities (DDV-Fe) calculated from measured bulk-wet fluxes show a large range but consistent seasonal trend. During the summer, the DDV-Fe ranged from 0.1 to 0.3 cm/s, but during the fall and winter ranged from 2.0 to 6.0 cm/s, averaging 1.7 cm/sec annually and close to model assumptions. Increase humidity and wind speeds at Bermuda during fall and winter could cause local marine particle aggregation as shown elsewhere, when mineral aerosols internally mix with sea salt and gaseous pollutants. This could increase the apparent DDV-Fe in the fall and winter atmosphere of the subtropical North Atlantic.

INTERANNUAL VARIABILITY IN THE INDONESIAN THROUGHFLOW
A times series of the monthly Indonesian Throughflow (ITF) velocity and transport from 1958 through 2004 is calculated from interoscean pressure differences in the Simple Ocean Data Analysis (SODA) output. The 2004 velocity and total transport are compared to in situ mooring data from the Makassar Strait, providing validation for the relationship between interannual variability of the ITF transport and the Southern Oscillation and the 1993-1997 El Niño event. These results demonstrate that variability of the ITF transport is correlated to the NINO3.4 index, showing an increase (decrease) in transport in La Nina (El Nino) years. The relationship between the ITF, both in terms of its profile and its total transport, and the Indian Ocean Dipole has been investigated via EOF and Fourier analyses.

ICE-TETHERED PROFILER OBSERVATIONS OF A DOUBLE-DIFFUSIVE STAIRCASE IN THE CANADA BASIN THERMOCLINE
Ice-tethered Profilers (ITP) deployed between 2004 and 2007 provide year-round temperature and salinity measurements of a double-diffusive staircase centered around 200 m depth at the boundary between water of Pacific origin and the relatively warm and salty Atlantic Layer in the Canada Basin (Arctic Ocean). A well-formed staircase found throughout the central Canada Basin indicates that double-diffusion is the dominant mechanism for upward heat transport from the Atlantic Layer in this region. The double-diffusive staircase supports heat fluxes of 0.2-0.3 W/m^2, with lowest values in the eastern sector of the basin, and with no apparent seasonal dependence. Heat fluxes are about 50% greater than found in a study of the region two decades ago, a manifestation of the recent warming of the Atlantic Layer. The staircase is absent in near-boundary regions of the basin (ice-breaker CTD data from the Beaufort Gyre Freshwater Experiment), where it appears that enhanced turbulent boundary mixing could yield a greater regionally-averaged heat flux.

The influence of mariculture on microorganisms in the water and sediment around the fish cage in the Gulf of Trieste

A multidisciplinary approach was used to identify and quantify the most relevant physical, chemical and biological indicators to determine the impact of a fish farm on the surrounding ecosystem in the Gulf of Trieste (Northern Adriatic) within ECASa project. A synoptic sampling system was designed to provide accurate data at different sampling locations (water column, sediment) and different time intervals (before and after feeding in October 2005, April and July 2006). A set of environmental parameters: basic oceanographic parameters, currents, total suspended matter (TSS), nutrients, redox potential, chlorophyll a, phytoplankton pigments, bacterial chlorophyll a and phaeopigments, bacterial abundance, and bacterial production were assessed. Preliminary results showed significant differences in bacterial abundance, community composition and growth rates related to pre-feeding and post-feeding around the fish cage. Analysis of bacterial phyto-plankton biomass, nutrients and redox potential showed a high influence on sediment below the fish cage.

NUTRIENT DISTRIBUTION ACROSS THE INSULAR SHELF OF PUERTO RICO: ASSESSMENT BY ALGAL TISSUE NITROGEN

A survey was conducted to investigate possible presence of an inshore to mid-shelf gradient in %N and delta 15N tissue content of Acanthophora spicifera in coastal waters of La Parguera, southwest Puerto Rico. Percent N was highly variable along the shoreline (1.26% (SE = 0.08) to 3.25% (SE = 0.10)). Higher values were associated with well developed mangrove stands and lower values corresponded with less developed mangrove areas. The higher values were also significantly greater than A. spicifera collected at mid shelf. The reverse trend was observed for delta 15N inshore (2.06ppt (SE = 0.04) to 8.16ppt (SE = 0.14)). However delta 15N was generally lowest (1.86ppt (SE = 1.2) to 2.03ppt (SE = 0.05)) at mid shelf. The exception was delta 15N inshore downstream (delta 15N increased by secondary sewage input and a bird rookery. Results from both %N and delta 15N algal tissue content indicate low transport of nutrients from the coast to mid shelf.

PHYSICAL AND BIOLOGICAL OBSERVATIONS IN SAN PEDRO BAY, CALIFORNIA USING SPRAY GLIDERS

Two Spray gliders measured physical and biological characteristics in San Pedro Bay, California during September-October 2006 as part of the Huntington Beach 2006 experiment. Measurements at 3 km or smaller resolution revealed a subsurface salinity minimum throughout the region at depths of 20 to 40 m. Fluorescence measurements indicated a subsurface chlorophyll maximum near the base of the salinity minimum. Acoustic backscatter showed most populations coincident with the chlorophyll maximum at night, and migrating to approximately 200 m during the day. Mean currents were generally northwestward along the coast. Two cyclonic eddies were identified based on salinity anomalies. The physical and biological observations allow us to better understand a region that is heavily influenced by anthropogenic activity.

MENDING THE MAMMOTH AND THE MOMENTUM - CHAOS IN THE THERMAL BOUNDARY LAYER

Experiments in open channel flume are conducted to observe the effects of a live plant canopy on mean and turbulent flow structure under low speed flow conditions. Since flow structure is strongly affected by plant morphology and canopy density, real flexible plants are used to more realistically represent natural features and thus investigate the dependence of the flow field on the underlying vegetation. A detailed analysis is carried out using particle image velocimetry (PIV) techniques to measure the velocity field at the edges and within the canopy, and laser induced fluorescence (LIF) is used to look at advection and dispersion processes to determine both momentum and mass transport. The experimental results are discussed and comparisons made to predictions based on existing models in an effort to verify the model's usefulness. Additionally, we investigate typical assumptions that have been made in the literature to simplify the problem.

UNDERSTANDING THE PREDICTABILITY OF CLIMATE SIGNALS IN OCEAN MODELS

Quantifying the behavior of system and its ability to predict future states depends partly upon how skillful a model is in replicating a known state. The large scale, inter-annual variability of ocean models is assessed to quantify their ability to predict future states. First, statistically stationary areas that are important to climate are identified from observations examined over a given period (in this case before and after feeding in October 2005, April and July 2006). A set of environmental parameters: basic oceanographic parameters, currents, total suspended matter (TSS), nutrients, redox potential, chlorophyll a, phytoplankton pigments, bacterial chlorophyll a and phaeopigments, bacterial abundance, and bacterial production were assessed. Preliminary results showed significant differences in bacterial abundance, community composition and growth rates related to pre-feeding and post-feeding around the fish cage. Analysis of bacterial phyto-plankton biomass, nutrients and redox potential showed a high influence on sediment below the fish cage.

PHOSPHORUS FLUX IN THE DEEP SARGASSO SEA AND PARTITIONING BETWEEN LABILE AND REFRACATORY CARRIER PHASES

We report a 1-year record (July 2004–July 2005) of phosphorus (P) flux at the Oceanic Flux Program (OFP) time-series site off Bermuda. We measured P in both the particulate and dissolved (sorphenant) phases in sediment trap samples from three depths (500, 1500, and 2500 m). P-flux varied seasonally, with highest fluxes in the late winter/spring. P concentration and flux decreased an order of magnitude with depth, from an average flux of 260.3 mg m$^{-2}$ d$^{-1}$ at 500 m to 27.1 mg m$^{-2}$ d$^{-1}$ at 3200 m. P partitioning between the solid and dissolved phase also varied with depth. At 500m, 76.9% of P is dissolved, while at 3200m, only 23.2% is dissolved. There was no correlation between the dissolved fraction and the duration in the trap cup before recovery, indicating that P leached from the sediment/organisms reached a stable equilibrium within two weeks. The decrease in the leached P fraction with increasing depth suggests that mesopelagic depths, most P flux is associated with labile, easily–solubilized carrier phases, whereas bathypelagic depths most P flux is associated with refractory phases.

CONTRASTING GLOBAL AND LOCAL SATELLITE-DERIVED SST ESTIMATES IN A MARGINAL SEA

Global SST estimates commonly exhibit near-zero bias almost independently of the sensor used. Going down to regional scale can notably increase it, suggesting spatial dependencies in retrieval accuracies. To assess the performance of IR radiometers in the Adriatic Sea a validation exercise of several days during the autumn period was performed for the year 2003, whereas platform-measured SST was used for the year 2004. Validation results for the SST derived from locally–received NOAA 16 and 17 HIRPT temperature have been also compared to Level2 MODIS Aqua and Terra as well as Pathfinder v5 SST products. Night time results have considerably shown small (less than 2.1$^\circ$C) and rather large (less than 7.3$^\circ$C) increases around the spiral, depending on the distribution of the water mass and the change in water mass age and the rate of increase is variable in space and time depending on the distribution of the water mass age and the change in the rate of atmospheric CO$_2$ increase. The rates of increase of the water column inventories for anthropogenic CO$_2$ at 28N as are 5.6 gC m$^{-2}$ yr$^{-1}$ (1987–1992), 9.6 gC m$^{-2}$ yr$^{-1}$ (1992–2001), and 11.8 gC m$^{-2}$ yr$^{-1}$ (2001–2006).

**EFFECTS TOWARD FORECASTING HARMFUL MICROCYSTIS AERUGINOSA BLOOMS IN WESTERN LAKE ERIE**

The toxic cyanobacterium, Microcystis aeruginosa, has become a dominant component of the summer phytoplankton assemblage in the Great Lakes. Regional blooms have caused concern due to the use of these waters for recreation and as a source of drinking water. Research efforts are now underway to develop the capability to detect and monitor M. aeruginosa blooms in western Lake Erie. M. aeruginosa blooms have unique optical properties, due to the production of surface scum and the presence of phycocyanin, an accessory pigment. MERIS, a European ocean color satellite, has increased spectral resolution relative to MODIS and SeaWiFS, which aids in differentiating cyanobacteria from other phytoplankton. Various satellite derived products that have shown promise in detection are being combined through a rule-based model in an attempt to distinguish M. aeruginosa blooms from other non-harmful blooms. In addition, a hydrodynamic model has been developed for Lake Erie. These tools will be combined through the General NOAA Operational Modeling Environment to determine the usefulness of these models for monitoring M. aeruginosa in the western Lake Erie, through a retrospective case study.

**VALIDATING THE INTERNAL TIDES OF OPERATIONAL OCEAN MODELS USING QUANTITATIVE PROFILE DATA**

Operational ocean models with astronomical forcing, similar to the real ocean, generate internal baroclinic gravity waves when barotropic tide distorts stratified water near abrupt bathymetric features. These waves, commonly referred to as internal tides, are challenging to reproduce in ocean models because phase, amplitude, and modal structure all depend on the current state of the ocean. Methods to compute and quantify model accuracy from ocean profile sequences of adequate temporal resolution are developed.

**SEASONAL VARIABILITY IN DMS AND DMSP BIOGEOCHEMICAL CYCLING RATES IN THE SARGASSO SEA: A MONTHLY TIME-SERIES**

Monthly vertical profiles of dimethylsulphide (DMS) and dimethylsulphonpropionate (DMSP) biochemical cycling rates are sampled in the Sargasso Sea at the Bermuda Atlantic Time-series Study site. Sampling commenced in September 2005 and consists of 475 radioisotope determinations of DMS photochemical loss rates, biological DMScassumption rates, biological dissolved DMSP consumption rates, and the DMS yield from DMSP accumulation. Clear seasonal cycles are evident in biological DMS consumption with seasonal minima and maxima observed above and below the mixed layer depth respectively during strong summertime stratification. Photochemical DMS loss rates are well correlated to the availability of ultraviolet light suggesting similar chemical precursors across each season. No clear seasonal cycles are evident in DMSP consumption rates or DMS yield. With the exception of shallow summertime depths, microbial activity has the largest impact on common vertical modes allows the complex internal wave structure to be decomposed. Model fidelity is then obtained for individual components. Results include an error analysis of the Relocatable Navy Coastal Ocean Model using glider data.

**LINE W: A SUSTAINED MEASUREMENT PROGRAM SAMPLING THE NORTH ATLANTIC DEEP WESTERN BOUNDARY CURRENT AND GULF STREAM ABOUT 39Â° N 70Â° W**

Well-resolved records from multiple latitudes documenting interannual signals in water properties and transport of the North Atlantic Deep Water (NADW) system help build understanding of how variations in high-latitude water mass transformation are transmitted equatorward, and the impacts such signals may have on the Meridional Overturning Circulation. These issues motivate the Line W program presently returning observations of the DWBC and Gulf Stream about 39Â° N 70Â° W. The study combines a slope-spanning, hydrographically moored array and twice-yearly hydrographic sections extending along an altimeter satellite track from the continental slope towards Bermuda. Highlights from the analysis of historical and modern data about Line W include: the 2004-2006 estimated time-mean equatorward transport of intermediate and deep waters is 24.4 Sverdrup with 5-day samples ranging between 1.5 and 59.5 Sverdrup; Changes in Labrador Sea water convection products are manifested in Line W intermediate water salinity, PV and CFC within 5 years. A somewhat longer transit time (8-10 years) for deep waters is indicated by Cline-129 concentration data, possibly suggesting a different spreading path.

**MONITORING SEDIMENT RESUSPENSION IN CORAL REEFS AND SEAGRASS BEDS WITH IN-SITU OPTICAL MEASUREMENTS**

Island ecosystems may be significantly affected by human activities in or near areas of previously pristine environments. Navigation channels have been created in the Bermuda Islands to allow the access of large commercial and cruise ships from outside the reefs in order to transport towards the main ports. Ship traffic overloads sediments which then are transported to reefs and seagrass beds. Variations in the inherent optical properties (IOPs) as well as in the particle size distribution (PSD) were measured in order to estimate the amount and composition of dissolved and suspended materials being resuspended from the sediments. The navigation activities, the amount of those materials reaching coral reefs and seagrass, and the period of time that these resuspension events occur. Two permanent stations were located, one close to the main navigation channel in a coral reef/seagrass environment, and the other in a control area far from navigation activity. Temporal variations of IOPs and PSD were evaluated between high and low traffic periods of cruise ships.

**THE ENSEMBLED KALMAN FILTER IN ECOSYSTEM FORECASTING: CAN SATELLITE PRODUCTS IMPROVE FORECASTS?**

The localized Ensemble Kalman Filter (EKF) implemented in a 3-D coupled hydrodynamic-ecosystem model (POLCOMS-ERSEM) is evaluated in the Western English Channel (WEC, UK). The WEC encompasses coastal shelf, water, and open ocean inputs. The complex ecosystem model resolves the light-diffuse attenuation at three spectral bands: blue, green and red. Weekly assimilation of 5 day composites of satellite derived surface chlorophyll-a or multispectral attentuations at 440, 550 and 680 have been performed during 2006 and compared with in-situ observations at two stations. The observations include nutrients, diffusive attenuations, chlorophyll-a and phytoplankton biomass of several functional groups. The two year-long stations represent both the coastal regime (L4, weekly data) and the shelf waters (E1, monthly data). A collection of model skill metrics shows both assimilation experiments improve the performance of the system with respect to the "free simulation". The system capability to resolve the phytoplankton successional dynamics coupled with Multidimensional Scaling analysis (MDS). Further analyses include the impact of assimilation on the main carbon pathways therefore highlighting changes to the ecosystem functioning introduced by the sequential assimilation of satellite data.

**MODELING NEARSHORE HYDRODYNAMICS AND SEDIMENT TRANSPORT USING COBRAS-UC**

Recent advances in numerical modeling provide an opportunity to overcome the limitations of traditional nearshore hydrodynamic models. The volume of fluid (VOF)-type model based on the Reynolds-Averaged Navier Stokes equations, COBRAS, has been applied mostly for laboratory-scale monochromatic wave condition. However, its performance for wave zone processes owing to random wave breaking on field scale sandy beaches has not been investigated. It is the aim of this work to demonstrate the improvement in modeling of wave transformations on beaches using a modified version of COBRAS (COBRAS-UC, Torres-Frevermouth et al. 2007, J. Geophys. Res., 112) which reduces the computational effort, making it suitable for field-scale applications. By extending the numerical model to solve the mixture equations for fluid mud transport (Hsu et al. 2007, J. Geophys. Res., 112) along with a closure of sediment stresses using Bingham rheology, the model can simulate wave propagation, sediment-laden wave boundary layer, fluid transport and wave energy dissipation continuously with one single set of balance equations and closures. Model results obtained here are encouraging for future applications of various cohesive and non-cohesive sediment applications.
Tropical Instability Waves in HYCOM

Evolution and structure of tropical instability waves (TIWs) in HYCOM experiments are compared with those derived from satellite-derived sea surface height (SSH), sea surface temperature (SST), and surface currents in the Pacific Ocean. The wavenumber-frequency-spectral analysis of SSH anomalies shows significant spectral peaks along the dispersion curve of first baroclinic mode Rossby and Kelvin waves. A prominent peak in SSH fields at around 33 days and 1500 km wavelength along the Rossby wave dispersion curve is evident, and a similar peak is also found in SST fields. This upper ocean variability on these space and time scales is shown to be associated with TIWs. The spatial variation of 33-day TIWs are examined based on an analysis of time series filtered in the frequency-wavenumber domain. The maximum variability of SSH associated with TIW is located around 130°W, while that of SST is found around 2N, 100W. The phase relationship between SSH, SST, and surface velocity associated with TIWs is described based on the cross-correlation analysis. SSH and SST anomalies from HYCOM show similar peaks to those in satellite observations. Spatial and temporal structures of TIWs in HYCOM are also described by the same statistical analyses and discussed based on the comparison with those from satellite observations.

High Resolution Ross Sea Phytoplankton Primary Production Estimated by Multiple Variable Fluorescence Approaches

As part of CORSACS (Controls on Ross Sea Algal Community Structure), we characterized the phytoplankton photosynthetic processes during two cruises to the Ross Sea polynya during the austral spring and summer. Measurements of variable fluorescence were made with a bench-top Fast Repetition Rate Fluorometer (FRRF), a FRRF linked to the CTD, and a Pulse Amplitude Modulated fluorometer (PAM). All measurements were paired with hydrographic profiles and nutrient analysis. FRRF and FAM measurements were consistent and showed an increase in F_Fv/Fm at depth. Spatially, F_Fv/Fm ranged from 0.20 to 0.65, suggesting that micronutrient stress may occur in all seasons. A subset of these measurements were in parallel with 132C-based primary productivity incubations. We quantified the relationship between the measured and derived productivity estimates in order to predict productivity from fluorescence measurements, therefore allowing a higher spatial and temporal resolution of primary productivity to be obtained.

New Perspectives in the Si Marine Biogeochemistry

Global scale: So far, the best estimates for the net inputs of silicic acid to the world ocean overwhelm those for the net outputs of biogenic silica in sediments. The question of the steady state of the silica cycle in the modern ocean is still an open question. Regional scale: studies in the Southern Ocean and the East Equatorial Pacific show that the dissolution of biogenic silica can be as intense in cold surface waters as in warm in vitro studies. In vitro studies show that bacteria can accelerate the dissolution processes on the short term, only when their population contains the appropriate cell density and bacterial cells are attached to aggregated siliceous material. Aggregation is a key process for the control of the Si recycling in the mesopelagic layer. Recent studies show that the particle dynamic has the key role in the transport of biogenic silica from the surface to the ocean interior. Thus, the dissolution rate of biogenic silica and the ballast effect due to diatom frustules are minor factors to determine the depth of Si recycling. Modeling studies using both models and field works, the impacts of physical processes on the biogeochemistry of surface waters are described for the Southern Ocean, the northwestern subtropical Atlantic, and the subtropical Pacific Ocean. To better describe the cycle of Si and of other nutrients, and the pelagic ecosystem, at mesoscale is a new frontier for marine biogeochemistry.

Defining Natural River-Shelf Interactions for Trace Metals in the Coastal Beaumont Sea

As oil development continues to move offshore in the Alaskan Arctic amidst signs of climate change, studies are being conducted to define natural biogeochemical cycles in the context of potential future changes. Results for rivers obtained from 2001-2006 showed that more than half of the annual amounts of water, suspended sediment and dissolved solids were carried to a frozen Beaufort Sea in 2-3 weeks. Riverine concentrations of dissolved Fe and other trace metals including Cu and Zn, along with DOC and suspended solids, increased by 3- to 25-fold to reach peak values within 7 days after runoff began. A 1-2 m thick river plume was traced >15 km offshore under ice and the fate of river-borne particulates, metals resulted from scavenging and plankton blooms.

Impact of the South China Sea Throughflow on the Indonesian Throughflow

The Indonesian Throughflow plays a crucial role in the heat budget of the western tropical Pacific. One striking feature revealed by recent mooring observations in the Makassar Strait, the major pathway of the Indonesian Throughflow, is the subsurface maximum of the meridional current profile with strong vertical shear. Using OGCM experiments with and without the South China Sea throughflow (SCST), which is an anticyclonic circulation around Philippines Borneo, it is shown that the SCST plays a critical role in generating the subsurface maxima in the meridional velocity of the Makassar Strait throughflow. The maximum southward current in the Makassar Strait occurs at around 110 m depth when the SCST is allowed, but it surfaces when the SCST is inhibited. This is especially dramatic in boreal winter as the SCST is at its maximum due to the Asian winter monsoon. The heat transport is reduced by 0.18 PW owing to the SCST, indicating that the SCST may play an important role in climate variability.

Varyability of the Meridional Circulation of the Southern Ocean: The Role of Eddy Fluxes
The meridional circulation across the Antarctic Circumpolar current is thought to consist of an upper flow and a deep flow related to the AME. This study was cancelled by an eddy flux in the opposite direction. We demonstrate that this view emerges from eddying numerical models only when the meridional circulation is integrated across streamlines, and not in a zonal average. The calculation in a zonal average gives a completely different view and underestimates the eddy fluxes, especially in high resolution models. We apply the streamline framework to the eddying global model ORCA025 implemented by the DRAKKAR modelling group. We evaluate the variability of the meridional circulation and of its time-mean and eddy components over the last 30 years, and compare our estimates with those of low resolution climate models where eddies are parameterized.

ORIGIN AND DISPERSION OF MARINE AND TERRIGENOUS ORGANIC MATTER IN THE CONGO DEEP-SEA FAN

The Congo Canyon, fed by the second largest river in the world, extends over hundreds of km off the West Equatorial African margin, and is still affected by turbidity currents. These unique characteristics make it an ideal location to study the dispersion and fate of terrigenous and marine organic matter. We present a model analysis of linear alcohol biomarkers of surficial sediments taken on a transect along the Congo Canyon. We can thus infer bioavailability, onset of sedimentation, and the migration of organic matter. We also compare this model to the dynamics of the global ocean, as inferred from the broader Atlantic and Indian Oceans.

MECHANISMS RESPONSIBLE FOR THE TROPICAL THERMILOCINE COOLING IN THE INDIAN OCEAN

The vertical structure of temperature change in the Indian Ocean Basin during 1961-2000 indicates that an isolated region of tropical thermocline cooling accompanies the upper level warming of the Indian Ocean. The cooling appears in the Levitus data, SODA-POP data assimilation products, results from the HYbrid Coordinate Ocean Model (HYCOM), and is a robust feature of the POP model hindcast solution. The persistence of the cooling signal exceeds the data uncertainties and cross-model differences. Our results suggest that enhanced Ekman pumping velocity associated with the tropical winds mainly causes the cooling. The enhanced tropical upwelling appears to be consistent with the strengthening of the Southern subtropical cell (STC) of the Indian Ocean. The strengthening of the meridional overturning circulation is captured by SODA-POP and HYCOM results, with both datasets consistently indicating that the strengthening of the Indian Ocean subtropical cell is largely dominated by the spin up of the STC, and spin down of the equatorial flow. The cooling in the upper thermocline enhances toward the west in both SODA-POP and HYCOM. This westward enhancement results from Rossby waves that strengthen toward the west. Influence from the Pacific via wave transmission through the Indonesian Throughflow does not seem to be a major mechanism for the strongest cooling in the upper thermocline.

HYDROLOGIC CHARACTERISTICS OF TWO HAWAIIAN WATERSHEDS

Two Hawaiian watersheds are being studied to understand linkages between terrestrial and marine ecosystems. They differ in their physical and ecological characteristics. These differences illustrate how watershed approach affects the delivery of water and sediment to the ocean. Moving from coast to headwater in the Hanalei watershed (windward Kauai), rainfall increases from 2 to 11 meters annually. The Hanalei River is perennial, with a median flow of about 3.8 m³/s from 48.4 km² of the watershed. The highest recorded flow is 1.286 m³/s. The watershed is heavily vegetated. Moving from coast to headwater in the Kawela watershed (leeward Molokai) rainfall increases from 0.5 to 2.5 meters annually. Near the mouth, Kawela Stream (13.7 km²) is ephemeral, flowing about 38% of the days during 2004-06 with the highest flow recorded flow about 90 m³/s. The watershed is arid and heavily grazed by feral ungulates. During 2004-06, sediment yield (normalized to area) from Hanalei was over twice as high as from Kawela. However, 90% of the sediment load occurred during 3 days at Kawela compared to 34 days at Hanalei.

QUANTIFICATION OF COPEPOD GUT CONTENT BY DIFFERENTIAL LENGTH AMPLIFICATION PCR (DLA-qPCR)

Quantification of feeding selectivity and rates for key organisms such as zooplankton is an important step towards understanding of marine ecosystem functioning. Classical methods to assess feeding all have various limitations and there is a need to develop quantifiable methods that reliably estimates in situ rates. Recent studies using nucleic acids as biomarkers to investigate copepod feeding has yielded promising results, though are still semi-quantitative as they suffer from significant underestimation. To approach this problem, we developed a new method called differential length amplification qPCR (dLA-qPCR) that used to assess genomic prey DNA digestion in the gut of predators. Digestion profiles generated from this method was further used to correct for DNA digestion leading to absolute estimates. Applying the method on the calanoid copepod Calanus finmarchicus fed Emiliania huxleyi and Rhodomonas sp. yielded significant improvements of feeding rate estimates compared to standard qPCR. This technique therefore represents an important advancement towards the aim of developing a non-intrusive quantitative method for assessing zooplankton gut content in situ.

RECENT PERSPECTIVES ON TURBULENCE IN OCEANIC BOUNDARY LAYERS

Recent measurements indicate that existing paradigms and models fail to represent important aspects of turbulence in oceanic boundary layers realistically. In particular, near-bottom measurements indicate a potentially dominant role of Langmuir circulations, which are not necessarily represented adequately in existing, widely-used, Reynolds-averaged numerical simulations (RANS). Similarly, recent near-surface measurements suggest that the energetics and scales of turbulence generated by wave breaking and Langmuir instability are inconsistent with existing conceptual and mathematical RANS models. The existence of these nonrandom circulations in both top and bottom boundary layers have implications...
for flow effects on biota as well as coagulation kinetics and particle settling. The recent
measurements are reviewed and placed in context with RANS and large-eddy simulations
(LES). The implications for turbulence intensities, scales, and transport are discussed.

SEASONAL VARIABILITY AND THE DYNAMICS OF KUROSHIO PATH AND ITS
INTRUSION INTO THE LUZON AND TAIWAN STRAITS.

A fourth-order fully two-way-coupled duo-grids Pacific Ocean Model (DUPOM) is de-
veloped to simulate the regional circulation in the vicinity of Taiwan and Asian Marginal
Seas. The model uses 1/4° and 1/8° horizontal resolution for western and eastern Pacific
Ocean domains, respectively. Many important features in the Asian Marginal Seas are
reproduced. These include seasonal Kuroshio intrusion in the Luzon Strait compares well
with the observations. This feature is also included Kuroshio intrusion and retreat through Luzon Strait. It is found that the Kuroshio intrusion into Luzon and Taiwan Strait relates closely to the Kuroshio path variation east of Taiwan. The mean correlation is more than 0.6 whereas the highest value is 0.75. The throughput flow transport in the Taiwan Strait and Luzon Strait is also consistent with the field measurements. Results also show the importance of Kuroshio path on the throughput in the Luzon and Taiwan Straits, which affects the complex SCS circulation.

COMPARISON STUDY OF SPATIAL STRUCTURE OF SUBTROPICAL MODE
WATERS IN THE WORLD OCEAN.

We describe the characteristics of SubTropical Mode Waters (STMW) in the world ocean
using unified criteria, and discussed what factors determine the thickness of STMW
in each of the five basins: North Pacific (NP), North Atlantic (NA), South Pacific (SP),
South Atlantic (SA) and Indian Ocean (IO). We use the isopycnally averaged temperature
and salinity dataset (HydroBase) in summer of each hemisphere. STMW is defined as a
thermocline with temperature lower than 2.5°C and the thick-
ness greater than 100 m. First, STMWs revealing a single type of water characteristics
(NPSTMW, NASTMW and IOSTMW) are distributed mostly within the recirculation
area (RR), while STMWs having a several types of water characteristics (SPSTMW and
SASTMW) are distributed within and outside the RR. Second, it is shown that NASTMW
has the thickest STMW (276±21.1 m) in the South Atlantic Ocean. The thickness of
SASTMW and IOSTMW have almost the same thickness (168±15.8 m; 155±16.1 m; 149±14.8 m).
SPSTMW has the thinnest STMW (108±7.7 m) in the world ocean. The vertical structure
of SASTMW is unique in that its T/S stratification shows highly density-compensating
nature. It is presented temperature layer having the core layer temperature ±1°C, and the thick-
ness greater than 100 m. These characteristics of SASTMW are unique among the
three major subtropical gyres, resulting larger RR and thicker STMW.

TEMPERATURE AND ULTRAVIOLET RADIATION INTERACT TO CONTROL
INVASIVE WATERFISHES.

Climate induced changes of important environmental drivers may exacerbate other global
change problems. We demonstrate how temperature and ultraviolet radiation (UVR)
conditions can control the stability of nearshore spawning habitat for invasive waterwar-
ter fish species in Lake Tahoe USA. We surveyed a number of nearshore sites that varied in
temperature and UVR transparency. DNA dosimeters were incubated in each site to
assess ambient levels of DNA damage and larval waterfish were incubated in two sites
that differed greatly in temperature and UV conditions. Our data suggest larval fish
survival is high in low UV/low temperature conditions and decreases in high UVR/low
temperature conditions for some species but not others. Changes in temperature and UV
conditions of nearshore environments could facilitate the spread of invasive species
for some species but not others. Changes in temperature and

HOW DOES THE USE OF TECHNOLOGY AND SUPPORTING ORGANIZATION
DESIGN PRINCIPLES SUPPORT THE DEVELOPMENT OF THE COSEE NETWORK
AND COLLABORATIVE PARTNERSHIPS?

“Communities of Practice are groups of people who share a concern, a set of problems, or a passion about a topic, and who deepen their knowledge and expertise in this area by interacting on an ongoing basis” (Wenger, McDermott and Snyder, 2002). The COSEE network has the potential to be a community of practice. The deliberate design of a
community of practice helps support the internal direction, character and energy. Wenger has established 7 principles for guiding a community of practice design. The College of Exploration (TCOE) has incorporated these 7 principles and other organizational design principles to support our partnerships with many ocean science and ocean educa-
tion organizations and currently as active partners in 5 COSEEs. We have introduced technologies to advance collaborative actions and encourage open and transparent commun-
ication. Over 10 years we have networked and encouraged collaborative learning between 225 ocean related scientists and over 8000 educators. This session will present our experiences and these design principles and related organization and network theories and practices and offer suggestions for best practice for developing sustainable and col-
laborative partnerships.

SHALLOW SPECTRA AND BAROCLINIC INSTABILITIES AT THE OCEAN
SURFACE.

Recently it has been shown that, at sufficiently high effective vertical resolution, quasigeo-
stratification and instability in the presence of both surface and interior mean gradients produces a forward energy cascade at the surface, with a shallow (~5/3) spectrum. Charney or
Eady-like instabilities are necessary to excite this cascade, but need only generate energetic conversion in a narrow band of wavenumbers. Here we explore, using balanced numerical simulations with observed stratification and shear profiles, the degree to which this effect can explain observations and how it relates to submesoscale dynamics in the thermocline scale. We describe the detailed linear stability of a region, identify the vertical structure of the instabilities, and simulate the resulting turbulence with a model that completely resolves the surface modes (within a balanced model framework). The spectrum at the surface flattens at a scale deter-
dined by the competition between the forcing of interior and surface mode instabilities.

ECOLOGICAL DISTURBANCES IN THE ST. LUCIE ESTUARY AND THE
SOUTHERN INDIAN RIVER LAGOON, EASTERN FLORIDA, ELUCIDATED
THROUGH MACROBENTHYC MONTI ONING.

Benthic infauna are important indicators of aquatic environmental quality and are used in
many monitoring programs to assess overall estuarine health and to follow long-term
trends in estuarine communities related to anthropogenic impacts. Soft-bottom macro-
fauna off South Florida have been monitored quarterly since February 2005 from 13 sites in the St. Lucie Estuary (SLE) and the Indian River Lagoon (IRL). Frequency discharges of nutrient-rich freshwater from the C-44 Canal (Lake Okeechobee) have contributed to very poor envi-
ronmental conditions in large parts of the SLE, with an infrequent community dominated by a few opportunistic (r-strategic) species. However, the diversity and abundance of the benthic community further downstream at the St. Lucie Inlet. Under the Comprehensive Everglades Restoration Plan (CERP), managed freshwater
inputs and decreased sedimentation in the SLE are expected to improve the environmen-
tal conditions in the entire SLE. The data clearly indicate that the benthic communities respond quickly to environmental changes and that they reflect changes in discrete zones
within the studied areas in the SLE and IRL.

CALCIFICATION OF MUSSEL SHELLS IN A SETTING OF HIGH CARBON
DIOXIDE RELEASE ON A SEAMOUNT IN THE MARIANA VOLCANIC ARC: BIOTIC
RESPONSES TO A LOW PH OCEAN.

On the summit of Eifuku Seamount, vents of liquid CO₂ and H₂S are surrounded by ex-
tensive fields of the vent mussels Bathymodiolus brevis. Water samples collected directly
in mussels had pH ranging from 5.36 to 7.29 at 2.4 to 2.9°C. Calcification of shells is
compared to the same species from Luab Basin vents at pH 7.8 to 8.4. While mussels at
the two sites grow to similar sizes, Eifuku shells are 65% lighter and less than half the
thickness. There is no preferential thinning of the outer aragonite shell layer at Eifuku nor are there differences in crystal size or formation compared to Luab. As no secondary dis-
solution of aragonite is evident, the calcification process appears limited by the initial ion
availability. The calcitic layer forms daily micrometer thickness and showed constant growth
CONSEQUENCES OF EUTROPHICATION TO SALT MARSH BELOWGROUND BIOMASS

We conducted field experiments at a combination of geographically diverse and regionally-specific sampling areas and belowground plant biomass in western Atlantis, and Gulf of Mexico salt marshes to understand the belowground responses of Spartina alterniflora, the dominant salt marsh plant, to N, P, and Fe additions. The results indicate that nutrient enrichment will lead to lower root and rhizome biomass, and belowground production, and organic accumulation. Phosphorus additions, more than nitrogen, seem to reduce root and rhizome biomass accumulation. Higher soil respiration and a lower Eh are anticipated additional soil property changes. The cumulative effects of increased nutrient loadings to salt marshes may be to decrease soil elevation and accelerate the conversion of emergent plant habitat to open water, particularly at the lower elevation range of the plant. Eutrophication may be detrimental to long term salt marsh maintenance and development, especially in organic-rich wetlands soils such as the Mississippi River deltaic plain where large-scale river diversions are being developed.

TURBULENCE DRIVEN NITRATE FLUXES OVER SUBMARINE BANKS IN THE SEASONALLY STRATIFIED CELTIC SEA

In situ data, collected during two interdisciplinary cruises (July/August, 2003 and 2005) in the seasonally stratified Celtic Sea, were used to evaluate vertical turbulent nitrate fluxes \( (\tilde{\Gamma}_{NT}) \) into the subsurface chlorophyll maximum located within the thermocline. A combination of CTD, nitrate (N) and vertical diffusivity (K) measurements allowed calculation of \( \tilde{\Gamma}_{NT} \) using \( \tilde{\Gamma}_{NT} = -K\Delta N/\Delta z \). was increased over submarine banks (2.9 (near) - 15.7 (spring) mmol N m\(^{-2}\) day\(^{-1}\)) as compared to a flat seafloor (1.1 (near) - 2.8 (spring) mmol N m\(^{-2}\) day\(^{-1}\)), contributing a mean increase in annual new production of ~4% over the whole Celtic Sea. The data suggests the mechanism driving the increased nutrient flux is the formation and subsequent dispersion of a lee wave over the bank slopes. There is further evidence, supplied by chlorophyll concentrations measured by SeaSoar, to suggest lee waves formed over opposing sides of several banks due to the semidiurnal reversal of tidal currents. These regions of higher \( \tilde{\Gamma}_{NT} \) are of apparent importance to fisheries, with fishing efforts often concentrated over banks.

COMPARING EXPORT OF SHELF CARBON IN WHALE BIOMASS WITH CARBON FLUX IN OFFSHORE JETS OF THE CALIFORNIA CURRENT

Carbon budgets for shelf food webs have rarely included complete pathways for the communities of apex predators. In particular, the regionally and seasonally significant influence of whales in shelf systems are often missing in models of carbon flux. The ecological role of whales in the trophic transfer of shelf carbon was examined during GLOBEC Northern California Current (NCC) process cruises off Oregon (41.9°–44.7°N) during summer 2000 and 2002. Line-transect surveys of cetaceans were conducted across the shelf and slope, in conjunction with multidisciplinary investigations of the NCC. During the upwelling season, humpback whales Megaptera novaeangliae move onto the shelf, especially at ecological ‘hotspots’ such as Herceta Bank (44°N). There, they forage on high densities of euphausiid and fish prey, removing large amounts of carbon from productive coastal waters, and sequestering carbon in whale biomass. The amount of carbon that is seasonally sequestered in whale biomass, and ultimately exported from the shelf during the whales’ migration, is comparable with the amount of carbon transported cross-shelf by a jet of the NCC. Even the reduced numbers of an endangered population of whales contributes significantly to carbon flow in a coastal shelf ecosystem.

ROLE OF DIATOMS IN NICKEL BIOGEOCHEMISTRY IN THE PACIFIC OCEAN

Single-cell x-ray fluorescence (SRXF) analyses of phytoplankton cells collected from the equatorial Pacific Ocean reveal significant inter-taxa differences in cellular nickel quotas. Diatoms contain nearly 3-fold more Ni (per mole P) than autotrophic picoplankton cells, which in turn contain approximately 2-fold more Ni than larger autotrophic flagellated cells. Mapping of sub-surface Ni distribution suggests that cells with higher Ni may be concentrated in diatom frustules, which would explain the close correlation of dissolved Ni and silicic acid in vertical profiles reported previously. SRXF measurements of Ni/Si in newly deposited frustule material during grow-out experiments are comparable to water column Ni/Si remineralization ratios reported previously. Approximately 35-40% of the Ni in diatoms is calculated to be associated with the frustule. Frustule-bound Ni accounts for all of the Ni remineralized below ca. 1000 m but only 50% of the Ni remineralized above ca. 1000 m in the Pacific Ocean. Quotas of cytoplasmic Ni in diatoms (excluding frustule-bound Ni) are approximately 2-3 fold higher than those in other co-occurring cells. These higher quotas are needed to reproduce observed Ni profiles in the upper water column.

HYDRO_DYNAMIC CONTROLS ON THE MOLECULAR-LEVEL COMPOSITION OF ORGANIC MATTER IN SEDIMENTS ALONG WASHINGTON MARGIN AND CASCADIA BASIN TRANSECT

Fluvial systems discharge complex mixtures of particulate and dissolved terrogous organic materials to the oceans. Upon entering the marine realm, these materials are subject to a range of physical and biochemical processes. For particulate matter, hydrodynamic properties play a critical role as how this material is distributed and deposited on the sea floor. A suite of surface sediments collected along a transect were separated according to their grain size and hydrodynamic properties, and the organic matter characterized in terms of its bulk elemental, isotopic, and molecular properties. Systematic variations in the molecular-level composition of organic matter are observed across the transect, and these variations are manifested in different tracers of terrestrial organic matter, including the abundance and isotopic composition of higher plant waxes and soil microbe tetratheral lipids. Similarly, marine-derived lipids including alkenones and marine archaeal tetratera show strong distributional and isotopic variations across the transect. Together, these variations in terrestrial and marine biomarker properties inform on the sources, particle dynamics, and transport history of organic matter buried on river-influenced continental margins. The implications of these findings for the application of molecular markers as proxies of organic matter input, and of marine and continental environmental conditions will also be discussed.

SUBMESOSCALE INSTABILITY IN SUBTIDAL INNER SHELF CIRCULATION OFF PALOS VERDES, CALIFORNIA

A new class of submesoscale variability is simulated in a realistic, shelf-scale, high-resolution regional configuration with ROMS (Shepheitkin and McWilliams, 2005) for Palos Verdes (PV) Shelf, California, encompassing Santa Monica Bay (SMB) and San Pedro Bay (SPB). The variability comprises energetic submesoscale eddies detached from the cape PV and "filament" structure visualized by meandering fronts right at the shelf in both of SMB and SPB. The offshore extent of the filament is computed to be of O(1 km), and it is totally different from a classical view of offshore transport process by rip current, undertow, or shear waves associated with shear instability in longshore currents. Barotropic shear instability within the upwelling zone and baroclinic instability along the fronts are considered to be a key processes in generation of these submesoscale eddies and variability. We will discuss on further mechanism causing the submesoscale filament structure, and its role in cross-shelf mixing that links nearshore littoral dynamics to inner-shelf circulation.

ESTIMATION OF HEAT AND FRESWATER TRANSPORTS IN THE NORTH PACIFIC USING HIGH RESOLUTION XBT DATA

The mean heat and freshwater transports in the North Pacific subtropical gyre during 1996–2002 are estimated. High-resolution XBT/XCTD transects (PX-40 Honoluluhu, PX-37: San Francisco-Honolulu, PX-10: Honolulu-Guam, PX-44: Guam-Taiwan/Hong Kong) are used to calculate geostrophic transport across each of the ship tracks. Ekman transport is estimated from satellite-scatterometer wind stress. The mean heat and freshwater transport convergences (HTC and FTC) into the northern box bounded by the PX-40/37 transects and the Tsushima and Bering Straits are 0.26 +/- 0.16 pW (peta watts) and -0.26 +/- 0.11 Sv (10^6 m³/s/eqc), respectively. HTC and FTC into the western box bounded by the PX-40/10/44 transects and the Tsushima Strait are estimated to be 0.32 +/- 0.17 pW and 0.08 +/- 0.07 Sv, respectively. In both boxes, warmer waters transported inward by the Ekan flow and by the Kuroshio are compensated by the export of waters at cooler temperatures, whose peaks are found in the temperatures of the mode waters formed in the North Pacific. The salt budget is also described to consider the mechanisms of freshwater transport. Since, in particular, the western box includes the region with the strongest heat loss to the atmosphere and is possibly a key region for climatic decadal variation, it is necessary to continue the HRX measurement and to make an effort at improving the estimation of heat and freshwater transports, in order to contribute to advancing climate studies.

SALINITY VARIATION OBSERVED WITH TRITON ARRAY

Salinity variation in the Pacific warm pool is investigated by Triangle Trans-ocean Buoy Network (TRITON) data. On interannual time scale, a distinct feature appears in sea surface salinity (SSS) variation. During La Nina, higher salinity is recognized near the equator, whereas lower salinity appears between 5N and 8N, producing large salinity front between 2N and 5N. This front becomes weak during EI Nina. The front structure is mainly depending on zonal advection near the equator and fresh water flux by Intertropical Convergence Zone activity around 5N to 8N. In addition to SSS variation, another large variability is found near pycnocline especially between the equator and 2N, which de-
pend on a front of two water masses corresponding to North Pacific Tropical Water (NPTW) and South Pacific Tropical Water (SPTW). During La Niña (El Niño), NPTW (SPTW) indicates higher salinity value and increased thickness. These large salinity varia-
tions affect ocean dynamics through density changes of seawater. The high contribution of salinity variation to geotrophy evaluated by observed data requires further understanding of salinity variation in the Pacific warm pool.

SEISMIC REFLECTIONS WITHIN THE WATER COLUMN SOUTH OF SOUTH AFRICA: INDICATIONS FOR THE AGULHAS RETROFLECTION

With the publication of Holbrook et al. (2003) the field of seismic oceanography expe-
rrienced a major momentum. Several authors since then (Nandi et al., 2004; Holbrook and Fer, 2005; Paramo and Holbrook, 2005) could show that those reflections within the water column correspond to thin layers with strong vertical temperature gradients. Those reflections hence represent a chance to trace those temperature gradients over large dis-
tances. Weak seismic reflections within the water column south of South Africa gave rise to the question whether here traces of the Agulhas Current or Agulhas Retroflection can be observed. A careful reprocessing of the data led to the imaging of fields of reflections pointing upwards with amplitudes between 135 km broadband and about 1000 m deep reaching well stratified areas with strong reflection amplitudes and several weaker reflections extending down to at least 1500 m water depth over the whole area of investigation. To image both the boundaries between the water masses as reflections and the different properties of the long wave-
length velocity variations in depth special imaging techniques like pre-stack depth migra-
tion analysis were performed. Further, the temperature gradients from the short wave-
length properties as velocity and density contrasts were determined by a two step inversion of acoustic amplitude versus angle analysis to better quantify the variations of the water masses of the Agulhas Current.

NORTH ATLANTIC CARBON CYCLE RESPONSE TO CLIMATE VARIABILITY IN THE SUBTROPICS

Air-sea CO2 flux variability in the North Atlantic has been found to be small in a vari-
ety of observations and biogeochemical models and at least one atmospheric CO2 inversion study (McKinley et al. 2004), yet the mechanisms that damp variability in this region of large net carbon uptake are poorly understood. A biogeochemical general circulation model was used to assess the impact of climate variability from 1980-2006 on the CO2 flux and surface pCO2 in the North Atlantic. Results show a strong correlation between flux and pCO2 variability. Model output reveals that the influence of dissolved inorganic carbon (DIC), alkalinity (Alk), phosphate, nitrate, sea-surface temperature (SST), and sea-surface salinity (SSS) to assess the mechanisms driving pCO2 variability. These pCO2 components were regressed onto the North Atlantic Oscillation (NAO) index, the main mode of climate variability in the region. The effects of SST and Alk on pCO2 vari-
ability balance each other in the eastern subtropical gyre, such that the overall variability of pCO2 is small. Driving forces behind Alk/SST variability in the eastern subtropical gyre are evaluated in the context of ESTOC observations.

VELOCITY STRUCTURE AND EDDY PROPERTY FLUXES IN THE MID-SHELF FRONTAL ZONE OF THE NEW YORK RIGHT

Hydrographic fronts oriented roughly along isobaths at mid-shelf locations have been observed along a number of coastal margins during the winter months. The mechanism(s) responsible for the formation of these fronts and their influence on cross-shelf transport are not presently understood. Modeled observations of currents and temperature in the mid-shelf frontal region of the New York Bight during winter 2007 are used to describe the cross-frontal structure of velocity and hydrography. Preliminary results show strong wind forcing of the current and temperature fields. Mean and eddy heat fluxes are computed using the time series of velocity and temperature and are separated into tidal and subtidal components. The cross-shelf structure of the fluxes will be compared with the stratified area in two potential models of front formation, tidal dispersion and bottom boundary layer advection models, each of which predict or assume very different cross-shelf flux variability.

LIMNOLOGY AND AQUATIC FOOD WEB STRUCTURE OF A LARGE TERMINAL LAKE

Walker Lake is a large, terminal, saline lake in the Western Great Basin of the United States. Diversions have greatly reduced river inflow which has lead to a decrease in vol-
ume by 75% since the 1880’s. As a result there has been a concomitant increase in salinity levels and alteration to biotic community structure. This study provides a contemporary snapshot of the water quality, phytoplankton- zooplankton biomasses, and the lake’s food web structure. Water quality and chorophyl a and zooplankton were sampled monthly (March to October 2007) from six locations at discrete depths. Nutrient concentrations were highly variable (ammonium levels- 0 to 30 ppb, nitrate- 0-12 ppb, total and dissolved phosphorus-500 - 1000 ppb, and soluble reactive phosphorus-400 - 600 ppb). The food web structure determined from stable isotope measurements (carbon and nitrogen) and stomach contents suggests benthic resources contributed greatly to fisheries energetics.

BASIN-SCALE POPULATION GENETIC STRUCTURE OF CALANUS FINMARCHICUS IN THE NORTH ATLANTIC

Calanus finmarchicus is a cold-temperate copepod species that is seasonally abundant throughout the North Atlantic Ocean. The species has been hypothesized to inhabit three semi-distinct gyre systems in the North Atlantic: the Norwegian Sea, the northern North Atlantic, and the western North Atlantic. Although C. finmarchicus shows significant geographic variation in many life history traits, basin-scale population genetic variation of the species has not been comprehensively characterized. For this study, C. finmarchi-
cus was sorted from zooplankton samples collected during 2005 from diverse locations across the geographic range of the species. A total of 15 Single Nucleotide Polymorphisms (SNPs) were detected in three different nuclear protein-coding genes using multiplexed ABI SNaPshot protocols. Spatial patterns of the SNP allele frequencies were described, and patterns of population genetic diversity and structure were characterized in light of the three-gyre hypothesis.

CONTRIBUTIONS TO THE CO2 EFFLUX FROM THE LAURENTIAN GREAT LAKES

Several approaches (direct flux measurements, whole lake mass balance, concurrent photosynthesis and respiration measurements, stable isotope ratios, coupled ecosystem-
hydromodynamic model) have all indicated that Lake Superior is a net source of CO2 to the atmosphere. pCO2 concentrations in the lake follow a seasonal cycle with higher values in spring than in summer. Similar seasonal cycling of pCO2 in the other four Great Lakes has also been documented. The magnitude of the seasonal oscillation in pCO2 varies considerably among the lakes, being lowest in Superior and highest in Michigan. In this presentation we assess the relative roles of changes in temperature, pH, alkalinity, and DIC in driving the seasonal oscillations in pCO2 in the surface waters. If temperature or pH are the major driving variables, there will be little net emission of CO2 from the lake on an annual basis. In this analysis, we utilize both empirical correlation analyses as well as theoretical modeling to quantify the contributions of each factor.

DETECTION AND FATE OF ZOOPLANKTON PRODUCED FDOM IN MONTEREY BAY

Biological sources of colored dissolved organic material (CDOM) in seawater are poorly understood both in terms of rates of production and the types of material produced. Previous work has shown that copepods and larvae produced fluorescent dissolved organic matter (FDOM). During a thin-layer cruise in Monterey Bay, California in July 2006 we examined the production and fate of zooplankton produced FDOM. Grazing experiments were conducted with separate species to learn what types of FDOM different species produce. Bacterial and photo degradation experiments were conducted to exam-
in the turnover rate of zooplankton produced FDOM. These results will be discussed relative to water column FDOM profiles.
FORMATION PROCESS OF THE KUROSHIO LARGE MEANDER USING A REGIONAL ASSIMILATION SYSTEM MODE/LMCOM-WNP

Formation of the Kuroshio large meander (LM) in 2004 has been examined using a regional assimilation system (MOVE/LMCOM-WNP). The small meander (SM) that triggers the subsequent LM occurred in December 2003. A cyclonic eddy propagating westward and a frontal wave from the East China Sea play important roles in the SM generation. The SM remains stationary until the spring of 2004. Examining a vorticity balance, the advection and the bottom pressure torque on the continental slope is balanced. This balance is achieved as a result of reduction of the advection by a westward propagating negative temperature anomaly. The SM starts moving eastward around May 2004, when an anticyclonic eddy east of the Tokara is amplified by coalescing two eddies. At that time, an anticyclonic eddy in deep layer is generated below the Kuroshio. The upper and lower layers are well stratified due to inhomogeneity in the LM. A baroclinic analysis indicates that this process can be understood by baroclinic instability. From some sensitivity experiments, sufficient conditions for the stationary LM will also be discussed.

DISTRIBUTION OF TRACE METALS IN THREE VENEZUELAN ESTUARIES

Marine sediments and organisms, can be a sensitive indicator for both spatial and temporal trend monitoring of contaminants in the estuaries, since they can accumulate (concen- trate) trace metals and others substances. The estuaries of Cuare, Buche and Mochima are located within the subtropical environment of Venezuelan coastline. In this work, we report concentrations of selected major and trace elements in recent sediments, mangrove and oysters collected in these estuaries. Environmental factors as temperature (T), dissolved oxygen (DO), total dissolved solid (TDS), pH, conductivity (L) and salinity were also determined. Our results suggest that the variation of anthropogenic sources is the most important factor influencing the spatial variation of trace metals. Statistical analysis (one-way ANOVA) indicated that sediments, mangrove and oysters considered selectively can accumulate certain elements. Sampling of estuaries different along the Venezuelan coast revealed significant site-specific concentration differences for the elements Cd and Cr. This study, we investigate how well it is possible to define different water types from the in situ measured reflectance spectra and from MODIS and MERIS products. Also we explore different errors (sensor calibration, wind speed, cloud cover etc.) influence for capability to discriminate between the estimated water types. We show that despite the differences in optical active substances, reflectance spectra in Moderate and Turbid types cannot be distinguished by the standard processing scheme of the MODIS sensor. MERIS sensor was able to do that. Calibration errors were relatively small comparing other errors.

As a result of reduction of the advection by a westward propagating negative temperature anomaly, the SM starts moving eastward around May 2004, when an anticyclonic eddy east of the Tokara is amplified by coalescing two eddies. At that time, an anticyclonic eddy in deep layer is generated below the Kuroshio. The upper and lower layers are well stratified due to inhomogeneity in the LM. A baroclinic analysis indicates that this process can be understood by baroclinic instability. From some sensitivity experiments, sufficient conditions for the stationary LM will also be discussed.
that a positive mentoring experience is strongly correlated with success in science, and as such, the initiative promotes early exposure to professional oceanography throughout the pipeline from late graduate school through their early careers. MPower (Mentoring Physical Oceanography Women to Increase Retention) is a community-based program comprised of online and face-to-face mentoring opportunities. The MPower website (www.mpowercr.org) includes resources as well as online forums where junior and senior scientists interact. In May 2008, we will hold the first Pattullo conference to bring mentors and mentees together. In addition, statistics from institutions and survey responses from individual graduate students provide quantitative and qualitative measures to determine the program’s effectiveness at attaining its goals and objectives.

TERRESTRIAL BIODYNAMIC SILICA: AN OVERLOOKED SOURCE OF NUTRIENT SILICON TO THE COASTAL MARINE ENVIRONMENT

A recent reassessment of the global biogeochemical silica (Si) cycle indicates that about 15% of the riverine supply of reactive Si to the ocean is under the form of biogenic silica (bSiO2). The fate of land-derived bSiO2 upon entering the coastal zone is poorly known. We measured the dissolution rates of various biosiliceous materials in flow-through reactors supplied with seawater or freshwater. Although the rates varied among the different materials, for any given solubility the rate was systematically higher in seawater than freshwater, on average by a factor of five. This significant rate enhancement is attributed to the higher pH of seawater, and the catalysis by seawater cations of the hydrolysis of surface silicic acid. Enhanced dissolution at the land-ocean transition of bSiO2 produced by terrestrial plants and freshwater diatoms may represent a significant, but largely overlooked, source of nutrient silicon for nearshore marine ecosystems receiving large river inputs. In addition, river damming, land use changes, and global warming are causing major perturbations in the river supply of bSiO2, thereby affecting siliceous productivity in the coastal zone.

REAL-TIME MICROWAVE OCEAN SURFACE SPECIFIC HUMIDITY

The Naval Research Lab has undertaken the development of a real-time quality-controlled system with the goal of providing a remote-sensed global estimate of latent and sensible heat flux. The first real-time product was developed to be specific humidity, based upon the algorithms proposed by Jackson, Wick, and Bates (2006) using the individual microwave sensors flying on the DMSF and NOAA satellites. Validation was performed against collocated NCEP ship and buoy observations relative to predictions from the Navy Operational Global Atmospheric Prediction System (NOGAPS). 0.5-degree global model. Validation data were analyzed from October 2004 through June 2007, with each month providing over 300 separate observations. The data redundancy allowed statistics to be developed to characterize the accuracy and bias of these satellite observations compared with both the ship/buoy observations and the NOGAPS product.

FIRST EVIDENCE FOR HYDRAULIC SUBSTANCES AS IMPORTANT LIGAND FOR IRON IN COASTAL AND DEEP OCEAN WATERS

The mechanism that maintains a relatively constant iron concentration in deep ocean waters (~0.8 nM without inter-ocean fractionation is based on the hypothesis of control by unknown organic complexing ligands. Hydraulic substances (HS) are well-known to bind metals including iron in freshwater, but surprisingly little is known about their importance to the biogeochemistry of iron. Using a new method we have determined HS concentrations in coastal waters (Irish Sea) and a sample from the central deep Pacific. HS concentrations were found of 50 – 370 µg L-1 in the Irish Sea with an iron binding capacity of 1.4-12 nM, and 36 µg L-1 in the deep Pacific with an iron binding capacity of 0.8 nM without inter-ocean fractionation. The preliminary data suggests that such substances may be playing a critical role in controlling iron bioavailability and iron concentrations in surface waters of coastal and deep oceanic waters.

BEACH WIZARD: BATHYMETRY ESTIMATION BY REMOTE SENSING

A data-model assimilation method called Beach Wizard is presented with which the nearshore subtidal bathymetry can be accurately estimated based on video-derived observations of wave roller dissipation and variation of the intertidal shoreline, and radar-derived observations of wave celerity. Using many consecutive images, these observed properties are compared with the computational bathymetry and the best agreement is estimated based on the numerical simulations. The method can deliver coastal state information (i.e., simultaneous updates of bathymetry, waves, and currents) with high temporal and spatial resolution and can be used in conjunction with or instead of in-situ measured data.

ASLO/AQUATOS/ERF
by the effect of the interaction of their exhalent jets with the boundary layer flow. Aquatic plants may also reduce a phytoplanktonic canopy. Although turbulence intensity inside the canopy is increased, the flow reduction is large enough to create a relatively calm environment. Most studies to date have been devoted to the interaction of individual species and flow. Most natural systems consist of communities of species. E.g. in the Mediterranean, bivalves (Pinna nobilis) grow inside seagrass meadows, creating a substrate of large, rough elements submerged inside a flexible canopy. In the Oosterschelde lagoon, the movement of individual water masses. Alternatively, the SSOM explicitly tracks individual water masses, offering a new view of heat and tracer transport. Furthermore, the Lagrangian model is computationally efficient in transporting multiple tracers. Using an idealized wind stress and an imposed surface temperature similar to a zonally averaged Atlantic profile, the model can reproduce major features of the subtropical gyre circulation. We examine how a few leads are transported and cycled in the subtropical gyres. The results of these simulations are compared with companion experiments using a co-ordinate Eulerian ocean model (MITgcm). Further, we discuss implications for diagnosing the transport and air-sea exchange of various chemical species, such as CO2.

AN INDEX FOR THE INTER-ANNUAL VARIABILITY IN AGULHAS LEAKAGE

The Agulhas region, where the Indian and Atlantic Ocean meet, is of particular interest as it is an important part of the global scale Thermohaline Circulation. The high degree of nonlinearity of the region comes from the interplay of the equatorward flow, strong and varied winds, and the advection of heavy water, which would normally be found in the Antarctic Circumpolar Current, into the Agulhas region. As a result, the Agulhas Leakage Index is defined based on the location of the Agulhas front. The index is validated using the NCOM model. Almost 2 million isotopic drifters, released in the Agulhas Current, are tracked to determine the inter-ocean flux. As altimetry data is available in near real-time, the Agulhas Leakage Index can be used as a tool for monitoring the state of the interoceanic exchange on inter-anual time-scales.

OUTREACH AT THE COOPERATIVE INSTITUTE FOR OCEANOGRAPHIC SATELLITE STUDIES (CIOSS): SUPPORTING THE SMILE PROGRAM

CIOSS outreach activities include its partnership with the Science and Math Investigative Learning Experiences (SMILE) Program. SMILE helps to support the SMILE high-school program and to develop its Oceanography and Remote Sensing curriculum for after-school club activities, which prepare for the annual High-School Challenge. The SMILE Program addresses issues of higher education readiness, access and diversity through academic enrichment and outreach in science and mathematics for under-represented students in grades 4-12. SMILEs programmatic aims are to 1) Promote teacher professional development through workshops; 2) Provide the activities and materials for the after-school SMILE clubs; and 3) Hold a college-connection event - the annual High-School Challenge - where teams of students solve a scenario-based problem. By holding the Challenge on college campuses, high-school students envision themselves as potential college students. CIOSS/SMILE goals are to 1) motivate undergraduate students and researchers in creating and delivering ocean-related outreach; 2) increase teacher understanding of ocean science and remote sensing; 3) provide learning opportunities for high-school students in applied ocean sciences and remote sensing; and 4) promote students’ interest in ocean science, science careers, and higher education.

A MULTI-YEAR SURVEY OF SURFACE LAYER CARBON DIOXIDE DYNAMICS IN THE GULF OF MAINE

The Gulf of Maine represents a coastal ecosystem with a dynamic carbon cycle attributed to strong tidal mixing, seasonal stratification, coastal shelf exchange, and land-ocean export. An ongoing shipboard program, started in 2004, is providing a new data set for ocean surface layer pCO2 to address questions surrounding the impacts of biology and land-ocean interaction on the ocean carbon cycle and greenhouse gas exchange. Surface layer pCO2 and CO2 being collected along the Maine coast are used to create a multi-year continuous record of pCO2 and further chemical data from underway, discrete sample, and profiling systems. The program is complemented with an autonomous pCO2 buoy measurement system, two 5000 km² vector Oceans surveys in fall 2006 and 2007, and the summer 2007 NOAA Gulf of Mexico and Northeast U.S. Carbon Cruise. We will present data showing strong seasonal and shorter time scale pCO2 and DO signatures and evaluation of their covariance with riverine input and biological productivity. The composite data set provides a wealth of new spatial and temporal information for future modeling and observing system design efforts related to monitoring carbon dynamics in the coastal zone.

OCEAN BIOGEOGRAPHIC INFORMATION SYSTEM: EXPLORING ITS CONTENT

The Ocean Biogeographic Information System (OBIS), established by the Census of Marine Life programme, is an on-line, freely-accessible system for absorbing, integrating, and assessing data about life in the oceans. OBIS aims to stimulate taxonomic and systematic research, and to generate new hypotheses concerning evolutionary processes, maintenance of species distributions, and roles of marine organisms in marine ecosystems. Today, OBIS contains more than 13.4 million records of 82,000 species from 222 databases. Analysis shows geographic gaps in the data for the mid-oceans and deep-sea, and taxonomic gaps for invertebrates; a significant part of the bias is due to real differences in observer effort between countries. However, the present content makes it possible to start analysing the data so as to reveal global biodiversity patterns. Several biodiversity measurements are calculated and presented. Care was taken in interpreting such metrics because of sampling bias. A major effort of data cleaning, in collaboration with all data providers, is under way, to remove outliers and to harmonize taxonomic names and classification.

CO2 VARIABILITY WITHIN RETENTIVE EMBAYMENTS: THE NORTHERN CALIFORNIA UPWELLING REGION OF COOP WEST

From satellite imagery and shipboard data, retentive embayments stand out as warmer, elevated surface chlorophyll features within the CoOP WEST (Coastal Ocean Processes---Wind Events and Shelf Transport) region north and south of Point Reyes. Coastal carbon cycling research in the past has overlooked the contribution of these smaller, highly variable coastal features that are typically influenced by prevailing upwelling conditions. This area is unique in that it is subjected to the strongest recorded summer wind stresses along the U.S. west coast, yet maintains high biological productivity. The combination of strong upwelling winds and highly productive coastal waters also allows for phytoplankton to be retained and observed topographically extents north and south of Point Reyes. Here we evaluated how these specialized regions facilitated the outgrowth or drawdown of CO2, during three wind stress periods (upwelling, transition, relaxation) for 2001 and 2002. We quantified changes in CO2 concentrations from MODIS (sea surface temperature) and SeaWiFS (chlorophyll a) satellite imagery by deriving a satellite-based model of POC fluxes. Results highlighting the processes and relative importance of these coastal features will be presented.

THRESHOLDS OF HYPOXIA FOR MARINE BENTHIC COMMUNITIES

Hypoxia is a mounting problem affecting the world’s coastal waters with severe consequences on benthic communities, including death and catastrophic changes. Hypoxia is linked to eutrophication and it is forecasted to increase further in the future due to the combined effects of the use of synthetic fertilizers and the increase in temperature caused by global warming. We used a broad survey of the published literature to assess the thresholds of hypoxia for sublateral and lethal responses across a range of contrasting marine benthic communities. We conclude that the empirical sublateral and lethal thresholds of hypoxia are above the conventional definition of 2 mg O2/L to diagnose hypoxia for all groups tested. We further show that hypoxia thresholds vary greatly across organism groups.

CLIMATE VARIATION AND BIOTURBATION ON THE SEA FLOOR IN THE ABYSSAL NORTH PACIFIC

This research examined how the links between climate variation, phytoplankton activity, POC flux and benthic community activity affect deep-sea bioturbation and carbon sequestration. Echinocore nereidus, a deep-sea epibenthic echinoderm, was used as a proxy to study these changes because it is common at the study site and leaves distinctive trails that allow quantification of the amount of sediment covered. A long-time-series photographic record from 4100 meters depth in the northeast Pacific Ocean, showed a recent rapid increase in E. rostrata abundance coinciding with a small decrease in the average size of the observed individuals. The data from the photographic record was used to create an index of bioturbation potential (as seen in Solan, et al. 2004) which assigns scores to the size, mobility and abundance of the animals as they relate to sediment particle movement. Changes in the bioturbation potential over time allowed us to track particle mixing, availability of surface-derived POC and the incorporation of surface-derived carbon into the food chain and potentially back to the surface in the form of greenhouse gases.

BIODIVERSIC SILICA PRODUCTION IN EQUATORIAL PACIFIC SURFACE WATERS FROM 140°W TO 180°E

Diatom growth and production in the eastern upwelling sector of the equatorial Pacific are affected by insufficient concentrations of iron and may be further limited by silicon availability. A comparison with a limited number of studies in the western warm pool indicates that diatoms in the eastern equatorial Pacific are more active than those in the western equatorial Pacific. We determined the surface distributions of silicic acid, biologically-produced silica, diatom productivity and Si uptake kinetics between 2°N and 2°S from (140°W) to west (180°E) in the Pacific. Silicon uptake rates were assessed with the radiotracer 44Si. Euphotic-zone silicic acid concentrations, and biogenic silica concentrations and production rates decreased from 2 to 0.8 µM, 150 to 42 µM and at respectively, from 140°W to 180°E. Biomass-specific Si uptake rates also decreased (0.31 to 0.04 d-1) from 140°W to 180°E. In addition, we examined the effect of added Si on the rates of silicic acid uptake by diatoms. Results indicate that uptake rates were Si-limited along the length of the study area, with limitation most severe in the west.

PHYTOPLANKTON PHENOLOGY FROM SATELLITE OCEAN COLOR OBSERVATIONS

Climate change affects the timing and magnitude of numerous environmental conditions, such as temperature, wind, ocean circulation, and precipitation. These changes, in turn, are likely to cause a response in ecosystem productivity. In marine ecosystems, these changes are likely to affect the timing and magnitude of phytoplankton biomass and primary production. In order to establish a baseline from which to assess any future changes, we are constructing a climatology of the phenology - the timing of recurring natural phenomena - of global oceanic phytoplankton biomass using data from Sea-viewing Wide Field-of-view Sensor (SeaWiFS). Specifically, we are estimating bloom onset, maturity, decay and termina- tion from models of pentad (5-day) mean SeaWiFS chlorophyll concentrations in 3x3 bins fit by Generalized Linear Models. Preliminary results for the North Atlantic show that satellite remote sensing methods are able to monitor phytoplankton phenology with good results. In the future we plan to examine how the annual anomalies correspond with cli- mate variability, such as ENSO and the North Atlantic Oscillation (NAO).

PHYSICAL AND NUMERICAL MODELLING OF FLOW THROUGH THE EVERGELDES

We use measurements from a large-scale tracer release in the Florida Everglades to motivate and evaluate two different modelling techniques. The first is a numerical technique that is well suited to the Everglades, namely Lattice-Boltzmann modelling. This numerical technique can directly incorporate the spatial structure of vegetation, rather than using a bulk resistance technique. The new computational cost is modest, and the approach given in this paper must be considered to inform policy decisions. The second model we evaluate is a laboratory model designed to improve the utility of quantitative imaging in examining the small-scale details of flow through aquatic vegetation. To improve optical access in laboratory models, we introduce a new methodology for creating inexpensive refraction-index matched models of macrophytes and periphyton with flexibility resembling the actual plants.

COMPARISONS OF THE PATHFINDER SEA SURFACE TEMPERATURE DATA SETS

The Pathfinder Sea Surface Temperature (SST) time series provide the longest satellite derived climate data records, spanning 1885 to 2006. The work focuses on two versions, Version 5.0 (V50) of the data set were calculated at a 4km resolution while Version 4.1 (V41) were gridded at 9km. RMS differences between V50 and V41 and insitu data from the World Ocean Database (WOD) were calculated in the Gulf Stream (GS) and off the California Coast (CC). For the GS, V41 RMS differences greater than 1.0 degree Celsius peaked in June. Using V41 in the CC warm biases consistent with the summertime CC coastal upwelling were found. Maximum in SST gradients were consistent with periods of pentad (5-day) mean SeaWiFS chlorophyll concentrations in 3x3 bins fit by Generalized Linear Models. Preliminary results for the North Atlantic show that satellite remote sensing methods are able to monitor phytoplankton phenology with good results. In the future we plan to examine how the annual anomalies correspond with cli- mate variability, such as ENSO and the North Atlantic Oscillation (NAO).

TROPICAL PACIFIC SIGNATURE OF GLOBAL WARMING

The response of the tropical Pacific to increasing CO2 is a central topic in climate change research, as tropical climate conditions have far-reaching effects and they set the background for changes in the character of El Niño. The theoretical and modeling under-
standing, and observational evidence for long-term changes to the tropical Pacific climate system is high. In models with a simplified representation of atmospheric physics, feedbacks originating in the ocean drive the system to a "La Niña-like" state. In models with atmospheric general circulation components, thermodynamic constraints result in a reduction of the strength of the atmospheric overturning circulation – manifest primarily in the zonally-asymmetric (Walker) rather than zonal-mean (Hadley) compo- nent. In these models changes over the tropical Pacific Ocean resemble "El Niño-like" conditions, although the mechanisms are fundamentally different from those of El Niño. Even though modeling studies can help reconcile aspects of the diverging theoretical understanding, a true reconciliation requires observational evidence. Observations of sea level pressure indicate that over the 20th Century the Pacific Walker circulation has weak- ened; however, different reconstructions of historical SST are inadequate to distinguish between an increase or decrease in East-West SST gradient across the Pacific. We outline what a way forward, with paleo-proxy observations, to reconcile these diverging views.

INFLUENCE OF TIDES AND WINDS ON NEARSHORE HYDRODYNAMICS AND MORPHOLOGY DURING MILD WAVE CONDITIONS

Numerous studies show that bathymetry and currents in the nearshore region respond strongly to changes in wave conditions in the surf zone and its vicinity. In mixed wave-tide dominated coasts, the few studies that are available are primarily experimental, focusing mostly on tidal flats and macrotidal beaches (Kidd and Orford, 2002). Maiti et al. (2004) concluded that detailed examination of the sedimentation requires at the very minimum a crude coupling between wave and tide models. In this study, we will investigate the combined influence of waves and tides on the hydrodynamics and morphology during periods of wave action. At the FRF, Duck, NC, we will compare the hydrodynamic and morphological changes resulting from the combined forcing of waves, winds and tide to the individual forcings. The circulation model DELT3D will be used to simulate the hy- drodynamic and morphological response of the domain forced by the waves in the domain obtained from SWAN with the boundary conditions derived from the 8m array. The tides in the domain will be forced by specifying the dominant tidal harmonics at the boundaries

RELATIONS BETWEEN NORTHWARD OCEAN AND ATMOSPHERIC ENERGY TRANSPORTS IN A COUPLED CLIMATE MODEL

The climate general circulation model HadCM3 is used to analyse the relation between northward energy transports in ocean and atmosphere at centennial timescales. In a transient water hosing experiment, where suppressing the Atlantic meridional overturning circulation (MOC) causes a reduction in northward ocean heat transport of up to 0.75 PW (i.e. 75%), the atmosphere compensates by increasing its northward transport of moist static energy. This compensation is very efficient at low latitudes and near-complete at the equator throughout the experiment, but is incomplete further north across the northern mid-latitude storm tracks. The change in atmospheric energy transport enables the model to find a new global-mean radiative equilibrium after 240 years. In a perturbed physics ensemble of HadCM3 it was found that time-averaged meridional energy transports in ocean and atmosphere can act opposingly. Where model formulation causes an unbal- anced mean climate state, e.g. an excessive top-of-the-atmosphere radiative surplus at low latitudes, the atmosphere increases its poleward energy transport to disperse this excess. MOC and ocean poleward heat transport tend to be reduced in such model versions, and this offsets the increased poleward atmospheric transport of the low-latitude energy surplus. Model versions that are close to net radiative equilibrium also have ocean heat transport and MOC close to observed values.

REMOTE SENSING OF A NATURALLY IRON FERTILIZED PHYTOPLANKTON BLOOM AROUND THE CROZET PLATEAU, SOUTHERN OCEAN

A combination of Argo float, ocean colour, irradiance and alinity data are used to ex- plain the temporal and spatial structure of the chlorophyll distribution around the Crozet Plateau (50°A, 46°A). The area can be split into different productivity regimes, their characteristics determined by the physical and chemical interactions between the circula- tion and topography. From the chlorophyll response, the eastern islands are identified as the primary iron source. The bloom occurs north of the plateau due to the circulation pat- terns advecting water northwards and westwards from the islands. The bloom initiation is controlled by latitudinal gradients in light availability. High chlorophyll values persist immediately downstream of the islands, but further away concentrations remain low after the spring bloom. Iron, rather than light, is dominant in controlling the distribution of peak chlorophyll values. The area south of the plateau is upstream of the islands and has low chlorophyll, the concentration typical of the open Southern Ocean. Light is not limiting in this area for at least four months. Despite the shallow topography, the area over the plateau has relatively low chlorophyll concentrations.

SIMULATIONS OF MIXING AND TRANSPORT OF DISSOLVED WASTE DISCHARGED FROM NEAR-COASTAL AQUACULTURE PENS

The present study focuses on understanding the transport and fate of dissolved wastes from aquaculture pens in near-coastal environments using the hydrodynamic code SUTANS, which employs unstructured grids to compute flows in the coastal ocean at very high reso- lution. Simulations of pollutant outfall fields (in time and space) as a function of the physical setting and the local environment (bathymetry, stratification, rotation), flow conditions (tides, currents), and the location of the pens were performed to study their effects on the evolution of the waste plume. The presence of the fish farm pens cause partial blockage of the flow, lead- ing to the deceleration of the approaching flow and the formation of downstream wakes. Results of both the near-field (area within 10 to 20 pen diameters of fish-pen site) as well as the far-field behavior of the pollutant field will be presented. These results highlight for the first time the importance of the wave vortex dynamics on the evolution of the near-field plume as well as rotation of the earth on the far field plume. The results provide an under- standing of the impact of aquaculture fish-pens on coastal water quality.

ADJOINT SENSITIVITY STUDIES OF THE CENTRAL CALIFORNIA CIRCULATION

We use the Regional Ocean Modeling System (ROMS) to model the circulation of the Central California region, and its associated adjoint model to study the sensitivity of the circulation to different driving mechanisms. The adjoint model is particularly suitable for sensitivity analyses because it allows one to determine how a certain metric representative of a physical aspect of interest, evolves due to linear variations of the system variables, the external forcing, the initial state, and the open boundary conditions. We have identified various metrics that represent the upwelling processes of the Central California region, and the energetics and mean level field of the coastal circulation. The adjoint model results allow us to investi- gate the temporal and spatial distribution of the sensitivity of each metric to time-averaged external forcing and state variable initial conditions. This is invaluable information both for theoretical reasons and for practical applications such as the planning of observational efforts and data assimilation experiments. We show that sensitivities to large-scale and remote forc- ing for the coastal mean sea level metric are significant, whereas upwelling indices are locally driven. We also compare the results obtained using differently sized coastal domains.

EXAMINING PARTICLE FLUX WITHIN MESOSCALE EDDIES USING 210PO 210PB DIS-EQUILIBRIUM

The impact of mesoscale eddies on particle flux was examined in the Sargasso Sea and the lee of the Hawaiian Islands using 210Po-210Pb disequilibrium. Seawater samples for total activities were collected along transects through the eddies and at targeted stations. Particulate carbon, nitrogen and biogenic silica export fluxes were determined using the 210Po and the elemental-210Po ratio and/or the residence time of 210Po in the water column inventories of PC, Pb-N, and BSi. In the Hawaiian lee waters, elemental fluxes at 150 m within the eddies averaged 1.65 ± 0.10 mmol C m-2 d-1 and 0.30 ± 0.02 mmol N m-2 d-1 and 0.15 ± 0.01 mmol Si m-2 d-1. Relative to surrounding waters, eddy induced PC and PN export were not signifi- cantly different, whereas BSiO4 fluxes were enhanced by more than 6-fold. These results agree with other methodologies, i.e. 210Th-derived fluxes, sediment traps and 234Th mass balance, and reinforce the idea that 210Po as tracer of particle fluxes in these areas may be used as another independent and robust approach and investigated more fully.

COLLECTIVE MOTION OF ANTARCTIC KRILL IN A TURBULENT MIXED LAYER

We simulate schooling behavior in an individual-based model to investigate the ecologi- cal consequences of collective motion in krill. We formulate a coupled biological-physical
model of zooplankton foraging on a variable resource. The model includes a two-dimen-
sional patch model as a source of environmental variability; the circulation patterns affect the distribution of phytoplankton by upwelling nutrients into the euphotic zone, where the algae can grow, and by stirring the patchy algal concentrations. In the intermit-
tent resource field, schooling can represent a successful foraging strategy. We also examine how the emergent properties of schools depend on the parameters describing individual movement. Phase transitions occur when the swimming speed is varied; the density and spatial scale of groups are found to be inversely proportional to speed. Modeled schools are compared to observed aggregations of Antarctic krill. It is argued that acceleration patterns linked to the foraging behavior of krill might explain the observed qualitative changes in the depth and density of aggregations that occur over the diurnal cycle.

SOURCES AND SINKS OF HYDROGEN PEROXIDE IN THE GULF OF ALASKA

While photoproduction of hydrogen peroxide is likely the dominant source in coastal regions with high CDOM, dark (biotic) production has been proposed as a significant source in CDOM-poor waters. In this study, rates of dark and photochemical hydrogen peroxide pro-
duction were measured and compared in samples collected from a variety of seawater types in the Gulf of Alaska. While often net production of hydrogen peroxide was not observed in 24-hour dark incubations of unaltered seawater samples, decay was apparent in subsamples spiked with 100-250 nM hydrogen peroxide. Dark production rates were calculated assuming H2O2 decay rates in spiked and unspiked samples are equal and ranged from 0.5 to 8 nM/hr; faster than photochemical formation in some cases. Decay rates ranged from 1.5 to 20 hr^-1. Calculated hydrogen peroxide steady-state concentrations from these dark production and decay rates were 10 to 100 nM. Rates of dark production generally decreased with depth from a surface maximum down to 50 meters. A direct correlation exists between the rates of dark degradation and dark production of hydrogen peroxide.

PRIMARY PRODUCTION WITHIN THE SEA ICE ZONE WEST OF THE ANTARCTIC PENINSULA

In shelf waters west of the Antarctic Peninsula (wAP), with abundant macro- and micro-
nutrients, water column stability due to freshwater input from sea ice melting has been suggested as a key factor controlling primary production. The area is subject to the annual advance and retreat of sea ice characteristic of Antarctic waters. A 12-year time series (1995-2006) was analyzed to study spatial and temporal patterns in primary production as well as major environmental determinants. A strong onshore-offshore gradient is evident along the Peninsula at the height of the growth season with higher production observed in inshore waters. Regional production varied inter-annually by a factor of 7. Mixed layer depth shows the higher correlation with production while late sea ice retreat explains 58% of the variability in space and time. No regional trend in primary production was detected during this period. We discuss the influence of sea ice retreat and water masses in determin-
ing summer mixed layer depth.

FAKE OF CARBON AND NITROGEN IN MICROBIAL BIOMARKERS IN INTESTINAL SEDIMENT

The fate of microbial carbon and nitrogen in sediments has primarily been studied by compound-specific stable isotope analysis in combination with stable isotope labeling. These studies so far generally focused on either C or N, meaning that the direct coupling between the fate of microbial C versus N has remained largely unstudied. Recently, we compared the fate of microbial C and N by labeling the microbial community (bacteria and benthic microalgae) in estuarine, intestinal sediment with both 13C and 15N and its effect on larvae of the west coast native oyster Ostrea lurida. Sea water pH was lowered to an average value of 7.74 by increasing pCO2 with a CO2 incubator. Fluorescently tagged velger larvae were subjected to lowered pH water for three days; shell growth was measured and compared to control growth (larvae in 380 ppm pCO2). We saw a 23.5% decrease of larval shell growth in elevated pCO2 condi-
tions. Data from a Tomales Bay study over the period of 1987 to 1995 support the idea of a C/O2 heavy atmosphere decreasing pH. Oyster broodstock collected from Tomales Bay were assumed to be offspring of generations that withheld a 142 ppm pCO2 increase and a decrease in pH of 0.1 during the nine years.

UNDERSTANDING IMPACTS OF SEDIMENTATION ON MANGROVES AND CORAL REEFS TO IMPROVE LAND USE IN A WET TROPICAL ISLAND, PohnPelmicronesia

Pohnpei is one of the wettest places on earth. Rapid deforestation of upland watershed areas and plant salakas, Piper methysticum, resulted in the degradation of coastal coral reefs and the loss of fisheries resources. The Pohnpei Conservation Society (CSP), armed with quantitative data collected by regional researchers was able to work with local commu-
nities and traditional leaders to effectively address the impact of soil erosion on coastal marine areas. Researchers from the Palau International Coral Reef Center, the Australian Institute of Marine Science, and the University of Hawaii conducted a study to determine the impacts of sediment on mangroves and on coral reefs along a gradient of sedimentsa-
tion. CSP then used these biophysical data to conduct a series of community meeting/ presentations to rally the support of community to change farming practices. This has been one of the successful examples of using scientific data through a locally connected NGO to influence environmental practices and policy in Micronesia.

EXPLORING TIDE GAUGE LONG SEA LEVEL RECORDS FOR OCEAN AND CLIMATE STUDIES

Tide gauges provide unique in-situ measurements of monthly and longer period sea level variability going back many decades, but all records are confined to coastal and island locations. To make best use of these long tide gauge records in ocean modeling and assimilation efforts, it is essential to understand how representative they are of the large-scale sea level variability over the deep ocean. An attempt to address this issue is made using detailed com-
parisons of the tide gauge variability with that observed by satellite altimeters for the last 15 years, taking advantage of their near-global spatial coverage, and also with a number of different model simulations. Tide gauge/altimeter/model differences are explored as a function of location, temporal and spatial scale, model resolution and physical parameterizations, etc., with the goal of being able to extract maximum information from the tide gauge records. Analyses include the provision of error estimates that might be used to appropriately weight tide gauge data when using them as constraints in ocean climate models of the last century.
HIGH-RESOLUTION SEA SURFACE TEMPERATURE ANALYSIS SYSTEM IN THE GULF OF MAINE

High-resolution sea surface temperature (SST) fields are crucial for estimating upper ocean circulation and air-sea fluxes. To meet these critical needs, SST products are often constructed by combining measurements from a variety of sources. Here, we describe one such application that produces a regional SST product for the Gulf of Maine, and provide the results from an ongoing study to validate this product. These SST fields are derived using measurements from the geostationary operational environmental satellite (GOES) and analysis from the real-time global sea surface temperature (RTG SST) and the ocean surface temperature analysis (OSTA) system. This algorithm has been implemented into a prototype near-real-time production system that, since May 2007, has produced SST fields four times per day on a 4-km grid. This system also provides daily validation data constructed by collocating estimated SST values with in situ measurements from buoys. The average bias in the domain from May to August 2007 is found to be 0.02°C. The system was applied to analyze diurnal variability in the region, which revealed significant amplitudes and complex spatial distribution.

DESIGN AND VALIDATION OF AN OFFLINE OCEANIC TRACER TRANSPORT MODEL FOR CARBON CYCLE STUDY

An offline passive tracer transport model with self-operating diagnostic mode vertical mixing and horizontal diffusion parameterizations is used with assimilated ocean currents to find the CFC-11 cycle in oceans. This model is developed in NIES under carbon cycle research project inside the GOSAT (Greenhouse gas Observing Satellite) modeling group. The model borrows offline fields from pre-calculated monthly archives of assimilated ocean currents, temperature and salinity, and evolves a prognostic passive tracer with prescribed surface forcing. The model's performance is validated by simulating CFC-11 cycle in the ocean starting from the pre-industrial period (1938) with observed anthropogenic perturbations of atmospheric CFC-11 to comply with OCMIP-II flux protocol. The model results are compared with ship observations as well as the results of candidate models of OCMIP-II and a performance is assessed. The model simulates the deep ventilation processes in the Atlantic Ocean appreciably well and yields a good agreement in column inventory of CFC-11 amplitude and phase compared to the observation. The statistical skill test shows that this model outperforms other candidate models of OCMIP-II because of its higher resolution and assimilated offline inputs feeding and shows a potential role in improving transport calculation in the ocean with cost-effective computation.

DEEP WESTERN BOUNDARY CURRENT VARIABILITY OBSERVED IN THE WESTERN LABRADOR SEA

Since 1993 moored current and temperature-salinity observations have been carried out in the western Labrador Sea near 50°N (western end of WOCE-AR7 line), 53°N (exit of Labrador Sea) and east of the Grand Banks (at 43°N) as part of SFB 460. The time series at 53°N are continued under the NORDATLANTIK project. All moored, shipboard and Argo observations are evaluated for transport and water mass variability of the different Deep Water layers. While altimetry and model studies have suggested a decline of the overall sub-polar gyre circulation since the 1990s, direct current measurements at the 1500m level along the western continental slope of the Labrador Sea show interannual variability of the order of 10-20% during the 1996-2007 period. Alongshore correlations and relations to local forcing and boundary wave activity in response to upstream forcing changes are discussed.

DISSOLVED INORGANIC CARBON (DIC) IN THE MID-ATLANTIC BIGHT: CLOSING THE CARBON BALANCE

Carbon cycling on continental shelves is an important, yet poorly constrained, component of the global carbon cycle. Here we present an analysis of dissolved inorganic carbon (DIC) cycling along the Mid-Atlantic Bight (MAB). Samples were collected on three Oceans Margins Program (OMP) cruises including March and August of 1996 giving a seasonal comparison of total shelf DIC. The high spatial resolution of these measurements reveals clear gradients of DIC with depth and distance from shore. Results show a net deficit (consumption) of DIC on the shelf between 11 and 32 MTC/year for all three periods. This deficit is within the range of total organic carbon surpluses calculated for the same period of study. Air/sea transfer estimates indicate net uptake of atmospheric CO2 in March 1996 and net release of CO2 in August 1996. The air/sea flux of CO2 is dominated by temperature driven changes in solubility but there is a significant contribution by biological productivity. Results support the OMP hypothesis of net autotrophy in the MAB and illustrate a complete carbon budget approach to addressing the net trophic status of coastal margin systems.

THE MID-DEPTH CIRCULATION OF THE NORDIC SEAS FROM PROFILING FLOATS

The circulation of the Nordic Seas advects warm and saline waters to regions of water mass transformation and supplies the dense overflows that feed the North Atlantic Deep Water. This makes it an important element of the meridional overturning circulation. We use the surface position data of profiling floats, collected in the Nordic Seas from 2001 till now, to infer their subsurface displacements at parking depths of 1000 and 1500 m respectively. The subsurface float trajectories are then Lagrangian measurements of the mid-depth circulation. The multi-year mean circulation of the Nordic Seas at mid-depth is obtained from the space-time average of the float drift velocities. Cyclonic gyres with strong topographic steering are found in the four deep basins. Spatial averages over each basin shows a seasonal variation of the gyre speeds with maxima in winter. This is roughly in phase with the wind stress curl from NCEP/NCAR reanalysis data integrated over the basin areas. The results are compared with velocity fields from a high resolution data assimilation model of the Nordic Seas.

ACCUMULATION AND CYCLING OF TRACE METALS BY HETEROTROPHIC MARINE BACTERIA

The uptake and subsequent trophic transfer of metals in marine phytoplankton have been well-characterized, but fewer data are available regarding metal accumulation in marine bacterioplankton. Heterotrophic bacteria are ubiquitous and abundant in surface waters and can account for much of the particulate surface area in these waters. Particulate-reactive metals are therefore expected to associate appreciably with bacteria, which can then serve as an enriched source of metals for microbial loop food webs. We used gamma-emitting radioisotopes to experimentally determine the rate and extent of bacterial uptake of six metals (Mn, Fe, Zn, Cd, Cu, As) with varying chemical properties and biological uses. Six strains of gram negative bacteria showed little difference in uptake of any one metal, but there were significant inter-strainal differences. Steady-state was reached within 12 hours, at which time concentration factors ranged from 102 for Cs to 105 for As. Additionally, data on the trophic transfer of metals from bacteria to protozoa was presented, as well as the effect of viral lysis on the release of bacterial metal and its bioavailability to bacteria and phytoplankton.

COMBINING CTD-YOYO DATA WITH SEISMIC REFLECTIONS

Small scale ocean mixing processes like interleaving or internal waves are difficult to image by traditional oceanographic methods. With its much higher lateral resolution, reflection seismics is an important tool in the horizontal domain. The joint analysis of these datasets gives both, high temporal and spatial resolution, and can account for much of the particulate surface area in these waters. Particle-reactive metals are therefore expected to associate appreciably with bacteria, which can then serve as an enriched source of metals for microbial loop food webs. We used gamma-emitting radioisotopes to experimentally determine the rate and extent of bacterial uptake of six metals (Mn, Fe, Zn, Cu, As, Cd) with varying chemical properties and biological uses. Six strains of gram negative bacteria showed little difference in uptake of any one metal, but there were significant inter-strainal differences. Steady-state was reached within 12 hours, at which time concentration factors ranged from 102 for Cs to 105 for As. Additionally, data on the trophic transfer of metals from bacteria to protozoa was presented, as well as the effect of viral lysis on the release of bacterial metal and its bioavailability to bacteria and phytoplankton.

THE COUPLED DUST AEROSOL (AOT) AND SURFACE PHOTOPHYSIS ON THE REPRODUCTIVE PERFORMANCE OF MARINE MOLLUSCS

CARBOSCHOOLS – CARBOOCEAN AND CARBOEUROPE’S COMBINED INITIATIVE TO EDUCATE SECONDARY SCHOOL STUDENTS IN LATEST MARINE AND TERRESTRIAL CARBON CYCLE RESEARCH

The European educational initiative CarboSchools is based on interdisciplinary school projects and has been successfully connecting latest carbon cycle research and education over the last 2 years. The project has been driven by the two European Integrated Projects (IP) CARBOOCEAN and CarboEurope working on the generation of the missing scientific knowledge that is essential to a global quantitative risk/uncertainty judgment on the expected consequences of rising atmospheric CO2 concentrations. Both European Commission-funded IPs make their latest knowledge available to pupils via the interactive website http://www.carboschools.org and the implementation of individual school projects. The website acts as a multimedia portal and allows for downloading of science-based education material and teacher-participants’ methodology. The Norwegian CarboSchools project was recently successfully performed in Bergen with secondary school pupils on board of the RV Hans Brattstrøm. A short video was prepared to visualize how a marine school project could be realised. To order the dvd and further educational material, please visit http://www.carboschools.org

ADAPTIVE MANAGEMENT AND COMPREHENSIVE EVERGLADES RESTORATION PLAN: UTILIZING SHELFISH RESPONSES IN SETTING WATER QUALITY TARGETS IN SW FLORIDA ESTUARIES

Ecosystem restoration and management seek to repair or improve a suite of desired environmental conditions for a specific ecosystem. Oyster responses are being used as performance measure indicators of estuaries as part of the Comprehensive Everglades Restoration Plan (CERP). This study investigated the effects of seasonal changes in water quality, including freshwater inflows and salinities on oyster responses in the Caloosahatchee River, Florida. Significant relationship exists between freshwater inflows and salinities (R² 69 - 84%) at various locations in the estuary. Prevalence and intensity of Perkinsus marinus infection varied over the sampling period and decreased with increase in freshwater inflows and lower salinities. Condition index of oysters varied with the reproductive activity of oysters. Oysters appear to spawn continuously between May - October, a period that coincides with freshwater releases. Inflows between 500 and 3500 cubic feet per second would result in optimal salinities that would support and enhance oyster reefs in the Caloosahatchee estuary. Freshwater inflows should be minimized during the spawning months to facilitate the spat recruitment of oysters onto oyster reefs. Results are being used in setting freshwater inflows as part of the CERP

Fu, L. C., Jet Propulsion Laboratory, California Institute of Technology, Pasadena, USA, THE ROLE OF VORTICITY FLUXES IN THE DYNAMICS OF THE ZAPIOLA ANTICYCLONE

The Argentine Basin in the South Atlantic Ocean is one of the most energetic regions in the ocean with complicated dynamics, which plays an important role in the global climate. A number of observations have discovered an intense anticyclonic gyre of barotropic circulation around the Zapiola Rise in the center of the basin. Theoretical studies have shown that the Zapiola Anticyclone represents an eddy-driven flow controlled by bottom friction. Recent advances in high-resolution global-ocean data synthesis, performed using NASA supercomputing facilities, provide realistic simulations of the circulation and variability in the Argentine Basin. Using these simulations and satellite altimeter observations we analyzed the vorticity balance of the Zapiola Anticyclone. Our results suggest the dominance of the planetary vorticity flux in determining the inter-seasonal and inter-annual variability of the gyre, whereas the planetary pressure flux also plays a role in the intra-seasonal scale.

ON THE RELATIONSHIP BETWEEN SATELLITE-DERIVED AEROSOL OPTICAL THICKNESS AND CHLOROPHYLL IN THE MEDITERRANEAN SEA

The coupling between dust aerosols (AOT) and surface photopnthesis concentrations (MCHL) in the Mediterranean Sea, a LNRIC region, is examined at different time scales using SeaWiFS observations from 1998 to 2002. Seasonally, AOT and MCHL exhibit very different spatial patterns. AOT shows a meridional gradient with maximum values close to the dust sources and mainly during spring and summer, while MCHL exhibits a zonal gradient, with the western basin being more productive, especially during winter and spring. Weekly averages of MCHL and AOT are significantly correlated during the dusty season. However, this analysis cannot distinguish between real photopnthesis response and artifacts due to residual dust in the atmosphere or water. Daily progression of AOT and MCHL, for single dust events, and their temporal cross-correlation were examined. An increase in MCHL within two days was found after AOT events and most of the cross-correlations were significant at zero lag. Nonetheless, both positive and negative correlation was observed at lags 3-7 days indicating no compelling evidence that dust enhancement of photopnthesis growth is significant in the Mediterranean Sea.

IS THE ATLANTIC MULTIDEcadAL VARIABILITY EXCITED BY ATMOSPHERIC NOISE? RESULTS FROM AN ENSEMBLE OF COUPLED CLIMATE MODEL SIMULATIONS

In simple ocean-only models spontaneous multidecadal variability can appear. In these models, an oscillation appears because the large-scale equilibrium flow obtained under restoring conditions is unstable under prescribed heat flux conditions and an internal mode of variability grows on the equilibrium flow. The oscillation is characterized by temperature anomalies propagating westward across the basin in combination with variations of the strength of the meridional overturning circulation. In coupled ocean-atmosphere models, the oscillation is damped, and it has been suggested, that atmospheric noise is needed to excite the oscillation to amplitudes observed in reality. In this presentation we study the mechanism of the Atlantic Multidecadal Variability in a large ensemble (17 members) of simulations with a fully coupled climate general circulation model (ECHAM5/OMI). In particular, we compare with the mechanism found in simple ocean-only models. Furthermore, we study the relation between atmospheric noise (with the spatial/temporal statistical properties of the North Atlantic Oscillation) and the Atlantic Multidecadal Variability.

VELOCITY STRUCTURE OF PLUME EDDIES IN A ROTATING STRATIFIED ENVIRONMENT, WITH APPLICATIONS TO THE GREENLAND SEA

Turbulent plumes are found in many geophysical phenomena. They can be described by the turbulent plume model of Morton, Taylor and Turner (1956). As a negatively buoyant plume sinks, it entrains ambient water, and spreads laterally once it reaches its neutrally buoyant level. Once the effect of rotation is added to this, the lateral spreading is bounded by the Rossby deformation length and a so-called plume eddy forms. In this paper we present experiments examining quantitatively the horizontal velocity structure in such a plume eddy. The experiments undertaken follow those of Helgesson and Battisti (1991), using methods similar to those of Helgstrom and Armi (1988) to visualize the velocities. The goal of this work is to compare the experimental velocity structure to theories by Gill (1981) and Speer (1989), and to observe variations in submesoscale coherent vortices (SCVs) in the Greenland Sea. The Greenland Sea is known to be a site of deep water formation, and plumes that form under sea ice may be involved in deep convection and the formation of SCVs.

BLACK BAND DISEASE DYNAMICS: ASSESSING NUTRIENT IMPACTS AND MICROBIAL COMMUNITY VARIATION

Black band disease (BBD) is a pathogenic microbial assemblage that infects scleractinian corals worldwide. Despite over thirty years of BBD research, the microbial community composition of this disease and the environmental conditions that promote infection remain elusive. The research presented here specifically examines the potential role of nutrient concentration in BBD occurrence. Regression analyses indicated significant positive relationships between dissolved inorganic nitrogen and BBD prevalence in both the Florida Keys (FK) and Lee Stocking Island (LSI) Bahamian studies. This study is one of few to quantitatively address the potential difference in coral disease dynamics between human-impacted (FK) and relatively pristine (LSI) reef systems. In addition to investigation of the environmental drivers that affect BBD prevalence, this study utilized length heterogeneity profiles of the BBD microbial community. Multivariate ordination and nonparametric analyses of the LH-PCR profiles revealed significantly distinct BBD microbial communities sampled from different geographic regions of the Caribbean. The results of this study, in concert with the findings of previous and ongoing molecular analyses of BBD bacterial communities, attest to the intrinsic variability and complexity of this dynamic microbial assemblage.

A NEW TOOL TO MEASURE THE UPWELLING POLARIZED SPECTRAL RADIANCE DISTRIBUTION

We have developed a new instrument to measure the upwelling polarized spectral radiance distribution in the ocean. This instrument is based on combining 3 of our NuRADS instruments.
instruments into one package, with a linear polarizer inserted into each instrument. The images of the separate systems are obtained synchronously and can be combined to obtain the linear polarization state of the light field. The calibration/characterization procedures are more difficult than for a radiance system, but the polarization can be determined to within +0.05 in normalized Stokes vector units. This instrument has been used on several cruises, and we will present data from a clear water station off Hawaii. The measurements show that the upwelling light field is highly polarized in this clear water, with the degree of linear polarization exceeding 50% in some directions.

NITROGEN FIXATION RATES AND HETEROZOOSPIRATORY ACTIVITY UNDER HIGH PCO2 IN FREE DRIFTING MESOSOMES IN THE BALTIC SEA

In July 2007 six free floating mesocosms with ~60m3 of volume were deployed in the southern Baltic Proper for two weeks. pcO2 levels in the mesocosms were adjusted 3 times (after exchange of water) to yield concentrations between 312 µatm (ambient) and 1600 µatm. The response of nitrogen fixing species was measured and heterotrophic activity calculated based on the uptake of radiolabeled thymidine. There was no consistent response in nitrogen fixation rates. Only in the size fraction <10 µm N fixation rate decreased with increasing pcO2. A daily cycle of N fixation rates was only visible in the fully mesocosm with ambient pcO2, and, which also had highest N-fixation rates of up to 1.4 nmol N/L/h, suggesting that seawater acidification and mixing adversely affected the diazotrophic cyanobacterial community. A sharp decrease within the first 24 hours after acidification was also occurred with regard to cell specific bacterial biomass production but, in contrast to N fixation, showed higher activity with increasing CO2 concentration during the rest of the experiment. Our results indicate a potential decoupling of primary and secondary production under increasing CO2 concentrations.

PHYSICAL CONTROLS ON BENTHIC EXCHANGES ON THE MID-SHELF OF THE SOUTH ATLANTIC BIGHT: RIPPLE EVOLUTION AND TURBULENCE MEASUREMENTS

Data on nearbed sediment mobility, bedform evolution and water column turbulence are presented from a Benthic Observatory and Technology Testbed (BOTTOMS-UP) operating on a medium sand bed on the Mid-Shelf of the South Atlantic Bight. The project examines benthic exchanges and ripple dimensions to identify their role in the advection processes of porewater transport and particulate exchange rates. In addition to wave-induced orbital velocities, strong tides (up to 15 cm/s) and wind-driven circulation contribute to near-bed stress levels. Initial results from a 5-beam VADCP during storm events are used to evaluate the importance of tidal modulation in determining maximum near-bed velocities. The ripple geometry data is compared with recently developed time-dependent ripple evolution models and the role of turbulence due to mean flows is presented as a factor for ripple height diffusion. Full-depth Langmuir cells develop during strong wind/wave forcing, evidenced by clouds of strong backscatter, highly correlated with vertical velocity, originating from both surface and bottom boundaries. Their effect on near-bottom suspension events and benthic exchanges is also considered.

THE IMPACT OF LARGE FRESHWATER DISCHARGE EVENTS ON THE DELAWARE ESTUARY

The Delaware Estuary, a well-mixed coastal plain basin in the mid-Atlantic region of the US, has a large watershed within Delaware, Pennsylvania, New Jersey and New York states, and primary freshwater inputs supplied by the Delaware and Schuylkill rivers. Typically, strong tidal forcing creates a well-mixed water column and a fairly predictable salinity gradient, which controls the physical and chemical properties of the estuary. During large storms, freshwater discharge overcomes the tidal forcing effect, redistributes the salinity gradient further downstream, and alters the estuarine biogeochemistry. In attempt to evaluate the watershed influence, we examine long-term databases for large discharge events, which have become more frequent since 1999. Occasional large storm discharge events may introduce large watersheds, DOM, and suspended sediment concentrations to USGS gauging stations along the Delaware Estuary's main tributaries. Large storm events indicate that the watershed can cause changes in the estuarine biogeochemistry.

THE MOVING WATER QUANDARY

A spectral content of the internal waves is a fundamental measure that can be made from seismic images of water structure. However, this is not as robust as it may first appear. An underlying assumption in the seismic method is the reflection boundary is fixed in space. This is not true for boundaries in water. These are dynamic and the larger-amplitude lower-frequency internal waves, which are the easiest to map, are those moving with the fastest velocity; which may be on the order of a meter per second. This speed is significant when compared to the velocity of the seismic acquisition vessel. We observe asymmetry in apparent structure on data acquired as part of the EU funded G0 data. Also, deceleration velocity analysis reveals a more complex stacking velocity field than expected. We demonstrate that both these effects can be predicted using simple models and, when appropriate corrections are applied, how the correct images can be obtained.

ANALYSIS OF MONOSACCHARIDE COMPOSITION OF CARBOHYDRATE IN SEA WATER USING METHANOLOGY METHOD

Monosaccharide composition of carbohydrates provides various clues such as origin and diagenetic state and organic matter in seawater. It is essential that we reconstruct the carbon cycle of the oceans. Methanolysis reaction was used as a standard procedure of depolymerization since several decades ago, but the hydrolysis is only applicable to neutral sugar because other carbohydrate species such as uronic acid (UR) are unstable under hydrolysis procedures. Here, we develop methodology, which can be applicable to the measurement of the concentration of UR because UR is relatively stable under methanolysis processes. Methanolysis reaction was completed using HCl/Methanol solution. The liberated monosaccharides were converted into trimethylsilyl derivatives, and were analyzed by gas chromatography-mass spectrometry. Seawaters were collected at Sato-Nada in Japan, and particulate organic matter was obtained by filtration. Total particulate carbohydrate (T-PCHOs) concentrations ranged 25-90 µg C/L, accounting for 10-17% of particulate organic carbon (170-310 µg C/L). The T-PCHO concentrations were 3.3–8.7% of T-PCHO. The vertical profile showed that the proportion of the UR in T-PCHO tends to increase with depth.

STRUCTURAL CONTROL ON CONTINENTAL SHELF SEDIMENT DYNAMICS, NORTH ISLAND, NEW ZEALAND

Over 850km of Edgetech chirp sub-bottom profiles were analyzed in order to investigate regional structural control on stratigraphy-forming processes operating along the gently (<0.7%) sloping Waiapu continental shelf. Shelf stratigraphy is dominated by a reflection surface, identified as Miocene-age sedimentary rock, which is exposed on the seafloor in the eastern portion of the shelf and dips down towards the south. The outer shelf is heavily faulted and folded, creating a structural low on the continental shelf. Seismic interpretation indicates that sediments are thickest on the central and southern continental shelf, and more laminated in the southern continental shelf, indicating preferential deposition in these structural lows. This suggests that in the geologic past the primary direction of sediment transport and preservation was not simply offshore but was structurally steered towards the south. These observations are consistent with recent findings indicating that modern flood deposits are primarily transported and preserved on the southern Waiapu continental shelf. These data further suggest that current sediment transport models should include the effects of bathymetry on sediment dynamics even on gently sloping continental shelves.

BATHYMETRIC INFLUENCES OF THE EMPEROR SEAMOUNTS UPON THE NORTH PACIFIC SUBARCTIC CYRE BOUNDARY CURRENT ALONG THE EASTERN SIDE OF THE EMPEROR SEAMOUNTS

To make bathymetric influences of the Emperor Seamounts upon the North Pacific subarctic gyre, numerical experiments were performed using two-layer model with an idealized eddy and ridge. Seasonally varying interior Sverdrup transport to the east of the ridge partly returns along the eastern side of the ridge as a western boundary current. A ratio of the boundary transport to the interior transport depends on a ridge height (HM) and stratification (N). For smaller HM, the ratio increases with HM, but it changes little with N. For larger HM, the ratio decreases with N but is independent of HM. Spatial distribution of geostrophic contours is a key to understanding the dependency of the ratio on HM and N. For smaller HM, the ratio almost coincides with a ratio of the number of closing geostrophic contours to one of all geostrophic contours. For larger HM at which all geostrophic contours in the eastern region cannot cross over the ridge, bottom pressure decreases with N to allow more transport across the ridge.

of internal waves. Rhodamine WT was injected in a streak perpendicular to the axis of the dominant wind. The dye cloud was mapped daily for three days, and temperature microstructure profile were measured concurrently. Throughout the experiment, wind forcing and the internal wave field were measured by a lake station. We relate the behavior of the dye cloud to the forcing and evaluate two mechanisms for generating intrusions: bottom turbulence caused by seiche currents and mixing caused by breaking internal waves.

THE WEST SPITSBERGEN CURRENT: STRUCTURE AND VARIABILITY
Based mainly on synoptic observations conducted by the Institute of Oceanology Polish Academy of Sciences in the area of the West Spitsbergen Current (WSC) and Fram Strait, the Atlantic Water (AW) properties, heat and salt transports and its surface heat variability are presented and analyzed. The AW northward flow structure, dynamics and warm signal propagation by the WSC are discussed. Dependence of the WSC hydrology on the upstream conditions as exchanges through the Iceland-Svalbard Ridge and Norwegian Atlantic Current fluctuations are considered. Two sources of the warm water observed since 2003 has been recognized: core of the WSC flowing along the Barrents Sea and Spitsbergen shelf-break as prolongation of the barotropic Norwegian Atlantic Slope Current and the baroclinic western branch. The WSC western branch being extension of the Norwegian Atlantic Current outer branch continues over the submarine ridges. This flow has been neglected for the long time and only recently its importance has been recognized. Role of the western branch for the WSC warming and AW northward transport is discussed.

EFFECTS OF INFAUNA ON PERMEABLE SEDIMENT CHEMISTRY AND TRANSPORT PROCESSES: MULTIPLE SITE AND SPECIES COMPARISONS
Significant changes to permeable sediment biogeochemistry due to complex interactions among bioturbating infauna and porewater advection are increasingly evident. Dynamic physical properties and methodological limitations have inhibited in-situ studies of infauna in permeable sediments. An important research goal is to evaluate the nature, extent and species-specificity of these effects within realistic porewater advection regimes. We present findings from field studies of several different intertidal flats, inhabited by five taxonomic different infauna. We determine the solution and sedimentary properties, bulk sediment granulometry, and density of infauna within experimental plots. Different infaunal species exert significantly different effects on porewater transport and sediment biogeochemistry, which appear to be related to feeding strategies and burrow characteristics. Deep burrowing deposit feeders increased porewater advection, while effects of surface deposit feeders appeared to depend more on the burrow type. Strikingly, within site effects of infauna are independent of sediment properties, while across-site infaunal effects may be dependent on site characteristics. Although we lacked the same dominant species among sites, our results provide evidence of functionally specific effects of infauna on permeable sediments in a range of diagenetically important environments.

NEW TOOLS FOR SATellite SURVEILLANCE OF RAPIDLY MOVING CYCLOONES ALONG THE MARGIN OF THE LOOP CURRENT: GULF OF MEXICO
This paper presents an improved method to track cyclonic mesoscale eddies along the outer margin of the Loop Current (LC). Recent research has shown the critical role that these features play in the intensification of surface currents, as trigger mechanisms for deep flows and LC eddy shedding, and for hurricane intensity changes. The rapid motion of these features (35 km/day) makes their study problematic. We discuss new advances in the integration of data from several remote sensing systems to track the motion of LC frontal eddies in real-time and in hind-cast mode. Mid-infrared (35-39 micron) measurements from GOES GVAR, available every 15 minutes over the Gulf, provide an excellent source of de-clouded night-time surface temperature information. Measurements in this atmospheric window maximize ocean information in cloudy and humid regions such as the Gulf. On the other hand, satellite altimetry measurements provide the only remote sensing technique that directly measures a dynamical variable of ocean state - the surface height. Detection of mesoscale eddies has been improved by combining multi-mission measurements from TOPEX-Poseidon, ERS-2, GFO, Jason-1 and Envisat into a gridded product, updated daily. Ocean color sensors (MODIS, OCM) provide surface pigment information that can aid in the discrimination of eddies as well as the detection of hurricane-induced upwelling and associated near surface bio-geochemical changes.
exert many harmful effects on sealife and cause severe respiratory symptoms in humans.

LONG TERM TREND OF TEMPERATURE IN THE CHINA SEAS AND THE 
KUROSHIO REGION IN THE PAST 40 YEARS
Global warming is known as a remarkable phenomenon of the atmosphere-ocean system, 
which has been studied through global and basin scales intensively. However, long term vari-
ability of temperature in continental margins, including the Yellow Sea (YS) and the East 
China Sea (ECS), has been rarely studied and poorly understood. To fill this gap, long term 
data from 1957 to 2001, long term trend of temperature in the YS and ECS and their 
relationships with variations in the Kuroshio region are studied. Trends of warming and 
cooling are both observed in the study waters with complicated spatial patterns. In summer, 
sea surface temperature (SST) showed warming tendency in the northern YS and most part 
of the ECS including the Kuroshio and Taiwan Warm Current (TWC) regions, while cool-
tendency in the south YS and north edge of the ECS. In winter, temperature in most part 
of the YS and the ECS warmed up. The two warming centers correspond to the re-
regions of the TWC and the Yellow Sea Warm Current (YSWC), respectively. As the origin 
of the TWC and YSWC, the Kuroshio area warmed with smaller amplitude.

TOWARD A MERCURY MASS BALANCE MODEL IN THE ARCTIC OCEAN: WHAT 
CAUSED THE MERCURY CONTAMINATION IN BEAUFORT SEA BELUGA WHALES?
One of the major findings regarding the global mercury (Hg) pollution is the highly elevat-
ed Hg levels in beluga whales from the Beaufort Sea of the Arctic Ocean. The Hg levels in 
Beaufort belugas were on average 10-fold higher than during the 15th to 17th centuries. 
Long-term concentrations of this persistent bioaccumulative Hg have further tripled from the early 
1950s to the mid-1990s. The atmospheric Hg deposition, including the tropospheric mercury depletion 
events (MDEs), alone seems insufficient to explain such high Hg burdens and large varia-
tions. As part of the ArcticNet program, extensive studies have been carried out to probe 
the causes of Hg contamination in the Beaufort Sea beluga whales, Mercury and methylmer-
cury (MeHg) concentration, speciation and flux from a variety of possible Hg sources 
and sinks were studied or estimated. These included the atmospheric deposition, rivers, 
coastal erosions, oceanic circulation, sea ice loss, and sedimentation. Further studies were 
conducted on the habitats and feeding patterns of beluga whales and the food web struc-
tures. The results allowed us to construct the first mass balance model of Hg in the Arctic 
Ocean. The Hg is found to be in a quasi-steady state in the Arctic Ocean, and only a very 
small fraction of the Hg in MeHg is accumulated in biological systems. The rapid Hg 
bioaccumulation observed in marine mammals in recent years is thus unlikely purely mass 
driven. Alternative processes such as biotic and climatic drivers are proposed.

IMPLICATIONS OF MICROBIAL COMMUNITIES ASSOCIATED WITH ALIEN 
MARINE SPONGES FOR HAWAII REEF ECOSYSTEMS AND HUMAN HEALTH
The coral reef ecosystems of the Hawaiian Islands are sensitive to alien marine species 
because of their isolated nature. Alien sponges alone constitute nearly one-third of intro-
duced marine species in Hawaii. These alien sponges harbor microbial pathogens and 
other diverse microbes and represent a great source of bioactive natural compounds; some 
of these sponges have become invasive. Consequently, alien sponges and their micro-
bial symbionts have significant implications for the reef ecosystems and human health. 
Mycal armata and Suberites zeteki are two of the most abundant alien sponges in Hawaii.
Using cultivation-dependent and molecular approaches, we have isolated and identified hundreds of fungi and bacteria from these two sponges. Both of these species harbor microbial pathogens with the origins of human, animals, and plants. Phylogenetic analysis revealed their unique microbial signatures, which may contribute to the invisiveness of M. aramta. Bioactivity assays indicated that some microbial strains derived from these two sponges produce interesting biological activities. In this talk, we focus on phylogenetic diversity and biomolecular potential of microbes isolated from these two sponges. In addition, we will discuss the potential impact of the invasive sponge M. aramta and the implications of sponge-symbionts on the reef ecosystems and human health.

INFLUENCE OF PHYTOPLANKTON COMMUNITY STRUCTURE ON PHOTOSYNTHETIC PHYSIOLOGY AND BIO-OPTICS IN SOUTHERN CALIFORNIA CURRENT ECOSYSTEM

Biophysics and physiology dynamics of pelagic photosynthesis were investigated during two process research cruises of California Current Ecosystem (CCE)-LTER projects in 2005 and 2006. Coastal and offshore waters of CCE have very different phytoplankton community structure and environmental forcing of photosynthetic physiology. Diatom dominate in coastal high chlorophyll area, while in oligotrophic offshore waters the community is mainly composed of much smaller phytoplankton such as Prochlorococcus, cyanobacteria Synechococcus and Phaeocystis. Results from photosynthesis-irradiance (P-E) experiments indicated that coastal waters tend to have higher light-saturation parameter (Ek), light-saturation value of chl-a specific rate of photosynthesis (Pmax), but relatively higher quantum yield (Fmax); as the contrast, offshore waters show the opposite trends. Modeling of ocean photosynthesis need to account for how community structure and acclimation to light condition by the light-saturation temperature matrix regulate the parameters of photosynthesis used in the models. Our goal as part of CCE-LTER is to be improve the knowledge of both community structure and environmental acclimation of phytoplankton to improve models of plankton ecosystems.

A COMPARATIVE STUDY OF CHESAPEAKE BAY’S RESPONSE TO THE HURRICANE ISABEL AND FLOYD

Hurricane Floyd swept through the mouth of the Chesapeake Bay on September 16, 1999 as a category 1 storm moving northeastward along the coast of the mid-Atlantic. Hurricane Isabel, on the other hand, made landfall on September 18, 2003 near Outer Banks of North Carolina as a category 2 storm moving west-northwestward inland. The two hurricanes differed in many aspects, including their magnitudes, storm paths, and accumulated precipitation. Hurricane Floyd passed through the eastern side of the Bay generating northerly wind and created a setup the in upper Bay. In contrast, Hurricane Isabel passed through the western side of the Bay generating a persistent southerly wind that gave rise to a second component of surge in addition to the initial surge coming from the continental shelf. As a result, it induced an unexpected large setup in the upper Bay. Another difference is the amount of precipitations. A band of 12-16 inch rainfall fell directly onto the Bay proper over 24 hour period during Hurricane Floyd, whereas only 3-5 inch of rain fell directly onto the Bay during Hurricane Isabel, resulted in a significant difference of the buoyancy influx and subsequent response of the Bay. A three-dimensional unstructured grid model (FE) was used for the simulation. The model results compare favorably with observation data and elucidate the barotropic and baroclinic responses of a large estuary to hurricane forcing.

ARCTIC OSCILLATION AND DIPOLE ANOMALY AND THEIR CONTRIBUTION TO SEA ICE EXPORT FROM THE ARCTIC IN THE 20TH CENTURY: OBSERVATION AND MODELING

The winter Arctic Oscillation (AO) and Dipole Anomaly (DA) in the Arctic atmosphere and their contribution to sea ice export are investigated by using both the NCEP reanalysis and a high-resolution coupled general circulation model. The spatial patterns of the first two leading EOF modes of winter mean sea level pressure and geopotential height at 500 hPa north of 70oN obtained by the long-term simulation (1900-2010) are highly similar in the high resolution run (H) and the coarse resolution run (L), the coastal upwelling is much stronger in H than in L and the warm biases are partially removed in H. It indicates that the coastal SST and upwelling rate are mainly determined by the coastal wave dynamics and cannot be explained by Ekm dynamics. An idealized ocean-gene circulation model (OGCM) is also used to further demonstrate that it is true for the idealized setting as well as for the fully coupled regional model of the tropical Atlantic. Since the coastal upwelling is one of the major biases in coupled GCMS, and the primary production of ecosystems is largest in coastal upwelling regions, the next generation of GCMS must either parameterize or resolve the coastal undercurrents and associated Kelvin waves.

ASSESSING WETLANDS RESTORATION IMPACTS ON NEARSHORE SALINITIES IN BISCAYNE BAY, FLORIDA

To evaluate the impacts of planned restoration and compare alternative restoration measures, we have adapted a previously developed salinity model of Biscayne Bay to focus more explicitly on the nearshore region downstream of the coastal wetlands targeted for restoration. Historic forcing from wind, tides, and observed canal-discharges are imposed on the one-layer 2D hydrodynamic finite element model for the period 1996 to 2005 to quantify the model performance as a measure of validation. Salinity data from a number of monitoring efforts over the past 10 years are analyzed in conjunction with model hindcasts. The nearshore brackish zone is on the order of 500 m wide due to the relatively small quantities of freshwater runoff interacting with the 0.5m tides in the very shallow water less than 1 m deep. To refocus on this nearshore region, the horizontal resolution in the area is increased in two phases. Various scenarios for the spatial and temporal redistribution of freshwater flows, including those of the State of Florida’s Acceler8 program and the federal Comprehensive Everglades Restoration Plan, were used to drive the model.

EROSIONAL AND DEPOSITIONAL CHARACTERISTICS OF REGIONAL OVERWASH DEPOSITS CAUSED BY HURRICANES IVAN AND DENNIS ALONG SANTA ROSA ISLAND, FLORIDA

Regional-scale washover deposits along the Santa Rosa Island induced by hurricane Ivan in 2004 and hurricane Dennis in 2005 were studied through coring, trenching, GPR (Ground Penetrating Radar) imaging, aerial photography, and pre- and post-storm beach profile surveys. Erosional and depositional characteristics in different barrier-island environments, including dune field, interior wetland, and back-barrier bay, are examined. Over the eroded dune fields, the washover deposits are characterized by an extensive horizontal basal erosional surface, truncating the old dune deposits, and horizontal to slightly landward dipping bed. Over the marsh wetlands in the barrier-island interior, the washover deposits are characterized by steep tabular bedding, with no erosion at the bottom. The homogeneity of sediment along the northern Florida coast makes distinguishing between washover deposits from Ivan (2004) and Dennis (2005) difficult. The aerial extents of washover deposits are controlled by both the storm intensity and the pre-storm morphological characteristics.

AN ISOTOPIC EXCHANGE METHOD FOR MEASURING PHOTOPRODUCTION OF CO2 FROM DISSOLVED ORGANIC MATTER IN SEAWATER

Accurate measurements of CO2 photoproduction from colored dissolved organic matter (CDOM) in oceans are important for understanding carbon cycling and budgets. A new 14C exchange method could provide an independent comparison to the standard ‘pool depletion’ method. When measuring small increases of CO2, ambient dissolved inorganic carbon (DIC)
concentrations pose problems of high background. This is reduced by replacing DIC carbon with 14C by flowing a 13CO2 (600 ppm) gas mixture over the samples. The production of CO2 can be calculated by the change in the 13C/12C ratio before and after photoreactions, measured with isotope ratio mass spectrometry. Procedures that may alter the chemical properties of CDOM - adjusting sample pH and stripping of CO2 - are thus avoided. Instrument sensitivity is adequate for small (3-4 nl) samples. The isotope shifts for 13CO2 are more than 37 parts per thousand for coastal water samples irradiated for less than two days, with a precision of 5.4 pmol or better. Hence, measuring blue-water samples may be possible. Results of the two methods are compared for a coastal water sample.

EKMAN WAVE AND THE WIND ENERGY PATHWAY INTO THE SUBSURFACE OCEAN

Motions in the Ekman layer, including the case with time-dependent wind, have been traditionally assumed to originate from the Ekman spiral. However, such motions can also be interpreted as waves because they can be cast in the standard forms of wave. The concept of Ekman wave is illustrated by using two long-term mooring observations. Ekman wave propagates vertically downward to the subsurface ocean with amplitude decreasing exponentially with depth. The characters of Ekman wave, including the dispersion relation and the group velocity, are examined in this study. Since the group velocity can represent the transfer speed of the energy, energy flux from the wind to any depth of the ocean can be estimated. Energy flux at the sea surface obtained from the framework of Ekman wave is the same as that discussed in classical literatures, i.e., it is the total production of the wind stress vector and the surface Ekman flow velocity. Applying the Ekman wave method to the global ocean and assimilating the WP wind stress dataset, the total energy flux from the wind to the Ekman layer is estimated as 2.76 TW, in which 0.21 TW is within the near inertial range. Using the Levitus monthly mean mixed layer data, the total energy flux penetrating the base of the mixed layer is estimated at 0.74 TW, in which 0.13 TW is within the near inertial range, and they are less sensitive to the choice of the eddy diffusivity.

MODELING AND PREDICTING TIDES IN MONTEREY BAY, CALIFORNIA

During August 2006, a tide-permitting, real-time data assimilation and forecasting system configured from the Regional Ocean Modeling System (ROMS) was used to support several field experiments at Monterey Bay, California. The system is forced by atmospheric forcing fields and eight-daily wind stress fields at its open boundaries. Besides the three-dimensional temperature, salinity and current fields, the system also provided real-time tidal predictions, such as the depth-integrated baroclinic tidal energy and energy flux. The tidal predictions indicate that the northern flank of the Sur Platform south of Monterey Bay is associated with large baroclinic tidal energy and northward energy flux. The semidiurnal baroclinic tidal energy at the site changes by a factor of 3 during the semi-diurnal tidal cycle. The study summarized the experimental prediction practice for August 2006 and compares tidal prediction with high spatial survey data from SeaSoar, high resolution oceanogra

INTERACTIONS BETWEEN LARVAL DEEPWATER SCULPIN AND THE VERNAL COASTAL WARMINING IN LAKE MICHIGAN

In Lake Michigan the deepwater sculpin, a benthic glacial relict species restricted to depths greater than about 70 m, has epipelagic larvae that emerge during the spring warm-up. Warm-up in the four deep Great Lakes proceeds in a way that initially generates a coastal thermal bar of 5°C, with colder isothermal water offshore, and warmer coastal water. During the thermal bar period we found statistically more larval deepwater sculpin shoaled offshore of the thermal bar than shoaled offshore of the thermal bar. The shoreward station bottom depths were much shallower than where the adults are found. Larval deepwater sculpin shoaled offshore of the thermal bar were also larger than those offshore. The post-barmal bar fate of these coastal larval deepwater sculpins is uncertain, but work on larval fishes that emerge later in the season suggests offshore transport. Because the larvae that are inside of the thermal bar may have originated farther offshore, it may be that the most successful larvae are those that serendipitously end up near the coast. Their success will depend on later offshore transport, however.

ON THE HORIZONTAL AND VERTICAL STRUCTURE OF TURBULENCE

Vertical and horizontal structure of turbulence can be obtained by using micro and fine-scale sensors on a AUV. We will illustrate this from data obtained on the T-REMUS vehicle in a shallow region of Monterey Bay at nighttime on 2006 as part of the LOCO experiment. Eight hours of data are collected over a repeated cross isobath track runs of 2.5 kilometers. The vehicle was operated at a ground speed of 1.2 m/s at a 5 degree yo-yo mode. This allowed turbulent dissipation rate to be estimated on vertical scales of 30 meters and over horizontal scales of 150 meters. The most intense turbulence occurs near boundaries, surface and bottom, with characteristic horizontal scales of order 500-1000 meters. However patches of strong turbulence also occurred within the pycnocline. The two dominant larger scales features observed during the experiment were the intrusion of a warm water plume and the occurrence of internal solitary waves. We will examine the relationship of these features to the spatial structure of the turbulent field.
The monitoring of recreational waters is important to gauge potential risks to human health. In this study, water and sand samples taken from beach sites innants may be polluting beaches. In this study, water and sand samples taken from beach sites...
processes that influence residence time. The residence time is particularly sensitive to the exchange between the Hudson River and New York Harbor, a complex junction of tidal channels. Regions like this can represent a difficult challenge for structured grid models because adequate resolution in all channels would typically require a high percentage of grid points over land resulting in computational inefficiency. To create the numerical grid of this complex system we developed a novel technique called composite grids that allow multiple structured grids to be combined and solved simultaneously. We employ the technique with the ROMS model and demonstrate how this capability permits an unlimited number of grids to be connected together to allow more accurate resolution in regions with complex interconnected embayments and channels. This method provides a sound technique to more accurately model the residence time in the Hudson River Estuary.

A NUMERICAL INVESTIGATION OF FORM DRAG INDUCED BY STRATIFIED TIDAL FLOW OVER ROUGH TOPOGRAPHY WITHIN AN ESTUARY

Form drag is a force felt by a fluid as it flows over an object and experiences an adverse pressure gradient. In a stratified estuary, form drag works to convert barotropic tidal energy to baroclinic features such as internal waves and eddies, and to directly dissipate energy. A numerical experiment was performed to investigate the form drag as stratified water flowed over idealized topography similar to that found at Three Tree Point in Puget Sound, WA, where observations of form drag have previously been conducted (Edwards et al. 2004, IPO). The flow was tidally forced through an area 5 km wide, 200 m deep channel with sloping side-walls and a Gaussian-shaped headland on one side-wall. The width and length of the channel was designed to mimic the scale of the side-walls of the tidal excursion, and the tidal excursion distance were all varied to see how they affected the total form drag. These topographic and flow features were reduced to drag coefficients that can be used in larger scale models to more accurately parameterize mixing and dissipation of fluctuating flow over topography.

PARAMETER RANGES ENCOUNTERED IN SOUTH CHINA SEA SOLITARY WAVE PREDICTIONS

The Apel parameters that describe the presence of solitary waves are calculated in the South China Sea for the period of April and May 2001. Solutions are constructed for a range of Apel model parameters. The background for the calculations is obtained from 3D hydrostatic NCOM model predictions with tides. NCOM predicts internal bore locations that correspond to the solitary wave train locations. Predictions with the fully nonlinear nonhydrostatic 2D Lam model are undertaken along selected tracks. The predictions involve the generation of solitary waves in the Luzon Strait and their propagation towards the ASIAEX experimental site. The parameters ranges of Apel and Lam models are compared to observed solitary wave structure in the South China Sea (SAR, ASIAX, and WISE observations). The flow was tidally forced through a 5 km wide, 200 m deep channel with sloping side-walls and a Gaussian-shaped headland on one side-wall. The width and length of the channel was designed to mimic the scale of the side-walls of the tidal excursion, and the tidal excursion distance were all varied to see how they affected the total form drag. These topographic and flow features were reduced to drag coefficients that can be used in larger scale models to more accurately parameterize mixing and dissipation of fluctuating flow over topography.

THE PROPAGATING RESPONSE OF INNER SHELF CIRCULATION TO WIND RELAXATIONS IN A COASTAL UPWELLING SYSTEM

Following relaxation of upwelling winds along the west coast of North America, coastal currents quickly shift from equatorward to poleward. Using an array of moorings, surface current observations from high frequency (HF) radar and satellite imagery, we examined the response of inner shelf circulation along central California to wind relaxations. Relaxations occur most frequently in late summer and least frequently in winter. A conspicuous response of the inner shelf circulation is the propagation of warm water poleward along the coast. Propagation speeds of the nose of warm water are linearly related to temperature differences, consistent with buoyancy forcing as described by Lentz and Helfrich (2002). As the nose propagates offshore, warm water warming leads to the formation of hyper-saline water flows offshore below. The alongshore flow after passage of the nose is weak. HF radar-derived current patterns show that the propagating events are disturbed by sub-mesoscale flow features such as small eddies. We speculate that these events are important in the settlement of some invertebrate species along the central California coast.

PACIFIC WATER TRANSPORT IN THE ARCTIC OCEAN SIMULATED BY AN EDDY-RESOLVING COUPLED SEA ICE-OCEAN MODEL

The Pacific water transport from the Chukchi Shelf to the southern Canada Basin is investigated by using an eddy-resolving coupled sea ice-ocean model. The simulation results show that the inflow of the Pacific water into the Canada Basin depends on sea ice condition during summer. When sea ice margin is located in the basin, eddies are vigorously generated by instability of the Barrow Canyon jet and promote the Pacific water transport into the basin. On the other hand, when sea ice remains in the shelf even in late summer, the sea ice–ocean stress and the surface heat loss play a great role in braking the jet. In that case, the eddy generation and the Pacific water inflow are suppressed. In addition, these results also indicate that the sea ice growth in winter is delayed in the southern Canada Basin when the Pacific water gains enough heat in the Chukchi Shelf.

IMPACTS OF LOWERED PH ON FLOCCULATION OF MARINE SUSPENDED DEBRIS

Sinking debris or marine snow is thought to be food source for herbivorous or omnivorous zooplankton in the ocean and the sinking flux determine the character...
istics of deep sea ecosystem. Smaller marine particles aggregate or flocculate each other and form gradually larger marine aggregate. The sinking speed of marine aggregate is influenced by the size. The change of sinking flux from upper layer will affects the food availability for the organisms inhabited in deeper layer in the ocean. And moreover marine aggregates have higher concentration of organic matter than the ambient water, they provide a suitable habitat for the microorganisms such as bacteria or heterotrophic nanoflagellates. This study investigated the flocculation ability of marine debris exposed by lowered pH controlled with elevated CO$_2$ or HCl. Marine debris, which were collected from near the sea bottom (100 m depth) in Toyama bay and from 1000 m depth in the western north Pacific, were stirred in seawater with various pH (6.0 - 8.0). The larger aggregates were formed in normal pH but lowered pH inhibited the flocculation of marine debris. As the reduction of the aggregate size is thought to change the sinking speed, the available amount of food source for planktonic organisms will affected, and the microhabitat of the microorganisms depend on the marine aggregates will decrease.

SPATIAL STRUCTURE OF TIDAL AND RESIDUAL FLOWS AT A TIDAL INLET

Located on the northeastern coast of Florida, Ponce Inlet is a shallow, short estuary with depths between 2m in the shallows up to 10m in the thalweg. Current speeds, surface and profiling measurements of conductivity, temperature and depth were collected over a semi-diurnal tidal cycle on September 5, 2007. The mean flow in this estuary agrees with the flow structure of tidally dominated residual flow: inflow in the deeper channel and outflow through the shallower shoals. However, lateral gradients in density with values close to 0.01 kg/m$^3$ observed during ebb but become negligible during flood. The importance of the forcing caused by the ebb-tide density gradient relative to tidal influence and bathymetric effects are assessed.

ACCURATE MONITORING OF THE NORTH ATLANTIC AIR-SEA CO2 FLUX FROM A NETWORK OF VOLUNTARY OBSERVING SHIPS

Since the start of 2005 under the EU’s Carbo-Ocean project, we have participated in co-ordinated observations of sea surface pCO2 and related variables from a network of commercial vessels in the North Atlantic. Typically five vessels are operating at any one time. The observations will be used to reconstruct the sea-surface pCO2 field, and hence estimate air-sea fluxes, with unprecedented resolution and accuracy. Using the observations for the calendar year 2005, we use a variety of geostatistical methods to derive the precision with which regional fluxes can be obtained. The observations are generalized to the entire North Atlantic from 10N to 65N by exploiting relations between surface pCO2, SST and mixed layer depth. Using semi-varograms or an empirical technique of selective data deletion applied to the residuals, we obtain a 1-sigma uncertainty of 6% on the annual flux into the region as a whole. This is very much more precise than has been possible for any comparable region of the world (land or ocean) up to now.

SOLVING THE IMPACT OF EL NINO ON THE GENE FLOW OF MARINE SPECIES IN THE SOUTHERN CALIFORNIA BIGHT

The signal of population connectivity can be seen in the genetic structure of populations, thus genetic markers are tools of choice to infer patterns of connectivity. In an effort to understand the relationship between patterns of circulation, larval dispersal and genetics we have developed a spatially-realized model of gene flow for nearshore sedentary species in the Southern California Bight. The model combines coastal circulation simulations of larval dispersal with a single demographic model, allowing us to specify life history traits (e.g. pelagic larval duration) and alter flow regimes (i.e. simulate El Nino and non El Nino conditions). The results produced by the model provide common metrics of population connectivity (e.g., isolation by distance and input for software like STRUCTURE) that can be used in direct comparison with empirical studies. Using this model we have simulated the impact of climatic changes on the genetic connections for the whelk Kelletia kelletii and have compared results to empirical data.

STIRRING IN THE GLOBAL OCEAN

Global variations in lateral stirring in the surface ocean are examined by calculating finite-time Lyapunov exponents (FTLEs) from surface geostrophic currents derived from satellite-altimeter measurements. These show that stirring in the surface ocean is highly non-uniform, and vary on a wide range of scales. The probability distribution functions (PDFs) of the FTLEs are broad, asymmetric, and have long high-stretch tails. The mean FTLEs and widths of the PDFs vary with the level of mesoscale activity: There are large mean values and very broad distributions in regions of high strain rates and eddy kinetic energy (EKE), e.g., western boundary currents and the Antarctic circumpolar current, and weak mean values and narrower distributions in low strain and EKE regions, e.g. eastern subtropical oceans. The FTLEs also outlast these variations are related to the characteristics of coherent vortex structures. There are low FTLEs inside vortices and filaments of high FTLEs in strain-dominated regions surrounding these vortices.

STORM SURGE FORECASTING IN LAKE PONCHARTAIN

As an extension to the NOPP project entitled Real-Time Forecasting System of Winds, Waves and Storm Surge in Lake Pontchartrain. Working with our NOPP (National Oceanographic Partnership Program) team, we extended the NOPP domain to include predictions for Lake Pontchartrain. For the Lake region, we use the SWAN wave model to calculate the wave heights and the wave forces. The wave forces are used together with the winds and pressure to force the ADCIRC circulation model. We will briefly discuss the domain, resolution, and efficiency of the Lake modeling system. Preliminary ground truthing of our forecast results indicate that the model accurately predicted the magnitude of the storm surge for the hurricanes of 2005. We present results of hindcast analysis using our model system. Hurricane Katrina is revisited, and results from our previous NOPP forecast/hindcast are compared to the current modeling approach. Results showcase our current capabilities in forecasting hurricane storm surge and the abilities of our NOPP system to be extended to any local scale domain.

MODELING SMALL-SCALE SEDIMENT TRANSPORT AND MORPHOLOGY

Bedforms play an integral role in nearshore hydrodynamics. While some features may be small compared to typical coastal longfshcales, they are nevertheless efficient at dissipat-
ing wave energy in the bottom boundary layer. Additionally, their presence is known to alter net sediment transport in the cross-shore direction due to phase differences between fluid forcing and sediment entrainment. Such impacts are quantifiable at large scales, but specific details regarding small-scale sediment transport processes in the generation of sedimentary structures—like sand ripples—remain elusive. Of particular interest are the roles of bedload and suspended load during rippled evolution. The scarcity of information is due to the lack of advanced methods to monitor such processes directly.

**CULTURAL SENSITIVITY, RELEVANCE, AND THE IMPORTANCE OF FAMILY: WORKING WITH UNDERREPRESENTED STUDENTS IN COASTAL MARGIN SCIENCE**

As a new National Science Foundation Science and Technology Center, the Center for Coastal Margin Observation and Prediction (CMOP) is dedicated to increasing the numbers of underrepresented students in ocean sciences education and careers. Although CMOP approaches diversity efforts as an integrative continuum across research, education and knowledge transfer, we focus here on specific CMOP K-12 education programs during summer 2007. Together with an education partner, Saturday Academy, CMOP recruited underrepresented students to participate in a week-long summer camp, and in a 8-week Apprenticeships in Science and Engineering (ASE) program. This presentation shares the expected and unexpected experiences both CMOP and Saturday Academy had while working to identify and engage students. Immediately apparent was the importance of family support and understanding. Forms, location, gender expectations and roles, tribal culture, and science itself are just some of the variables that served as barriers to program participation. We will present strategies we developed to respond to the needs of students and their families, and how our programs will evolve in response to these needs, while providing relevant and meaningful coastal margin education programs.

**FERRYBOX IN THE CONTEXT OF THE EUROPEAN CONTRIBUTION TO GEOSS - GMES**

For long time, ships of opportunity are used to obtain oceanographic observations to improve the monitoring capabilities of the oceanic environment. Within the recent years a severe improvement of observation systems that are available especially using existing commercial ships such as ferries and cargos has taken place. Instrument packages onboard of these vessels are nowadays also referred to as Ferriesboxes. A network of Ferriesboxes has been established within the North Sea/Skagerakk and Norwegian Sea. Through the high frequency of repeated transects of the vessels valuable data sets are obtained, that are able to visualise the reaction of the ecosystem on changes within the physical environment. Within the presentation an overview of the obtained data from the Ferrybox network will be shown and initiatives forming the basis for the European contribution to the overall efforts of the Global Earth Observation System of Systems (GEOSS) and the Global Monitoring for Environment and Security (GMES) programs will be presented.

**VALIDATION AND APPLICATION OF ENSEMBLE KALMAN FILTER IN THE GULF OF MAIN**

A Kalman Filter package, including Reduced Rank Kalman Filter (RRKF), Ensemble Kalman Filter (EnKF), Ensemble Square-Root Kalman Filter (EnSRKF) and Ensemble Transform Kalman Filter (EnTKF), from M.L.T. has been implemented into the unstructured-grid Finite-Volume Coastal Ocean Model (FVCOM). After the proof-of-concept applications with three idealized regimes, a twin experiment approach has been adopted mimicking the observational configuration in the Northeast Channel of the Gulf of Maine for evaluating the performance of ensemble Kalman filter method in the coastal ocean. The Northeast Channel is the major passage connecting the basins of the Gulf of Maine and the slope water of the Northwestern Atlantic Ocean. The transport crossing the channel, the geostrophic flow water on the northwestern side of the channel, water on the south-west side, play an important role in controlling the cyclonic circulation in the gulf. In this study, the EnKF is test by assimilating the temperature, salinity and current data along and cross the channel. The sensitivity of EnKF to the location of observational data, ensemble size, forcing errors has been examined.

**NORMAL MODES OF THE SOUTH INDIAN OCEAN**

The Indian Ocean displays a large variety of bathymetric features, with ridges, oceanic plateaus and continental islands outlining a considerable number of abyssal plains. Consequently, barotropic variability in the Indian Ocean is strongly controlled by bathymetry, and is in many cases organized in spatially coherent modes. In this presentation we will present results of a few studies of barotropic modes of the Indian Ocean. These modes are determined through normal mode analysis in a barotropic shallow-water model of the South Indian Ocean, and
provide a dynamical basis for several modes of variability that have been observed in recent years. In particular the bi-monthly oscillations in the Mascarene Basin will be discussed, as well as the region of high variability in the Australia-Antarctic Basin.

Weigartner, T. J., University of Alaska, Fairbanks, USA, weigartner@ims.uaf.edu; Danielson, S. L., University of Alaska, Fairbanks, USA, seth@ims.uaf.edu; Kasper, J., University of Alaska, Fairbanks, USA, jfk@uaf.edu; CIRCUITITION IN THE LANDFAST-ICE ZONE OF THE ALASKAN BEAUFORT SEA

We discuss year-round bottom pressure, velocity, and temperature-salinity-transmissivity data collected from the nearshore (-10 m depth) Alaskan Beaufort shelf. Seasonality is set by the presence of ice, arctic river runoff, and the brief openwater season. When landfast ice is present, currents are along-shore polarized, weak (~5 cm/s), uncorrelated with winds, and have de-correlation length scales of ~100 km. Cross-shelf flow is negligible. During the spring freshet highly sheared, strongly stratified and turbid under-ice plumes spread offshore at ~10 cm/s. After the break-up, currents are swift (~20 cm/s), wind-driven, and coherent over length scales of ~200 km. Runoff induced stratification results in a pronounced asymmetry in the velocity profiles under upwelling and downwelling winds. Subtidal currents are coherent year-round with along-shore sea level slopes of O(10^-6). In summer the momentum balance is amongst the wind, bottom friction, and along-shore pressure, while in winter under-ice and bottom friction balance the pressure gradient. The annual sedimentation cycle involves: 1) rapid deposition of the terrigenous sediment load under the ice in spring and 2) fall re-suspension into the water column and pressure.

Weise, M. I., University of California Santa Cruz, Santa Cruz, USA, weise@biology.ucsc.edu; Costa, D. P., University of California Santa Cruz, Santa Cruz, USA, costab@biology.ucsc.edu; ZONES OF AREA RESTRICTED SEARCHING IN MALE CALIFORNIA SEA LION (ZALOPHUS CALIFORNIANUS) IN RELATION TO OCEANOGRAPHIC FEATURES IN THE CALIFORNIA CURRENT SYSTEM

California sea lions are one of the most abundant apex predators in the California current System, yet we have little understanding of what physical oceanographic features drive the spatial and temporal distribution of their foraging efforts. In this study satellite relay data loggers (SRDL) were used to investigate the spatially explicit foraging behavior of subadult and adult male California sea lions following the breeding season during 2003-04, 2004-05, and 2005-06. Zones of Area Restricted Searching (ARS) were identified using a new fractal landscape method that describes the peaks and valleys of fractal dimension along the path of sea lions. To identify environmental variables that best explain the variability in foraging behavior of sea lions in ARS zones we used the BIO-ENV approach. This is an iterative procedure that compares Bray-Curtis similarity matrices of behavioral data with Bray-Curtis similarity matrices of environmental variables and identifies individual or a subset of environmental variables that has a greater weighted Spearman rank-correlation. Cluster analysis and non-metric multidimensional scaling were used to corroborate BIO-ENV approach and visualize the relationships between ARS and environmental variables.

Weissberger, E. J., U.S. Environmental Protection Agency, Narragansett, USA, weissberge@epa.gov; Coiro, L., U.S. Environmental Protection Agency, Narragansett, USA, coiro.lauraj@epa.gov; Davey, E. W., U.S. Environmental Protection Agency, Narragansett, USA, davey.earl@epa.gov; EFFECTS OF HYPOXIA ON ANIMAL BURROW CONSTRUCTION AND CONSEQUENT EFFECTS ON SEDIMENT REDOX PROFILES

Hypoxia may affect the behavior of burrowing animals, which may in turn affect sediment chemistry. We investigated effects of hypoxia on burrowing behavior of three common marine species (the hard clam Mercenaria mercenaria the polychaete worm Nereis virens, and the amphipod Leptocheirus pluvialis) and consequent effects on sediment redox profiles. Animals were introduced at natural densities into defaunated sediment cores and allowed to burrow for four months at mildly hypoxic (2 ppm) and saturated (7 ppm) dissolved oxygen levels. Sediment redox profiles were taken at varying temporal intervals for the duration of the experiment. At the end of the experiment, cores were imaged using a computed tomography scanner and burrow volume measured. Sediment redox profiles differed between oxygen treatments, but not animal treatments. It is possible to burrow through hypoxic sediments, but not at the same rate as anoxic. Although mild hypoxia directly affected sediment redox profiles, it was not severe enough to affect the burrowing behavior of the animals in the experiment, which had no additional effect on redox profiles.

Weissman, D. E., Hofstra University, Hempstead, NY, USA, oggleow@hofstra.edu; Bourassa, M. A., Florida State University, Tallahassee, FL, USA, bourassa@oesps.fsu.edu; ESTIMATING AIR-SEA MOMENTUM FLUX WITHIN RAIN

The momentum exchange between the boundary layer and the sea surface is dependent on the short wave waves. In some ranges of wind speed and rain intensity, the impacts of rain droplets will create waves and similar disturbances that will alter momentum transfer. Ku-band scatterometer measurements are affected by the presence of rain through the precipitation and the atmosphere and estimate the change related to surface roughness. This study combines satellite based Ku-band data with high-resolution 3-D volumetric rain measurement, from simultaneous NEXRAD data. The results to be presented were acquired during a significant rain event in the Gulf of Mexico. This rain-modified surface will alter the transfer of momentum, and in effect will change the drag coefficient and stress. These changes in drag and stress is often associated with active weather and strong ocean forcing. Neglecting these changes causes systematic errors in the climatic distribution of surface forcing, and hence the ocean response.

R., Stanford University, Stanford, CA, USA, kosofi@stanford.edu; Thomas, F. I., Hawaii Institute of Marine Biology, Kaneohe, HI, USA, fithomas@hawaii.edu; THE COUPLING OF HYDRODYNAMICS AND NUTRIENT EXCHANGE IN NATURAL SEAGRASS CANOPIES, PART ONE: FLOW CONDITIONS

Nutrient exchange processes in and around aquatic plant canopies are controlled by a dynamic combination of physical and biological influences. Our work in Florida Bay provides direct measurements of these components, allowing insight into their complex coupling. A field-deployed racetrack flume was used to regulate nutrient exposure and water motion in patches of submerged vegetation. The canopies, which were dominated by the Caribbean species Thalassia testudinum, were subjected to a broad range of unidirectional and oscillatory flow conditions. High-resolution ADVs captured full-depth velocity profiles for each of the thirty-three cases we investigated. A supplemental multi-instrument array was also deployed to survey natural flow in the flume’s vicinity. This collection of devices measured bulk water properties, spatial and temporal flow variability, and mixing layer dynamics. Our field results uncover the natural complexity of these exchange regimes, highlighting factors that are often forfeited in the transition to laboratory or numerical investigation.

Weller, R. A., Woods Hole Oceanographic Institution, Woods Hole, USA, rweller@whoi.edu; Farrar, J. T., Woods Hole Oceanographic Institution, Woods Hole, USA, rweller@whoi.edu; BUOY-BASED OBSERVATIONS OF THE DIURNAL CYCLE IN UPPER-OCEAN AND SURFACE METEOROLOGICAL PROPERTIES

We describe and analyze detailed buoy-based observations of surface meteorology and the evolution of temperature and velocity in the upper ocean, focusing on diurnal variability. The observations were collected at sites in the eastern Pacific having contrasting large-scale meteorological and oceanographic conditions. At a site beneath the intertropical convergence zone, strong diurnal cycles of surface temperature were observed during the season of active deep convection and weak mean winds. At a site beneath the expansive stratus decks of the southeastern Pacific, diurnal variability was observed in the upper ocean during times of relaxing trade winds. The buoy observations of surface air temperature, wind speed, wind direction, and water temperature agree with previous studies that captured surface atmospheric signals. This buoy network allows accurate estimation of the surface forcing on the ocean and examination of potential feedbacks from the ocean onto the atmosphere at diurnal timescales. Near-surface thermal evolution was observed with good vertical resolution (better than 1 m), and there are some observations of velocity within the warm layer.

Wells, A. I., DAMTP University of Cambridge, Cambridge, United Kingdom, A.I.Wells@damtp.cam.ac.uk; Cenedese, C., Woods Hole Oceanographic Institution, Woods Hole, USA, ccenedese@whoi.edu; Farrar, J. T., Woods Hole Oceanographic Institution, Woods Hole, USA, jfarrar@whoi.edu; Zappa, C., Lamont-Dobertly Earth Observatory of Columbia University, Palausades, USA, zappa@deo.columbia.edu; VARIATION IN OCEAN SURFACE TEMPERATURE DUE TO NEAR SURFACE FLOW: STRAINING THE COOL SKIN LAYER

The aqueous thermal boundary layer near to the ocean surface, or skin layer, has thickness O(1mm) and plays an important role in controlling the exchange of heat between atmosphere and ocean, and its dynamics can be modified by near surface flows. We present a quantitative experimental investigation of the dynamics of the skin layer in the presence of local upwelling. A non-dimensional formulation is presented that identifies different dynamical regimes for the skin layer with corresponding differences in surface temperature, or skin temperature. In laboratory experiments, we observe an increase in skin temperature above regions of upwelling flow, and show that previous theories accurately describe the observed difference between the skin and interior temperature for large Péclet numbers. The non-dimensional formulation allows us to predict that straining of the cool skin by internal waves is unlikely to be responsible for large changes in skin temperature. However, this formulation may prove to be important in the description of other scalars, such as the transfer of gases between the ocean and atmosphere.

Wells, J. R., Ocean & Resources Engineering, University of Hawaii, Honolulu, HI, USA, jrwells@hawaii.edu; Pawlak, G., Ocean & Resources Engineering, University of Hawaii, Honolulu, HI, USA, gpawlak@hawaii.edu; Merrifield, M. A., Oceanography, University of Hawaii, Honolulu, HI, USA, markm@soest.hawaii.edu; OFFSHORE FORCING OF NEARSHORE CURRENTS: INTERNAL WAVE EFFECTS

Motions in the main 500m-deep embayment of Mamala Bay, Oahu, are dominated by internal tides which induce large vertical displacements and strong baroclinic currents. Field observations are used to investigate the nearshore structure of the internal wave field and to assess its influence, in combination with surface wave and barotropic tidal forcing, 496
on nearshore currents. Kilo Nalu, the University of Hawaii cabled observatory, is located on the upper shelf which has a maximum depth of 50m. ADCP data, collected at the 10m site since 2004, provides the time series needed for separating barotropic from baroclinic motions, describing the temporal structure of baroclinically-driven currents, and evaluating the variance unexplained by barotropic tides and surface waves. Recent REMUS surveys and the deployment of cross-shore and along-shore instrument arrays help define the spatial structure of water column data is also examined. Data from a thermistor data logger installed last May show a normally well-mixed water column subject to intermittent stratification. The ADCP record shows cold bottom water events occurring regularly at the M2 frequency with coterminous intensified currents.

THE INTRUSION DEPTH OF A DENSITY CURRENT IN A STRATIFIED WATER BODY

We present theory and laboratory experiments describing the depth at which a density current intrudes into a linearly stratified water column, as a function of the entrainment ratio E, the buoyancy flux in the dense current B, and the magnitude of the stratification, N. We show that the depth of the intrusion scales as Z ~ 4 B^1/3 N/tau from laboratory to oceanographic scales, i.e. a variation of six orders of magnitude. We anticipate that this scaling law will allow the fidelity of numerical models to be tested. As an example, the depth at which the Mediterranean plume intrudes has important implications for the stability of the present climate due its important role in the global thermohaline circulation so it is important to understand how the intrusion depth might change in a future climate. Density currents also occur in lakes and reservoirs, and here the depth at which a cold river intrudes into the thermally stratified water column can determine where pathogens are placed or the locations of biological hot spots.

FE(III) COMPLEXING ORGANIC LIGANDS STRONGLY RESTRICT ECOSYSTEM RESPONSES TO ATOMIC IRON ENRICHMENT IN HIGH NITRATE LOW CHLOROPHYLL WATERS

Mesoscale iron enrichment studies have been performed repeatedly in the subarctic Pacific Ocean, equatorial Pacific, and on the Southern Ocean. Density-similar experiment designs describe the magnitude of the diatom growth response has varied dramatically. For example, the SEEDS and SEEDS II iron enrichment experiments were conducted at similar locations in the western subarctic Pacific yet their growth responses differed by an order of magnitude. Deckboard incubation experiments demonstrated that diatom growth during SEEDS II remained iron limited despite significantly elevated iron concentrations (0.5 nM) in the patch. The negative influence of strong Fe(III)-complexing organic ligands on iron availability to diatoms likely is the reason for this condition; a view supported by Cu enhanced phytoplankton growth. These findings bear on the inverse relationship between mixing depth and bloom size observed in artificial iron enrichments. Though this relationship has been attributed to physical forcing (temperature, light, mixing) it instead may result from low inorganic Fe ratios in the fertilized patch. If true, most atmospheric iron inputs to HNL waters may have little impact on diatom growth, in contrast to the current paradigm.

COMPARING USE OF MANGROVES BY BOTTLENOSE DOLPHINS ON WEEKENDS AND WEEKDAYS

When boat traffic is high during the weekends in Sarasota Bay, bottlenose dolphins are difficult to find indicating they might seek shelter in the secluded water of the mangroves. This study determined whether bottlenose dolphins use the mangroves more on the weekends than weekdays to escape from boat traffic. Data for this project were collected opportunistically by kayak tour guides and during a dedicated kayak-based survey. Dolphins did appear to be using the mangroves more on the weekends than weekdays to escape from boat traffic signifying that dolphins are excluded from their preferred habitat 2/7 of the week. This is causing the bottlenose dolphins of Sarasota Bay habitat to become condensed and this could possibly decrease Sarasota’s Bay carrying capacity.

SATELLITE MICROWAVE MEASUREMENTS OF THE HYDROLOGICAL CYCLE: WATER VAPOR, TROPOSPHERIC TEMPERATURE, PRECIPITATION, AND EVAPORATION

Satellite microwave observations show that water vapor, a natural greenhouse gas, has increased by 2.4% during the last 20 years. Satellites can also measure the temperature of the troposphere, and these measurements indicate the troposphere has warmed by 0.8°C during the last 20 years, which is in general agreement with surface thermometers. Thus, the water vapor has increased at a rate of 6% per degree of global warming. Climate models predict a similar rise with temperature. There is no serious discrepancy between the satellite observations and the climate models with regards to the increases in water vapor and temperature. Estimates of precipitation and evaporation can also be obtained from satellite microwave observations. When averaged over the globe, evaporation must equal precipitation. This equality provides us with a useful consistency check. We find that the precipitation and evaporation trends do agree; they both indicate an increase of 6% per degree of warming, the same as water vapor. This observational result disagrees with climate models, which indicate a smaller increase of 1-3%. This is a significant discrepancy that needs to be resolved.

MAJOR DIFFERENCES OF BACTERIAL DIVERSITY AND ACTIVITY INSIDE AND OUTSIDE OF A NATURAL IRON-FERTILIZED PHYTOPLANKTON BLOOM IN THE SOUTHERN OCEAN

The response of heterotrophic bacterial activity and diversity to a phytoplankton bloom induced by natural iron fertilization in the Southern Ocean (Kerguelen plateau) was investigated in January-February 2005. In surface waters in the core of the phytoplankton bloom, heterotrophic bacteria revealed rates of production ([3H] leucine incorporation) and respiration that exceeded those in surrounding HNL waters by factors of 6 and 5, respectively. Based on 165s rDNA clone libraries, the dominant operationally taxonomic units in the bloom were the Br-2 and NAC11-7 cluster. SAR11 and a CFb cluster related to the agg58 group, whereas in HNL waters, SAR11, Roseobacter RCA and <Polaribacter> dominated. We designed specific probes and applied fluorescence in situ hybridization and microautoradiography (MICRO-FISH) to determine the relative contribution of these bacterial groups to bulk leucine incorporation. Our results revealed contrasting dynamics of these bacterial groups in terms of abundance and activity in the bloom compared to the HNL site. These results indicate that the Kerguelen bloom is associated with a specialized bacterial community that mediates the cycling of carbon and probably iron.

ECOLOGICAL FORECASTING AND HINDCASTING IN THE INTERITIONAL ZONE: FROM WEATHER AND OCEANOGRAPHY TO BODY TEMPERATURES, MORTALITY RISKS, AND BIOGEOGRAPHY

Mechanistic heat budget models, coupled to NOAA weather forecasts (North American Model, Global Forecast System, WaveWatch III), NASA sea surface temperature (SST), and tide predictions are used on a daily basis to generate worldwide 7-day forecasts of animal body temperatures in intertidal zones. Hindcasts using the same models are based on ICOADS and NOAA Reanalysis data. Heat budget models were validated against biomimetic data loggers, and predicted intertidal body temperatures were congruent with data logger observations. Forecasts successfully predicted unusually high temperatures coincident with mass mortality of Echinocardium burrowing sea urchins in New Zealand in 2003, an abnormally hot summer in the US west coast in 2006, and Mytilus mussels on the US east coast in 2006. The hindcasts provide mechanistic understanding of geographic range shifts of species on decadal and centennial time scales. Large shifts in biogeographic limits of ecologically dominant intertidal species were associated with SST changes over the past 75 years. These tools can provide resource managers and ecologists with near-term warning of mortality risk and probable long term shifts associated with climate change.

EVALUATING PHYTOPLANKTON RESPONSES TO HURRICANES AND TROPICAL STORMS WITH DIFFERENT CHARACTERISTICS (TRAJECTORY, RAINFALL, WINDS)

Beginning in the mid-1990s, the U.S. East and Gulf Coasts entered a period of elevated hurricane activity. Hurricanes and tropical storms can cause significant nutrient loading to estuaries that are unmanageable. We examined the ecological impact of several large storms varying in their characteristics on N.G. Neuse R. Estuary. The water column was stratified and nitrogen was limiting to phytoplankton growth prior to Tropical Storm Helene. Mesozooplankton chlorophyll a increased 2.5 fold after the storm, resulting from localized freshwater input and mixing of sediment-bound nutrients to the euphotic zone. Prior to passage of Hurricane Isabel, the water column was mixed and nutrient concentrations were high. As a result, the storm had minimal impact on phytoplankton biomass despite its significant freshwater/nutrient inputs. Hurricane Alex mixed a stratified water column and chlorophyll a nearly doubled in the mesohaline region after its passage. These results suggest that the mesohaline region is particularly sensitive to storm-induced nutrient inputs, but that the phytoplankton response depends on both the characteristics of a storm and the physical-chemical conditions of the water column prior to storm passage.
Trichodesmium and Crocosphaera. Here we will address how phosphorus compartment...

improving quantitative literacy in undergraduate marine science courses

Mathematical skills and concepts are required for interpreting oceanographic information.

The on-line Spreadsheets Across the Curriculum (SSAC) library consists of activities to reinforce or teach quantitative literacy or mathematical concepts and skills in context. Each activity (called a module in the SSAC project) consists of a PowerPoint presentation with embedded Excel spreadsheets. Each student works through a presentation, thinks about the in-context problem, figures out how to solve it mathematically, and builds spreadsheets to calculate and examine answers. SSAC modules were created by faculty from all over the country in various disciplines (e.g., marine science, chemistry, biology, geology, and geophysics) and are freely available at the on-line Science Education Resource Center (serc.carleton.edu), searchable by quantitative skill, subject area, and Excel level. We hired under-graduate students to use and evaluate select SSAC modules during the summer of 2007. Twenty-four students with diverse majors completed pre- and post-tests as well as personal interviews to gauge their familiarity with and attitudes toward using Excel and mathemat- ics. Overall student responses were positive, especially regarding gains in Excel skills.

Lateral exchange in a straight channel with fringing vegetation

Lateral exchange of momentum and suspended sediment between an open channel and fringing vegetation is important for river–floodplain interactions and tidal marsh dynam- ics. Here experimental results are described for lateral turbulent exchange at the bound- ary between a straight open channel and a region of model emergent vegetation. Evidence is given for coherent structures formed by shear instability that contribute significantly to lateral sediment transport. Based on experimental studies, a simple model is presented for lateral exchange of suspended sediment in a channel with fringing vegetation. The advection–diffusion equation with deposition and a vegetation-dependent diffusivity is used in conjunc- tion with a turbulent flux condition at the vegetation interface to predict suspended sedi- ment concentration and deposition within the vegetation. The magnitude of the lateral turbulent flux is compared with lateral advective fluxes from overbank flooding in a typical tidal marsh and incorporation into morphodynamic models is discussed.

Gigantocuticular characterization in Hawaiian archipelago fishes: toxicity identified by n2a bioassay

Ciguatera is the most common form of seafood poisoning worldwide. One difficulty in preventing ciguatera is lack of adequate screening methods, due in part to the presence of multiple ciguatoxins (CTX) congeners in fish tissue. CTX congeners are commonly under- studied to differ by region. As the Hawaiian Archipelago is the most remote island chain in the world, it is reasonable to expect that CTX in Hawaii’s fishes may be unique as well. The objectives of this project were: 1) identify ciguatoxins using a sodium-channel specific neurotoxin (N2a) bioassay; 2) determine how ciguatoxins vary among fish species throughout the archipelago; and 3) determine molecular masses of putative ciguatoxin congeners using HPLC/MS. Fishes were opportunistically collected from 14 islands, atolls, and reefs within the archipelago. Muscle tissues were extracted in dichloromethane and analyzed for toxicity using the bioassay. Results for 294 samples indicate 16% of fish exhib- ited toxicity. Chi square results indicated no significant differences in spatial distributions, or between herbivorous and carnivorous fishes. HPLC/MS analysis of extracts resulted in identification of several candidate peaks that may represent CTX congeners.

Evolution and oceanic dispersal of bonamia parasites of oysters

Bivalve oysters (Crassostrea gigas) are native to the Caribbean and Indo-Pacific. Australia (B. roughleyi), New Zealand (B. exitiosa), and North America (B. perspura). The taxonomy of recently discovered, congeneric parasites is under debate. It is argued that various austral Bonamia parasites, dispersed perhaps by oysters rafting (B. perspura). The taxonomy of recently discovered, congeneric parasites is under debate.
cies may indeed have become widespread, occurring from New Zealand to Australia and Argentina. Even more interesting, at least one additional cryptic species may exist in Chile. The uniqueness of the Chilean Bonamia sp. ITS sequence data, is discordant with an oyster genetic study that supports rafting of B. exitiosa host Ostrea chilensis from New Zealand to Chile. Also, the widely distributed austral Bonamia has recently been observed in North Carolina, USA, and Tunisia. Oceanic rafting of oysters may well contribute to the observed distribution of Bonamia species; however, other dispersal factors are clearly at work as well. White, E. **DEEP WATER VARIABILITY AT THE BERMUDA TIME-SERIES SITES**

The chemical composition of carbon dioxide (CO2) is an important pathway for mineralization of dissolved organic matter in seawater. A semi-automated analytical system was developed to determine photochemically produced CO2 in marine waters. To detect low levels of produced CO2, dissolved inorganic carbon (DIC) was removed before irradiation by acidification and sparging with low-CO2 air (pool depletion method). The pH was adjusted back to the original value and the resulting low-DIC seawater sample was transferred pneumatically to air-tight quartz tubes for irradiation. During analysis, irradiated samples were pneumatically transferred to a sample loop, injected, and acidified. CO2 was then stripped out, dried, and carried to a non-dispersive infrared CO2 analyzer for quantification. The method detection limit was 60 nM. Measured CO2 photoproduction rates ranged from 25 nM/h in coastal seawater to 6 nM/h in open ocean Gulf Stream water. Our results compared well to CO2 production rates determined employing a carbonate exchange method, verifying the accuracy of the pool depletion method.

**DEEP WATER VARIABILITY AT THE BERMUDA TIME-SERIES SITES**

Deep water formation is an intrinsic component of climate regulation through mechanisms such as the Atlantic Meridional Overturning Circulation (AMOC). Hydrography profiles from Hydrostasys’ 5 (1954-2007) and the Bermuda Atlantic Time-Series Study (1989-2007) present a valuable framework for assessing variability in some of the deep water masses. Analyses of these depth averaged data reveal significant long term changes, most notable a steady decrease in temperature and salinity for both water masses over the past 20 years (LSW: ΔT = -0.27 °C, ΔS = -0.040 °C; NEADW: ΔT = -0.02 °C, ΔS = -0.007 °C). Short-term variability is particularly evident in LSW with variances in T and S an order of magnitude higher than in NEADW. Furthermore, changes in the LSW properties at Bermuda appear well correlated with source conditions at a time lag of 7-8 years, consistent with previous findings. This suggests that deep water variability observed off Bermuda is related to changes in the AMOC.
N fertilization experiment in two salt marshes in the northeastern USA. In each marsh 4 replicate plots were treated with 4 different Si:N ratios (ambient, 2x Si:N, 0.5x Si:N, and N only). Algal community composition and biomass (determined by cell counts, chlorophyll, and CN analysis) were altered by fertilization and changes to the Si:N ratio. We also report changes in the Si and N content of the periphyton following the treatments. While eco-
logically altered Si:N have received attention in open waters of estuaries, similar changes can alter the periphyton and may affect the lower food web of salt marshes.

CONSOLIDATION AND EROSION ACROSS A MUD-SAND GRADIENT

Sand-mud transitions are a common feature of many continental shelves. Accompanying this transition is a fundamental change in bed erodibility. Here we present field and laboratory measurements of erosion rates and sediment properties across a gradient in the mud-sand content of the bed. The field measurements were made along a cross-shelf transect in the Gulf of Lions, NW Mediterranean, and included grain size of bed and suspended sediment, bed porosity, and erodibility measured using a Guc erosion chamber. Laboratory measurements are being made on clay-sand mixtures that consolidate for varying lengths of time, with a focus on clay fractions associated with the transition from cohesive to non-cohesive erosion behavior (~7.5%). The field measurements show a distinct difference in sediment mass eroded vs. shear stress relationship for predominantly muddy beds compared to higher sand-lower clay content beds, consistent with expectations for cohesive and non-cohesive beds. The laboratory measurements are used to better resolve this difference and its dependence on clay fraction. The results will be useful for sediment transport modeling and for understanding the processes associated with mud-sand transitions on the shelf.

THE IMPACT OF SENSOR RETRIEVAL ERRORS AND DIURNAL WARMING ON THE ACCURACY OF BLENDED MULTI-SENSOR SEA SURFACE TEMPERATURE PRODUCTS

The blending of complementary retrievals from infrared and microwave sensors provides the potential for enhancing the accuracy and sampling of sea surface temperature (SST) products. To achieve these improvements in accuracy, however, differing uncertainties in the products and diurnal warming effects must be carefully accounted for. Previous research has revealed uncertainties in each individual SST product dependent on different environmental parameters. In this work, the impact of incorporating the uncertainties and diurnal warming corrections in blended-multi-sensor SST products is evaluated. The bias and variability of individual infrared and microwave SST retrievals from multiple sensors are derived from colocations with in-situ measurements from moored and drifting buoys. The accuracy of blended SST products relative to independent buoy measurements is compared with and without compensation for the individual retrieval bias and variability. Identified biases are directly subtracted from the retrievals. Differing variability in the retrievals is accounted for in the relative weighting applied to each. Compensation for the estimated amount of diurnal warming present in daytime observations is explored based on the application of simplified look-up tables derived from diurnal warming calculations. Interannual variability is greater than 5Sv and a large component of the interannual variability of the Pacific to Indian interocean exchange. Geostrophic (relative to 700m) plus Ekman transports are examined across 3 independent XBT lines. Interannual variability is greater than 55% and a large component is strongly correlated to remote wind forcing in the equatorial Indian and Pacific Ocean. The velocity response to Indian wind changes is very different compared to that for Pacific wind changes. Transports shall also be compared to those derived from the 3 years of direct velocity measurement attained through the INSTANT project.

NUTRIENT SUPPLY TO THE WESTERN AUSTRALIAN SHELF

Recent estimates of nutrient supply to the continental shelf off Western Australia indicate that terrestrially derived inputs are small (~1%) compared to primary estimates of nitrogen derived from Leeuwin Current advection and eddy activity (8%) and seasonal upwelling along the shelf (7%). By closure the budget suggested that 84% of primary production was recycled on the shelf, thus, even considering the uncertainties in the offshore input estimates, the continental shelf off the west coast is primarily a recycling system. Elsewhere in the world similarly narrow shelves are typically export systems, however our preliminary budget suggests that just 7% of the shelf productivity is transported offshore and 5% exported to the deep ocean. Ongoing fieldwork is focusing on the benthic pelagic coupling of the shelf to help constrain a 3D biogeochemical model of the system. Model output is assessed against field and in-situ observations and the model is used to quantify the spatial and temporal dynamics of the continental shelf carbon and nitrogen biogeochemistry.

WETLAND PROXIMITY AFFECTS METHYLMERCURY IN THE AQUATIC FOOD WEB OF CHEQUAMEGON BAY (LAKE SUPERIOR)

We examined the influence of wetlands and tributaries on concentrations of methylmercury (MeHg) in the food web of Chequamegon Bay, a 167 km² embayment on the south shore of Lake Superior. Concentrations of MeHg in seston (1.8-11.4 ng/g), benthic macrophytes (15-109 ng/g), and fish muscle (22-66 ng/g) were generally greater than those typically observed in open water sites of Lake Superior, but less than those in inland lakes of the region—a pattern also observed in small planktivorous (yellow perch) and benthivorous fish (Eurasion ruffle and johnny darter). Within the Bay, concentrations of MeHg in surficial sediment, zooplankton, and fish were highest in tributary- and wetland-influenced sites. Spatially, the concentration of MeHg in benthic macroinvertebrates increased concomitantly with increased exposure to organic matter from allochthonous (wetland and riverine) sources, as inferred from isotopic analysis of carbon. These results indicate that Chequamegon Bay is a transitional zone, where the entry of MeHg into the aquatic food web is strongly influenced by proximity to terrestrial landscape features, particularly wetland environments.

SEASONAL VARIABILITY OF BIOGEOCHEMICAL PROPERTIES AND WATER QUALITY WITHIN A COUPLED MODEL OF CHESAPEAKE BAY

Seasonal variability of biological and chemical properties of Chesapeake Bay is studied through application of a numerical ocean general circulation model with a fully coupled ecosystem. The physical model is the Princeton Ocean Model System (ROMS). The ecosystem model has been modified from the standard Fasham-type formulation packaged as part of the ROMS distribution to include components that explicitly simulate the impact of river borne sediments, inorganic nutrients and dissolved organic matter. Wet and dry deposition of atmospheric nitrogen, spatio-temporal variation in phosphate limitation and sediment resuspension have been incorporated. For the Chesapeake Bay Program. A series of sensitivity studies, the relative contributions made by each of the included leading order processes toward successfully realizing the Bay’s seasonal biogeochemical evolution are assessed.

ASLO/AGU/TOS/ERF 2008 Ocean Sciences Meeting
MEASURING TURBULENCE IN LOW ENERGY BOTTOM BOUNDARY LAYERS
Recent developments in using acoustic Doppler current profiler techniques for measuring turbulence are opening up new opportunities for the direct measurement of long time series of turbulent mixing processes. In this contribution we use data from lake environments to investigate the ability of a structure function method to resolve the low levels of turbulent dissipation in the water column. The results are compared with a more conventional approach through spectral fitting to the Kolmogorov -5/3 law. In the two lakes considered forcing is by internal seiche motions (~ 2cm/s) induced by the wind. Velocity profiles from Llyn Tegid (North Wales) clearly show the modal structure of these motions, with the observed decay rate indicating a useful way of valuating measurements of dissipation within the boundary layer. An alternative validation, employed in studies in Lake Alpachr (Switzerland), is by comparing structure function dissipation estimates with estimates based on temperature microstructure. The measurements from both lakes demonstrate the potential of ADCPs to estimate low levels of turbulent dissipation (~ 10-6 Wm-3).

IMPACT OF IRON AVAILABILITY ON DIATOM VALVE STRUCTURE AND GRAZING PROTECTION
Iron limitation has been shown to increase the silica content of diatoms. To date, however, it remains unknown, if this results in an increased valve thickness and stability which might lead to a better grazing protection. In the current study we investigated the effect of iron availability on the valve structure of the cosmopolitan diatom Coscinodiscus wailesii and the Southern Ocean species Fragilariopsis kerguelensis using scanning electron microscopy, confocal laser scanning microscopy and atomic force microscopy. We further analyzed the stability of the frustules for these two and the four additional species C. granii, Thalassiosira rotula, T. tumida and Porsoria pseudodenticulata using micromanipulator techniques. While the valve thickness seemed to be unaffected by iron availability, a modified valve morphology with significantly thicker interstriae was observed under iron limitation. These changes in valve structure resulted in an increased stability under iron limitation for all species investigated. Our results suggest a better grazing protection of diatoms growing under iron limitation. Therefore anthropogenic iron fertilization or changing iron availability over geological time scales might have a strong impact on the food web structure.

Wilkinson, C. N., Hampton University, Hampton, USA, carissa.wilderson@pipeline.hamptonu.edu

COMPARISON OF NEKTON UTILIZATION OF THREE INTERTIDAL HABITATS IN THE HAMPTON RIVER (CHESAPEAKE BAY, VA)
This study was conducted in the Hampton River, specifically along the campus of Hampton University, in order to better understand how fish utilize different shoreline types that have been selected. In the summer 2007, we compared the selected habitats in terms of urban influence and nekton utilization. Three nets were used at each of the three selected sites with a total of nine nets that were deployed all at once. They were suspended over the habitat prior to sampling with the use of a wooden frame. The length of shoreline sampled was a 10m section with the net extending toward the high water level depending on the slope of the habitat. Nekton were identified, counted and measured to determine utilization of the selected habitats. The results contributed to the evaluation of the effects of shoreline modification in terms of fish utilization in urbanized tributary in the Chesapeake Bay.

INFLUENCE OF THE SAN FRANCISCO OUTFLOW ON THE PRODUCTIVITY OF THE GULF OF THE FARALLONES
The San Francisco Estuary drains about 50% of the California watershed and is highly urbanized with roughly 70 tons of N produced daily as effluent from wastewater treatment plants that employ secondary treatment, discharging primarily ammonium. There are considerable riverine inputs of nitrate and silicate. However, because of severe light limitation of productivity and the inhibition of phytoplankton nitrate uptake by ammonium in the estuary, most N is exported out to the ocean. A portion of the estuarine outflow turns seaward forming a buoyancy plume along the Marin coast, carrying high ammonium concentrations that will likely extend the zone of inhibition and result in low N and C production. We report here preliminary results of a series of cruises to the Marin coast to investigate the effect of the San Francisco outflow on the pattern of primary production in the adjoining Gulf of the Farallones.

PREDICTIBILITY OF MESOSCALE VARIABILITY IN THE EAST AUSTRALIA CURRENT SYSTEM GIVEN STRONG CONSTRAINT DATA ASSIMILATION
Incremental, Strong constraint, 4-Dimensional Variational (IS4DVAR) data assimilation with ROMS (Regional Ocean Modeling System) is used to initialize an operational forecast model of mesoscale variability in the East Australia Current. Observations assimilated are daily satellite SST, 7-day multi-satellite altimeter sea level anomalies, and XBT profiles from Volunteer Observing Ship transects of the Tasman Sea. The model uses open boundary data from NCOM and NOGAPS meteorological forcing. Control variables are initial conditions of a sequence of 1-week assimilation windows, and the model trajectory through each interval is deemed the best-estimate analysis for initializing the subsequent forecast. Using 2 years of analysis we generate a large set of multi-week forecasts, from different initial mesoscale states, with which to evaluate the system skill. To quantify forecast uncertainty, ensembles are produced using optimal perturbations computed from singular vectors of the ROMS Tangent Linear model. The data assimilation system has significant skill for forecasts up to 3 weeks. Forecast skill is enhanced, and uncertainty reduced, when empirical statistical subseaurface pseudo-observations and/or so-called balance constraints are used to augment surface satellite data.

EFFECT OF ZINC AVAILABILITY ON GROWTH RATE, CELL SIZE AND ELEMENTAL COMPOSITION IN A COASTAL AND AN OCEANIC DIATOM
Low dissolved Zn concentrations in marine waters can limit growth and productivity of phytoplankton as Zn is a required component of critical enzymes. We investigated the effect of Zn availability on growth rate, cell size, and macronutrient uptake and composition in the coastal diatom Skeletonema sp. and the oceanic diatom Thalassiosira oceanica. Under Zn limitation (pZn 11.46), Skeletonema sp. exhibited a decrease in maximum growth rate (~80%), chlorophyll content (~90%), and silicon content (~70%). Thalassiosira oceanica increased the surface to volume (S/V) ratio (80%). In T. oceanica, Zn limitation (pZn 12.58) was also responsible for a decrease in maximum growth rate (~60%) and chlorophyll content (20%), but did not affect biogenic silica content or the S/V ratio. The elemental stoichiometry in Skeletonema sp. was 82:4.5:8:1:N:P under Zn-limiting conditions compare to 84:13:12:6:1 under Zn-replete conditions. Elemental quotas for T. oceanica were 51C:25Si:6N:1P under Zn-limitation and 71C:25Si:6N:1P under Zn-replete conditions. These laboratory experiments suggest that Zn availability in the oceans may affect the stoichiometry of nutrient uptake and the structure of phytoplankton assemblages.

MICROBIAL ACTIVITY ASSOCIATED WITH SHALLOW POCKMARK GAS VENTS ON THE BEAUFORT SEA SHELF
A significant pockmark submarine feature on the Beaufort Shelf has been mapped. An assessment of the microbial community composition was ascertained by analyzing the fatty acid methyl ester (FAIME) profiles of the phospholipids fatty acids (PLFA) extracted from the sediments. The total amount of FAME in the sediment cores was typical of marine ecosystems. In reference cores total FAME decreased with core depth. In contrast the maximum total FAME occurred at intermediate depths in cores from the pockmark feature. Principle component analysis revealed that the FAME distinguished the samples by site of origin. Each of the sites in the present study had different profiles then previously reported from other cold methane seep sites. In spite of the absence of the sulfide-oxidizer mats observed at other seep sites, biomarker analysis suggested the presence of a more active sulfur cycle at the Beaufort pockmark site.

SPATIOTEMPORAL PATTERNS IN MICROCIAL FATTY ACID COMPOSITION AND CARBON CYCLING IN A SEAGRASS ESTUARY
Seagrass estuaries are highly productive ecosystems that support diverse microbial communities and complex carbon cycles. Generally, organic matter production in these estuaries is dominated by seagrass. Macroalgae, phytoplankton, and allochthonous terrestrial imports, however, also contribute to the organic matter pool, creating a mixed carbon source. Seasonal production, nutrient, and climatic processes influence carbon source availability and in part regulate microbial carbon cycling in seagrass estuaries.
determine environmental regulations on carbon use and cycling in a seagrass estuary (Florida Bay, USA). fast characterization of detrital components associated with specific stable isotopic biomarker methodologies were used. Fatty acid profiles and heterotrophic bacterial carbon sources were determined for pelagic, seagrass epibiotic, and sediment microbial communities over an annual seagrass production cycle. We hypothesize that these results will support the importance of seagrass production to microbial carbon cycling in Florida Bay.

INTERESTING MOVEMENTS OF COSTA RICAN LEATHERBACK TURTLES

We deployed satellite tags to track the movements of 14 leatherback turtles at Parque Nacional Marino Las Baulas in Costa Rica during nesting intervals (eight to ten days before nesting sets). Our goals were to determine (1) whether leatherbacks stay within the Las Baulas marine reserve during nesting intervals; (2) if there are any specific areas outside the marine reserve where leatherbacks aggregate; and, (3) if movement patterns change as the interesting interval progresses. No leatherbacks remained entirely within the marine reserve during the interesting interval. At the beginning of the interval, most turtles moved outside the marine reserve and many headed to the Gulf of Papagayo. Throughout the last three days of interesting, most turtles were within the marine reserve. Half of the turtles were in or near the Gulf of Papagayo during at least part of the interesting interval. Our results suggest the current marine reserve should be expanded to further protect interesting leatherbacks.

Williams, F. J., University of Miami, Miami, USA; ewilliams@rsmas.miami.edu

WIN-WIN INFORMAL AND FORMAL EDUCATION OPPORTUNITIES AS PART OF A COMMERCIAL CRUISE LINE AND ACADMIC PARTNERSHIP

In 2000, a cooperative agreement between Royal Caribbean Cruises, Ltd. and the University of Miami established two staffed laboratories aboard the 3400 passenger cruise liner, Explorer of the Seas, with comprehensive meteorological and oceanographic instrumentation. Coincident with the laboratory operations, an informal public outreach component was incorporated into the onboard facilities, which consists of a evidence of our onboard visiting scientist lecturer or researcher and interactive educational galleries. This unique combination research and education facility has the potential to reach 180,000 family vacationers annually and to provide training and education extension programs throughout the Caribbean region. In addition to the ongoing public outreach, the program has provided a win-win combination with the nearly 300 past visiting research scientists gaining valuable experience in public outreach and presentations. Since the program inception, under-graduate education and K-12 teacher mentoring programs have been added as extensions to the original outreach component of the program at very low cost. The program continues to introduce innovation and quality educational opportunities through this partnership. This presentation will attempt to evaluate and quantify the impact of five years of operation.

IMPACTS OF LAND COVER AND USAGE ON WATER QUALITY IN WESTERN LAKE ERIE WATERSHEDS

Land cover and usage classification were conducted on the Maumee and Sandusky watersheds for 2006 using ERDAS Imagine 9.1. Rock Creek and Honey Creek sub-watersheds classifications were extracted from the Sandusky watershed. Two accuracy assessment tests were performed overall accuracy and Kappa analysis. Water quality data was provided by the Water Quality Lab at Heidelberg College; concentrations of SS, TP, SRP, NO3, and TN were analyzed over the 2006 growing season. Land cover accuracy tests were fair assessments for both watersheds; land usage accuracy tests were strong assessment for both watersheds, except for Sandusky's cloud cover imagery which was fair assessment. The water quality data shows that flow has no correlation on concentrations of non-point source pollutants. Traditional Tillage has a higher impact on water quality degradation than Mulch and No Tillage. Soybeans have the highest impact on water quality degradation and corn has the lowest impact. Sub-watersheds had higher fluctuations of non-point source pollutants than the watersheds. Honey Creek sub-watershed and Sandusky watershed have a higher impact on water quality degradation than Rock Creek sub-watershed and Maumee watershed.

FINGERPRINTING DEPOTED SEDIMENTS IN A TROPICAL ESTUARY: A GEOCHEMICAL APPROACH

Accelerated soil erosion is a major environmental issue world-wide. Land use practices such as agriculture, urbanization and poor cultivation practices have contributed to the rapid loss of topsoil in the landscape. Increased sediment inputs to coastal environments have the potential to not only alter natural ecosystem functions, but also facilitate the transport and deposition of pollutants in these systems. A step towards addressing issues associated with enhanced sedimentation rates in estuaries is to identify the potential source areas within associated watersheds. In this study, sediment fingerprinting, a technique commonly used to identify sediment provenance was used to determine the origins of material in a tropical estuary. Grain-size analyses, X-ray diffraction as well as gamma spectrometry provided signatures for the determination of sediments deposited in the estuary. Results of this study will contribute to a larger project, examining the relationship between soil erosion in watersheds and sedimentation rates in the tropical estuaries in the island of Puerto Rico. Additionally, insights provided may potentially lead to better management practices.

COMPARISON OF IN SITU SURFACE MEASUREMENTS OF NONLINEAR INTERNAL WAVES WITH THOSE OBTAINED FROM REMOTE SENSING

During the summer of 2006, a vast array of instruments was deployed east of the New Jersey coast in shallow water near the shelf break. The Nonlinear Internal Waves Initiative (NLWII) was one component of an intensive set of measurements that included surface vessels, surface platforms, satellite and ship-based radar, and a variety of sub-surface moorings in an unprecedented attempt to characterize the internal wave field while simultaneously measuring acoustic propagation at a number of frequencies and using a number of signals. Among the surface measurements were those from Air Sea Interaction Spur (ASIS) buoys, which measured current, temperature, wave directional spectrum, wind speed and direction, and a number of other parameters within 15 meters of the surface, at two locations, 1 km apart. Measurements from these platforms will be discussed and contrasted with simultaneous data from measurements including ship and satellite-based remote sensors.

THE ROLE OF ORGANIC NUTRIENTS IN SUSTAINING EXPORT PRODUCTION AND CLOSING NUTRIENT BUDGETS OVER THE SUBTROPICAL NORTH ATLANTIC

Over the subtropical North Atlantic, there are two long standing questions as to how export production is sustained and how nutrient budgets are closed? These questions are addressed through a combination of field cruises in 2004 and 2005, and application of coupled circulation-nutrient and inverse models. The surveys found elevated dissolved organic nitrogen (DON) and phosphorus (DOP) in the surface waters in the tropics, associated with upwelling zones. The modelling study suggests that the transport and recycling of DOP is important in sustaining export production, particularly over the eastern side of the basin, accounting for up to 70% of the necessary phosphorus supply. DOP is less important due to its refractory content. The inverse model is applied to sections along 26N and 36N, which reveals an overall southwards transport of inorganic nutrients linked to the overturning. Between the sections, the transports imply a net loss of nitrate and phosphate. This loss is partially offset by the northwards transport of DON and DOP from the tropics, as well as augmented by smaller atmospheric inputs of nitrogen and phosphorus.

ADVANCES IN AUTONOMOUS BENTHIC SURVEYING AND CHARACTERIZATION OF BENTHIC HABITATS

Our research is focused on delivering advanced tools for marine scientists mapping and characterizing benthic habitats. Autonomous Underwater Vehicles (AUVs) can provide high-resolution, geo-referenced imagery of the benthos. While the imagery itself is useful for qualitatively characterising habitat composition, the volume of data can become unwieldy when trying to extract summary statistics. For AUVs to become truly relevant for qualitatively characterising habitat composition, the volume of data can become unwieldy when trying to extract summary statistics. For AUVs to become truly relevant for qualitatively characterising habitat composition, the volume of data can become unwieldy when trying to extract summary statistics. For AUVs to become truly relevant for qualitatively characterising habitat composition, the volume of data can become unwieldy when trying to extract summary statistics.
that can be related to underlying processes of interest. We are pursuing three areas of research to make autonomous marine systems useful in this context: 1) Terrain-aided and self-consistent mapping and navigation using stereo imagery and acoustic multibeam data. 2) Automated and semi-automated interpretation and classification of visual, acoustic and chemical data to produce estimates of distribution and abundance. 3) Repeatable and adaptive surveys based on 1) and 2) to enable change detection and efficient and/or exploratory surveys respectively. We present details of these research areas and results from surveys on the Great Barrier Reef and Ningaloo Reef in Australia.

DO ULTRAVIOLET (UV) TOLERANCE AND PHOTOTOENZYMATIC REPAIR VARY ACROSS TROPHIC LEVELS FROM BACTERIA AND PHYTOPLANKTON TO ZOOPLANKTON AND FISH?

The size, mobility, and trophic position of an organism may influence the extent to which it can utilize different defenses against changes in potentially damaging UV radiation. We used a specialized photostat that separates out photoresponse wavelengths from shorter- and longer-damaging UV-B wavelengths to examine overall UV tolerance as well as the relative contribution of photoenzymatic repair (PER) to UV tolerance in a range of aquatic organisms. UV tolerance varied among species with LED values ranging from less than 20 to over 350 J m-2. The contribution of PER to UV tolerance ranged from less than 10% in two benthic invertebrates to over 90% in a bacterium and a protozoan. Neither UV tolerance nor the prevalence of PER showed any consistent relationship to organism body size. In most taxa the overall level of UV tolerance was less than the equivalent of a single day of exposure during summer solstice, suggesting that either acclimation or a daytime refugia of shaded waters is necessary to avoid high levels of mortality in low DOC systems even under current UV exposure conditions.

MONITORING THE ATLANTIC MERIDIONAL OVERTURNING CIRCULATION USING A COMBINATION OF ALTIMETER AND ARGO DATA

In the far North Atlantic, at latitudes north of the boundary current separation, much of the meridional overturning circulation is confined to the ocean interior. Away from the steep ocean boundaries, the Argo array of profiling floats provides absolute velocity at depth and hydrographic data from the surface to 2000 m. By combining float data with altimeter data, spurious warming and cooling error can be reduced and accurate estimates of time-averaged, three-dimensional geostrophic velocity can be determined. In the far North Atlantic, such velocity estimates provide a de facto estimate of the upper, northward flowing limb of the overturning circulation. Results from an estimate of the three-dimensional velocity field in the far North Atlantic will be presented, along with inferred estimates of the overturning and net northward heat transport for the period from 2003 to 2007.

NOAA AND IOOS

The Integrated Ocean Observing System (IOOS) is a nationally important infrastructure that will enable many different users to characterize, understand, predict and monitor changes in coastal and ocean environments and ecosystems. This infrastructure is critical to understanding, responding and adapting to the effects of severe weather, global- to regional climate variability, and natural hazards. NOAA owns and operates much of the coastal and ocean observing and data distribution infrastructure. In late 2006, NOAA decided to standup an IOOS Program Office that will provide a central focal point for IOOS activities within NOAA and with our regional and other federal partners. In the near-term NOAA will concentrate on developing a data integration framework. A fully operational data integration framework will take significant time to develop. Education is a cross cutting thread throughout IOOS. The value of ocean education cannot be overstated. IOOS can bring ocean observing into the classroom, which will allow a better understanding of importance of the ocean and make the ocean more than just a deep blue mystery.

TURBULENT BORE WAVE EVOLUTION: COMPARATIVE RESULTS FOR A NON-BARRED AND BARRLED BEACH

Turbulent bore waves formed after wave breaking on beaches have been studied in the field with natural incident waves and in laboratory wave tanks for monochromatic and realistic wave spectra. We extend our previous research on the subject of turbulent bore evolution by adding a bar to the 1:25 sloped linear beach previously in use in the Max Hammond Wavetank at SRI, and performing detailed spectral investigations into the phase evolution and energy transfer for differing wave initial conditions. We study turbulent bore evolution to examine a simplified example for non uniform beaches, a beach with a bar. We study the evolution of differing initial wave spectra in detail, to determine the effects of the bar on the overall behavior of the incident wave field, focusing on the resulting turbulent bores. We test scalings derived from our uniform slope bottom results to determine their applicability to non uniform bottom profiles, and develop new scalings based on our current results. We investigate breaking wave harmonic structure for uniformly sloped and simply barred bottom profiles. We investigate the differing evolutionary pathways to breaking of spilling and plunging waves in the spectral domain using a beampath approach, wherein we estimate the beampaths for the evolving waves and from that extract energy transfer estimates, which are compared for the differing breaker types to determine if any underlying differences exist.

ESTIMATING THE PERMEABILITY OF COASTAL AND SEAFLOOR SANDS

Knowledge of the permeability of coastal sediments is required for understanding submarine groundwater discharge (SGD) and porewater transport, but studies of marine sediments typically report grain size analyses and porosity rather than permeability. Here data from 39 case studies were used to assess any consistent relationship of empirical expression linking permeability to grain size for clean sands from coastal environments. All samples fell between 2x10-1 and 4x10-3 m2, and the empirical expressions estimated sediment permeability to within an order of magnitude or less, depending on the sedimentary environment (inter-tidal, near-shore, continental shelf). Core-scale permeameter tests produce permeabilities up to 1.5 orders of magnitude lower than field-scale hydraulic tests. In situ probe tests agreed well with permeameter tests, suggesting that coring does not alter permeability significantly. Empirical estimates of permeability based on grain size are not appropriate for heterogeneous sediments, for example settings that include clay lenses or other layers
of different permeabilities. Because layering is very common in coastal and shelf environ-
ments, it is recommended that permeability measurements be routinely included on
undisturbed samples when characterizing sedimentological properties of these deposits.

TRICOSAN LONG-TERM TRACER FOR SEWAGE EFFLUENT IN ESTUARINE SYSTEMS
Pharmaceutical and personal-care products (PPCPs) and their degradation products are
introduced into the environment through sewage effluent. Once such PPCPs, Triclosan,
undergoes photodegradation and has an affinity for adsorbing onto organic rich particles
in aquatic systems. We can show Triclosan at a mean concentration of 30-35ng/g by
site (total range 3-70ng/g) from the George Washington Bridge to the open harbor. This
includes a) monthly deposition (determine by Jodine-131 in surface sediments) b) short-
term deposition (determined by Beryllium-7) of over the last 10 months at depths up to
10cm, and c) yearly retention times with deeper cores up to 40cm in depth. We can also
show that the variance within cores is not due to degradation processes, but rather can
be explained by the physical dynamics of the system. Triclosan may prove to be a modern
tracer for sewage effluent and a suit of anthropogenic compounds released annually.

NITROGEN FIXATION HOTSPOTS? AREAS OF PERSISTENT SUMMER CHLOROPHYLL BLOOMS IN THE Oligotrophic Gyres
Chlorophyll blooms constantly develop in the oligotrophic NE Pacific in late sum-
mer, isolated from both land masses and any sources of higher chlorophyll waters. The
environment and timing of the blooms are conducive to nitrogen fixers, which require
a relatively stable water column. A better understanding of the ubiquity of summer chlo-
rophyll blooms could improve our estimate of the global nitrogen fixation rate. Here,
global SeaWiFS chlorophyll data from 1997-2007 are examined, and similar blooms are
found to occur in five other areas within the oligotrophic gyres. Two of these are regions
where blooms have been previously identified: the SW Pacific and off the southern tip
of Madagascar. Previously unreported summer blooms are also identified: the NE and SW
Atlantic and in a band along 10°S in the Indian Ocean. There is considerable variation in
the intensity and frequency of blooms in the different regions. Similarities and differences
between the location of the summer chlorophyll blooms and estimates of the global distri-
bution of nitrogen fixation will be made.

PHYSICAL AND ECOLOGICAL INTERACTIONS IN CREEK HEADWARD EROSION.
The Santfe River Delta in South California is the largest deltaic complex on the east coast
of the United States and is characterized by extensive tidal wetland. Measurements from
geo-rectified aerial photographs indicate that Santfe saltmarshes contain numerous,
relatively short tidal creeks that are eroding headward at a rate of 2 m/yr. These creeks,
which average 100 m in length and 1-2 m in width, terminate in a dendritic structure on
the marsh platform. Current velocity measurements, geotechnical sediment analyses, and
field observations of vegetation density and crab activity suggest that creeks organize
themselves primarily as a function of marsh topography and that creeks are initiated at marsh edges and
gradually erode toward the interior of the marsh. We hypothesize a positive feedback ex-
ists between crab burrowing and Spartina alterniflora dieback. Tidal flow excess 15 cm/s
across the marsh platform and 40 cm/s in tidal creeks. Unvegetated, bioturbated sediment at
creek heads is susceptible to erosion by tidal currents. We are exploring the impact of
accelerated sea-level rise and attendant increasing flooding and draining of the marsh
platform on the dissection of the marsh.

MODEL VALIDATION FOR 2D SURF-ZONE CIRCULATION
In this study we investigate the ability of a depth- and phase-averaged (2DHz) numerical cir-
culation model (ShoreCirc), forced with a spectral wave model (SWAN), to predict measured
alongshore currents during the SandyDuck 1997 experiment. The SandyDuck experiment
provided a long (~months) continuous and spatially-extensive time series of observations,
allowing for a comprehensive model-data comparison over a variety of field conditions.
We will assess model skill through the duration of the experiment, including several days where
the observed circulation was significantly alongshore-nonuniform. During these nonlinear
cases the 2DHz equations of motion are often assumed to be accurate, but the literature is
relatively lacking in field comparisons. Indeed, preliminary results show that these more
complicated flows tend to be poorly predicted. We address specific causes for model error,
and attempt to justify the use of 2DHz models for surf-zone forecasting.

MONITORING GLOBAL SEA LEVEL RISE AND ITS CAUSES
Improving our understanding of sea-level rise and variability, as well as reducing associated
uncertainties, depends on the availability of adequate observations – an issue addressed at a
recent WCRP Workshop (http://wcrp.wcrp-jasmin.fr/Workshops/SeaLevel/). While recog-
nizing the need for new systems and renewed focus on conventional methods, we at the Workshop for existing systems to collect sustained, systematic observations. These in-
clude those directly observing sea level - the Jason satellite altimeters and GLOSS network of
~300 tide gauges. To estimate the change in sea level due to an increase in ocean volume (e.g.,
thal expansion), the Argo array of profiling floats observes the upper-ocean in ice-
free areas. To estimate that due to an increase in ocean mass (e.g., melting ice caps
and glaciers), GRACE observes the time-variating gravity field. Additional systems observe
changes in ice sheet & glacier topography and thickness - satellites utilizing radar and laser
altimeters, complemented by aircraft and in situ observations. All of these measurements
require a robust and stable International Terrestrial Reference Frame. Once launched,
G.OCE will observe the time-invariant gravity field to determine the precise geoid.

CHARACTERIZATION OF ZOOPLANKTON DIET AND PARTICLE FEEDING IN THE MESOPLAGIC ZONE USING FATTY ACID LIPID BIOMARKERS
Mesopelagic food webs are poorly understood, although it is hypothesized that consum-
ption of sinking particles and carnivory are essential feeding modes. We used fatty acid (FA)
biomarkers to characterize zooplankton diet and large particle composition in the meso-
pelagic zone (150-1000 m) at two contrasting time-series sites in the subarctic (K2) and
subtropical (ALOHA) Pacific ocean. Total fatty acid concentration was 14 times higher in
zooplankton tissue in K2, largely due to FA storage by seasonal vertical migrants. Fatty acids specific to diatoms, dinoflagellates, and bacteria measured in zooplankton implied more diatom-derived food sources at K2 vs. more dinoflagellate- and bacteria-derived
food sources at ALOHA. These FAs were also found in similar proportions in particles at
all measured depths, evidence that mesopelagic zooplankton consume sinking particles.
Carnivory indices increased significantly with depth at ALOHA, and exhibited distinct peaks at K2, representing an increase in dependence on other zooplankton for food. This comparison of zooplankton and particle FA biomarkers between contrasting environ-
ments will help our understanding of how variations in particle repackaging and carnivory
can affect the biological pump.

VALIDATION OF AATS RUSING THE ISAR RADIO METER - RESULTS SINCE 2004 AND A NEW APPROACH FOR A MATCH-UP QUALITY INDICATOR
The Infrared Sea surface temperature Autonomous Radiometer (ISAR) was specifically
developed for the validation of satellite SSTskin temperature data products, in particular
for the Advanced Along Track Scanning Radiometer (AATSR). Two ISAR instruments
have, since March 2004, been deployed on a continuous (one on, one off) basis on the
P&O ferry M/V Pride of Bibao, which sails between Portsmouth (UK) and Bilbao (Spain)
on a 3 day repeat cycle. A number of ancillary measurements, such as wind speed, short
wave radiation, long wave radiation, air temperature and humidity are recorded. In

presenting the validation results since 2004, we shall discuss the error budget associated with
match-ups. A novel quality indicator will be specified, using both ancillary and satellite data. This
is proposed as a robust and objective way for specifying the quality of each match-up, which is necessary in order to refine the quality assessment of the data products for AATSR.

TIDAL CIRCULATION IN A STARTTED ESTUARY
The three-dimensional tidal circulation in an elongated two-layer basin is described with a
linear model in the p-plane. Rotation alters the flow by introducing a lateral circulation of
comparable magnitude to the axial flow. In a two layer system, fluctuations at the interface
are driven by convergences of the lateral flow noted above, with the result that in certain
cases the interfacial amplitude can be much larger than the amplitude of the free surface,
and the resulting current field can be quite different from the case without stratification
OBSERVATIONS OF WAVE- AND WIND-INDUCED REYNOLDS STRESSES IN A WINDY BAY

Observations of current velocities and pressure were obtained at fixed locations in a windy bay in order to determine the spatial distribution of Reynolds stress in the water column and its temporal variability. Measurements were obtained over a fortnight in Bahia Concepcion, Mexico in January 2005. The observation period was characterized by sea-breeze peaks around 1000 m/s and wave periods typically less than 5 seconds. The maximum Reynolds stresses were restricted to the upper 2-3 meters near the surface. The variability of the Reynolds stresses associated with these observations is described in the context of theoretical results of wave-induced and wind-driven flows. The theory shows that high-frequency wave fields produce shear stresses due to the earth’s rotation of the same order of magnitude as the wind stress, and should be included in the total stress.

TRACE ELEMENT BEHAVIOR IN A FRESHWATER-SEA WATER MIXING ZONE WITHIN PERMEABLE SEDIMENTS

Sandy barriers developed during the Holocene transgressing sea are common features of many coastal regions throughout the world and often restrict the flow of continental runoff to the ocean. One such area is along the Southern coast of Brazil where an ca. 600 km barrier has created the Mirim-Patos Lagoon system, the largest in South America. Because of the limited surface connection of the lagoon system to the ocean, a substantial fraction of the regional freshwater runoff is transported through the permeable sands of the barrier within which freshwater and seawater mix. Groundwater samples collected from well points along an approximately 300 km length of the barrier indicates that freshwater and sea water mix within a narrow band beneath the ocean beach. Concentrations of Ba, Cd, Co, Cu, Fe, Mn, Mo, U and V, relative to salinity within the sediments pores water, exhibit considerably different behaviors from similar relationships observed for surface water. Results suggest that a combination of redox conditions and residence time are the controlling factors in producing this different behavior.

WRINKLES IN SPACE AND TIME: PATTERNS OF PLANKTONIC THIN LAYERS AND VELOCITY SHEAR IN COASTAL SYSTEMS

High-resolution vertical profiles of hydrographic and bio-optical properties permit the detection of planktonic thin layers in relation to local velocity gradients. The spatial extent and persistence of such layers can have considerable impact on local ecosystem dynamics. We use our extensive dataset of over 2000 such profiles from Monterey Bay, CA, the Oregon continental shelf and the Florida Keys, WA, from 5 different summers (1997, 1998, 2004, 2005, 2006), to characterize the spatial and temporal patterns of planktonic thin layer occurrence and persistence in relation to local velocity gradients. We have found that planktonic thin layers in these coastal regions occur over a range of temporal scales (minutes to hours) and spatial scales (kilometers to 10s of kilometers). We present these results in the context of the wind and tidal forcing of localized vertical mixing, which defines the threshold conditions for thin layer persistence in these coastal areas.

APPLICATION OF PALEOEOLOGY TO THE 50-YEAR EVERGLADES RESTORATION PLAN AND BEYOND

Paleoecologic data from sediment cores in Biscayne Bay, Florida Bay and southwestern coastal Florida are being compiled to examine anthropogenic and natural change in the south Florida estuarine ecosystem. These data provide restoration planners with information needed to set targets and performance measures for the estuaries. The Comprehensive Everglades Restoration Plan, however, does not factor sea-level rise into the 50-year planning cycle. Analyses of faunal remains in cores from the three estuarine regions of south Florida indicate that relative sea level has been rising over the last 1000 years or more, confirming earlier studies. Additional dating is required to determine the exact timing of this change and whether it was due to sea-level rise, decreases in freshwater supplied to the estuaries, or a combination of the two. Nevertheless, the highest elevation in south Florida today is ~2.5 meters above sea level, and even conservative estimates project a rise of 40 cm over the next century. Thus, it is critical to establish the patterns, causes and impacts of rising sea level and factor them into restoration planning.

VERTICAL ZONATION AND DISTRIBUTIONS OF CALANOID COPEPODS THROUGH THE LOWER OXYCLINE OF THE ARABIAN SEA OXYGEN MINIMUM ZONE

We provide the first comprehensive analysis of calanoid copepod vertical zonation and community structure at midwater depths (300-1000 m) through the lower oxygen gradient (oxycline) (0.02 to ~0.3 ml/L) of an Oxygen Minimum Zone (OMZ). Zooplankton were collected in day and night vertically-stratified MOCNESS tows during the JGOFS Arabian Sea study. Based on calanoid species zonation, three unique subzones with specialized community interactions occurred through the lower oxycline. These subzones were termed the OMZ Core, the Lower Oxycline, and the Sub-Oxycline. The calanoid community was most diverse in higher oxygen, but species rank order of abundance was similar in the Lower Oxycline and Sub-Oxycline. No diel vertical migration at these midwater depths was observed. A common oxycline species was detritivorous. Vertical zonation of copepods through the lower OMZ oxycline is a complex interplay between physiological limitation by low oxygen, potential predator control, and potential food resources. Pelagic OMZ and oxycline communities, and their ecological interactions in the water column and with the benthos, may become more widespread in the future ocean, if global warming increases OMZ extent.

ABUNDANCE AND DISTRIBUTION OF TWO IMPORTANT DECAPOD LARVAL SPECIES, CALLINECTES SAPIIDUS AND MENIPPE MERCENARIA, IN THE GULF STREAM OFF SOUTHEAST FLORIDA, USA

Knowledge of the abundance and distribution of the larval of commercially important crustaceans of the nearshore and offshore waters of Florida’s eastern coast is minimal, yet...
crucial, for future fisheries management implications. Analysis of the larval abundance of two commercially important crab species, blue crab, Callinectes sapidus, and stone crab, Menippe mercenaria, was conducted following bimonthly cruises in 2007 at 3 stations along an East-West transect in the Gulf Stream east of Port Everglades, Ft. Lauderdale, Florida. Preliminary analysis of abundance of total pleocytema larva revealed a fourfold increase in abundances from February and March to May and July. The combination of the species’ distributions and abundances, along with recorded seasonal changes in temperature and salinity, are expected to be indicators of the species’ peak spawning periods. Additionally, vertical distribution of the larva in the water column is expected to reveal the use of currents to disperse into and out of parent populations as recorded by acoustic Doppler current profilers.

CONNECTING THE CAPE BASIN WITH THE SOUTH ATLANTIC SUBTROPICAL GYRE USING FOURTEEN YEARS OF SATELLITE ALTIMETRY: ASTTEx IN THE BROADER CONTEXT

As part of the Agulhas-South Atlantic Thermohaline Transport Experiment (ASTTEx), sea level observations from the TOPEX/POSEIDON (T/P) and Jason-1 satellite altimeters are combined to obtain a 14-year record of mesoscale and large-scale ocean variability within the South Atlantic basin. Modes of non-seasonal sea level variability are evaluated in non-overlapping subregions of the South Atlantic, with the goal of understanding the relationship between variability at interannual time scales in different parts of the basin. Of particular interest are relationships between variability in the vicinity of the ASTTEx mooring array, which spanned the Agulhas eddy corridor in the eastern Cape Basin between January 2003 and April 2006, and variability in regions to the east and west. The primary mode of gyre-scale variability, representing interannual variations of sea level within a broad region of the center of the subtropical gyre, is weakly correlated with variability in the Cape Basin. Time-dependent variations associated with the second mode of gyre-scale variability closely track interannual variations in sea level in both the western and eastern part of the Cape Basin, with the relationship being particularly strong beyond the region of the most intense eddy mixing. Variations in sea level at the Agulhas Retracement region occur primarily at the high frequencies characteristic of eddy shedding and contain relatively little interannual time scales.

IN-SITU MEASUREMENTS OF WAVES, TIDES, BEDFORMS AND SEDIMENT TRANSPORT IN THE NEARSHORE ZONE

The LEACOAST2 project (http://pcwww.liv.ac.uk/civil/CRG/leacoast2/) is studying the effect of a shore-parallel breakwater system on the evolution of coastal morphology at Sea Palling on the east coast of England, facing the southern North Sea. Here there are strong tidal currents, and occasional storm wave conditions where the mixed sediment, ranging from coarse sand to silt, supplied from the soft boulder clay cliffs to the north, is quite mobile under tide and wave stirring. The breakwaters have trapped sand in embayments with tombolos and salients behind the breakwaters. As part of this project data were collected from 3 instrumented tripods deployed near the breakwaters, during 2 field campaigns (March-May 2006 and October 2006 - January 2007). The instrumentation includes acoustic and optical instrumentation (ADCP, ADV, LISST and bedform scanners). One tripod was deployed in the intertidal zone. The others were deployed in water depths of 6-8 m (tidal range is about 2m). A large dataset has been successfully obtained. Here we present a description of the hydrodynamic conditions, suspended sediments and bedforms, with first results for the suspended sediment flux and bedload transport.

INFLUENCE OF FLUVIAL AND MARINE ENERGY ON LAND-SEA SEGMENTATION: INSIGHTS FROM THE WAIPOA SEDIMENTARY SYSTEM, NEW ZEALAND

Marine environments are typically non depositional in high supply river-fed dispersal systems under Holocene highstand conditions. Over the last Holocene the shoreline of the high-supply Waiapoa sedimentary system (WSS) has filled in Poverty Bay, prograding over 12 km in the last 7 ka. Sand and gravel are largely retained in the alluvial plain and shoreface, but the majority of the mud-dominated total load reaches the sea. However the nearshore is predominantly sand, and the outer bay and shelf appear to largely bypass this mud, with minor accumulation driven by tectonic subsidence on the shelf. In contrast, other high supply systems (FLGanges) commonly show significant mud accumulation in shelf chlinoforms. Sedimentary process modeling suggests that mud bypass is due to relatively high marine energy, such that the WSS shelf is effectively a chlinoform topset. Furthermore, relative absence of mud in the nearshore suggests that shoreline progradation in the WSS may be largely dominated by fluvial processes, despite the high marine energy, demonstrating the complexity in fluvial-marine influences on shoreline migration.

ANOMALOUS T-S STEPS AND SUBTROPICAL FRONT MEANDERS IN THE UPPER SOUTHEAST INDIAN OCEAN

During the CLIVAR/CO2 repeat hydrographic survey along the 185 line in February and March 2007, anomalous T-S steps were observed in the Subtropical Front of the Southeast Indian Ocean, north of the Kerguelen Plateau. These steps are isothermal and isolineal layers of warm, salty intrusions, observed at depths of 200-400 dbar. The biggest step is 100 m thick, spans 0.1 (PS-78) in salinity and 0.4°C in temperature. Water data from nearby Argo float data that T-S properties of these steps are found at the base of winter mixed layers and equatorward of the Subtropical Front. It is hypothesized that meandering of the Subtropical Front during the 2006 Austral winter transported subtropical winter mixed layer water poleward into the Subantarctic Zone. The subsequent lack of mixing below the summer mixed layer allowed the subtropical water to survive as isolated homogeneous layers through the summer months. The presence of these anomalous T-S steps represents increase in upper ocean stratification, which could hinder formation of deep winter mixed layers in the Subantarctic Zone, thus indirectly affects local formation of Subantarctic Mode Water.

OASES IN AN OCEAN DESSERT

The western subtropical north Pacific Gyre is highly oligotrophic. Throughout the year, its chlorophyll-a concentration is mostly <0.05 mg/m³ and the top of its nutricline is as deep as 200 m. It is intriguing to ask whether this oligotrophic ocean desert can ever get ‘greener’, i.e. is there any possibility for phytoplankton blooms to occur? Using the synergy of 5 types of remote sensing data, including (a) ocean colour data (chlorophyll-a concentration and ocean colour spectra) from the NASA SeaWIFS (Sea-viewing Wide-Field-of-view Sensor) satellite, (b) aerosol data from the NASA MODIS (Moderate Resolution Imaging Spectroradiometer) satellite, (c) cloud-penetrating SST data from the TRMM (Tropical Rainfall Measuring Mission) satellite, (d) Sea Surface Height Anomaly (SSHA) data from the TOPEX/POSEIDON and JASON-1 satellites, and (e) ocean surface wind vectors from the NASA QuikSCAT satellite, here we analyze one complete year of data from 2003. We found that indeed blooms occurred in this ocean desert and the nutrients fueling the blooms might have originated from atmospheric depositions and from vertical mixing induced by super-typhoons.

INITIAL IchthyoplankTON ANALYSIS OF THE MACKENZIE PLUME FRONT

Annually the Mackenzie River transports approximately 300 km³ of freshwater to the Beaufort Sea. In summer this discharge creates a 60,000 km² plume over the Canadian Beaufort Shelf that can exceed 6 m in depth. In the present study ichthyoplankton assemblages associated with the plume front were sampled during July and August. The ichthyoplankton was comprised of six taxonomic families of marine fish. Arctic cod (Boreogadus saida), Pacific herring (Clupea pallasi pallasi) and sandlance (Gadus liparideus) were the most abundant larval fish. Analysis revealed significant size differences among Arctic cod were associated with different generations across the plume. A preliminary analysis suggests that the plume plays an important role in the ecology of marine larval fish on the Canadian Beaufort Shelf.

CLIMATE DRIVEN HABITAT BOUNDARIES: TRANSLATING COUPLED PHYSICAL-ECOSYSTEM DYNAMICS TO THE MID-ATLANTIC FISHERIES COMPLEX
Understanding the effects of climate variability and change on ecosystem dynamics is one of the most important and complex problems facing modern ecology. Analysis of climate effects on habitat boundaries and conditions is a powerful approach to this problem. Zooplankton can serve as holistic integrators of habitat conditions and provide a critical linkage between primary production and higher trophic levels. We used spatial techniques coupled with zooplankton community composition analysis to depict changes in fisheries habitat resulting from differing interannual hydroclimatic conditions in Chesapeake Bay, one of the most important fishery habitat areas in the Northeast US Shelf Large Marine Ecosystem. The dominant signal revealed in the analysis suggests that the timing and nature of the winter-spring transition determines the quality, quantity, and nature of fish nursery habitat as evident in the hydrographic, zooplankton community, and fishery recruitment profiles over the last two decades. These results illustrate the important linkages between physical processes and ecosystem dynamics that occur through variations in habitat conditions and boundaries and eventually affect upper trophic levels.

PERCEPTION OF PRESSURE PULSES: PATCHES, POROSITY AND PEREGRINATION

Hydraulic activities of infauna often result in transient pressure pulses in the porewater which can be measured with pressure sensors. The resulting measurements taken across a gradient of densities allow calculation of biogenic advective forces and resulting porewater flux. We have measured such pressure transients for a variety of species including arenicolous and neild polychaetes and tellinid bivalves and have been able to associate wave forms of those most active with particular animal behaviors. However, in other cases animal behaviors have resulted in no detectable pressure pulses. This absence appears to be the result of the following: (1) uninterrupted connections between the animal and the overlying water column, (2) high permeability of the sediment column, or (3) highly forced burrows. If pressure transients are detectable at distances due to animal activities, then advective forces may be significant. How often does this occur and how common are the organisms and are these the elements that drive the assemblage?

RECONSTRUCTING RELATIVE WAVE HEIGHTS RESPONSIBLE FOR HURRICANE-INDUCED DEPOSITS

Inverse modeling techniques are used to reconstruct flooding conditions for hurricane-induced overwash deposits from Laguna Playa Grande, a back-barrier lagoon located on the island of Vieques, Puerto Rico. Grain-size distributions for siliclastic sediment collected from these overwash deposits fine landward (away from the barrier and towards the mainland). A simple advective/settling model can explain this pattern of lateral sorting and is used to constrain the relative magnitude of probable flooding events. The deposit attributed to the 1928 AD San-Felipe hurricane is used as a modern analogue to test the technique, which produces reasonable estimates for wave heights that exceed the barrier during the event. A 5000 yr reconstruction for local flooding intensity is developed. This reconstruction shows that although the Vieques overwash record indicates periods in which hurricane strikes have occurred more frequently, no event appears to have carried coarse-grained sediment any farther than storms occurring during the historic period. Thus none of the 29 overwash deposits analyzed in this study appear to be associated with an anomalously large hurricane or tsunami event, with a sediment transport competence significantly greater than that of historical hurricanes.

RECRUITMENT IN UPWELLING-DOMINATED REGIONS DRIVEN BY THE MOVEMENT OF NEARSHORE FRONTS

A field study was conducted during the upwelling season in northern Monterey Bay to assess the influence of nearshore fronts on the recruitment of barnacles and nearshore fish species. During the upwelling season, the northern Monterey Bay is characterized by a distinct upwelling shadow. This water body creates strong fronts with cold, recently upwelled waters of the outer coast. Juvenile fish and barnacle recruitment were sampled at four sites (two within the upwelling shadow, two within the outer coast upwelling plume concurrently with physical oceanographic variables. Sites located within the upwelling shadow showed consistently low recruitment levels, while sites located within the upwelling plume showed distinct pulses of recruitment associated with the nearshore front. Northward movement of the upwelling shadow Front during relaxation events did lead to recruitment pulses. However, the location of the upwelling front could move also in response to local forcing leading to interannual recruitment pulses at outer coast sites. These results highlight the importance of nearshore oceanographic features in defining larval dispersal and observed recruitment patterns.

AMMONIA CONCENTRATIONS AND PROCESSES IN OLIGOTROPHIC WATERS

In wide areas of the world’s oceans phytoplankton productivity is limited by the availability of nitrogen. Surface waters in the Atlantic Ocean and Tasman Sea, are typically depleted of dissolved inorganic nitrogen species. Quantification of biogeochemical processes would not be practicable for these waters in the absence of reliable nutrient concentrations. An ammonium analysis technique is used based on ammonia gas diffusion across a Teflon membrane, followed by o-phthalaldehyde derivatization, and then fluorometric detection. Results from water column samples are presented from a research transect cruise from the UK, through both the oligotrophic north and south Atlantic gyres, to South Africa. Further results from a cruise in the Tasman Sea show fine scale near-surface profiles. Ambient concentrations of ammonia, often less than 5 nanomoles per litre, are reported showing a biologically derived maximum, over 100 nanomoles per litre, found at the top of the deep chlorophyll/nitrate maximum zone, which is characteristic of oceanic waters. Fine scale sampling in the upper 10 metres of the Tasman Sea are discussed in the context of previous experiments investigating ammonium photo-production.

EVALUATION OF AN AUTOMATED OBSERVATION QUALITY CONTROL SYSTEM TO SUPPORT DYNAMIC OCEAN MODELS IN AN OPERATIONAL ENVIRONMENT

The Naval Oceanographic Office (NAVOCEANO) operates a suite of ocean models that assimilate large amounts of satellite and in-situ observations using the Navy Research Laboratory (NRL) developed Naval Coupled Ocean Data Assimilation (NCODA) system. The performance of these ocean models is sensitive to the quality of the observations they assimilate. This presentation will evaluate the implementation of NCODA’s automated Ocean Quality Control (OcnQC) system at NAVOCEANO, with emphasis on the QC of ocean temperature and salinity profiles. We will compare datasets that have been processed through OcnQC to the same profiles run through the present manual process. These data sets will include known error types such as gaps, surface spikes and depth offsets. The evaluation will also include the effects of various QC tuning options, such as buddy checks, comparisons with climatology and/or model analysis fields.

A DECADE OF ACOUSTIC THERMOMETRY IN THE NORTH PACIFIC (A): USING LONG-RANGE TRAVEL TIMES TO TEST GYRE-SCALE TEMPERATURE VARIABILITY DERIVED FROM OCEAN MODELS

Large-scale temperatures in the North Pacific were measured by long-range acoustic transmissions from 1996–2006. Acoustic travel-time data are inherently integrating, suppressing mesoscale variability and providing accurate measures of large-scale temperature variability with high temporal resolution, subject to the limitations of the ray path sampling. Even at gyre scales, the ocean is found to be highly variable, with significant changes occurring on time scales as short as a few weeks. The interannual variability is large compared to trends in the data. Travel times equivalent to the measured travel times have been calculated using objectively mapped 0.75 m temperature fields for the global ocean derived from satellite altimetry and profile data. Similar comparisons have also been made using travel times derived from the Estimating the Circulation and Climate of the Ocean (ECCO) model, constrained by satellite altimetry and profile data using data assimilation methods. In both cases the measured and calculated travel times are similar, but they also show significant differences. These results suggest that the acoustic travel times can be used to provide meaningful additional constraints on model behavior.
As part of the Lagrangian Transport and Transformation Experiment (LaTTE), concentration and acoustic backscatter profiles, respectively. Model calculated velocities calculated from the bottom boundary layer model ranged from approximately 6 - 8 cm s⁻¹ over the course of the sediment transport event. In order to quantify the magnitude, direction, and duration of sediment transport at the inner-shelf site during the hurricane passage, critical bed shear stresses were calculated using the Grant-Madsen-Glen model (Stiles and Glen, 2000) and compared with bed stresses calculated from measured waves and currents. Shear velocities calculated from the boundary layer model ranged from approximately 6 - 8 cm s⁻¹ over the course of the sediment transport event. Large amounts of suspended sediment transport occurred in the along-shelf direction towards the southwest. Model calculated cm s⁻¹ over the course of the sediment transport event. Large amounts of suspended sediments in plume sampled in the Hudson River buoyant plume during contrasting discharge regimes in April 2005, sampling was carried out immediately following a period of record high discharge which resulted in the formation of a large recirculation zone that occupied the entire New York Bight. In contrast, sampling in May 2006 was carried out under moderate discharge conditions that resulted in a characteristic southward flowing coastal current. Metals in both phytoplankton and zooplankton were generally enriched closer to the Hudson River, where dissolved metal concentrations were also highest. In contrast, however, silver and inorganic mercury in zooplankton were highest, further south in the plume, particularly near large sewage outfalls along coastal NJ. For some metals, concentrations in zooplankton were correlated with those in phytoplankton and model calculations indicate that trophic transfer was an important pathway of metal accumulation in plume zooplankton.

A NEW PARADIGM FOR STUDYING LARGE-SCALE COASTAL MORPHODYNAMICS: THE DISTRIBUTED COASTAL LABORATORY

A new frontier in coastal morphology involves study of interdependent suites of hydrodynamic processes, coastal and shelf morphologies, and temporal sequences of change on scales of hundreds to thousands of kilometers. The complex process suites that dominate large deltaic and coastal margin systems require a new approach to experimental investigations. Experiments conducted in coastal margins were conducted within field laboratories having horizontal dimensions of order 1-10 km. The next morphodynamic paradigm shift can be facilitated by Distributed Coastal Laboratories (DCLs) spanning the entire U.S. Atlantic and Gulf coast and shelf or the entire region of the American Pacific Coast (NOAA’s Integrated Ocean Observing System (IOOS)), the NSF Ocean Observing Initiative (OOI), NASA satellites and numerous regional observatories. The envisioned DCL will be enabled by a robust information technology (IT) infrastructure that links the existing resources owned and operated by a diverse community. The DCL Service Oriented Architecture will integrate information and disseminate data and model results to scientists in standardized formats including GIS-compatible maps of key variables. Results from the existing prototype can be seen at www.openoios.org and www.oosthys.org.

NON-HYDROSTATIC MODELING OF VEGETATION EFFECTS ON FLOW MOTIONS

A three-dimensional non-hydrostatic model is developed to study the effects of aquatic vegetation on flow motions. Vegetation is modeled as resistance that is introduced as drag in the momentum equation and drag-induced turbulence production in the turbulence closure. The model incorporates a generic vegetation boundary layer model that is first validated against open-channel flow experiments. The model is then applied to examine flows through submerged and emergent vegetation. In the case of 1-D flow over submerged vegetation, model results show that flows are retarded inside the vegetation layer and a maximum turbulent intensity occurs at the top of vegetation, consistent with model calculations. Suspended sediment concentrations were measured well with the measured current and acoustic backscatter profiles, respectively.

As an ADCP was deployed on the inner-shelf of Long Bay, South Carolina as Hurricane Ernesto traveled up the South Carolina coast in August 2006. As the storm approached the area and passed through Long Bay, simultaneous measurements of wind velocity, atmospheric pressure, current velocity profiles, wave characteristics, and water levels were collected. Sustained winds on the inner-shelf were over 35 m s⁻¹, while current velocity ranges from 40 to 50 cm s⁻¹ towards the south and west, respectively. Measured wave heights were approximately 2 meters at the relatively low energy inner-shelf site, although wave heights were reported to reach over 6 meters on the mid-shelf. In order to quantify the magnitude, direction, and duration of sediment transport at the inner-shelf site during the hurricane passage, critical bed shear stresses were calculated using the Grant-Madsen-Glen model (Stiles and Glen, 2000) and compared with bed stresses calculated from measured waves and currents. Shear velocities calculated from the boundary layer model ranged from approximately 6 - 8 cm s⁻¹ over the course of the sediment transport event. Large amounts of suspended sediment transport occurred in the along-shelf direction towards the southwest. Model calculated current and suspended sediment concentration profiles compared well with the measured current and acoustic backscatter profiles, respectively.

Sediment transport processes on the inner-shelf of South Carolina during Hurricane Ernesto

An ADCP was deployed on the inner-shelf of Long Bay, South Carolina as Hurricane Ernesto traveled up the South Carolina coast in August 2006. As the storm approached the area and passed through Long Bay, simultaneous measurements of wind velocity, atmospheric pressure, current velocity profiles, wave characteristics, and water levels were collected. Sustained winds on the inner-shelf were over 35 m s⁻¹, while current velocity ranged from 40 to 50 cm s⁻¹ towards the south and west, respectively. Measured wave heights were approximately 2 meters at the relatively low energy inner-shelf site, although wave heights were reported to reach over 6 meters on the mid-shelf. In order to quantify the magnitude, direction, and duration of sediment transport at the inner-shelf site during the hurricane passage, critical bed shear stresses were calculated using the Grant-Madsen-Glen model (Stiles and Glen, 2000) and compared with bed stresses calculated from measured waves and currents. Shear velocities calculated from the boundary layer model ranged from approximately 6 - 8 cm s⁻¹ over the course of the sediment transport event. Large amounts of suspended sediment transport occurred in the along-shelf direction towards the southwest. Model calculated current and suspended sediment concentration profiles compared well with the measured current and acoustic backscatter profiles, respectively.

Aggregated Transport and Transformation Experiment (LaTTE), concentrations of several trace metals (Hg, MeHg, Cu, Ag, Pb, Fe, and Ca) were measured in phytoplankton and zooplankton sampled in the Hudson River buoyant plume during contrasting discharge regimes. In April 2005, sampling was carried out immediately following a period of record high discharge which resulted in the formation of a large recirculation zone that occupied the entire New York Bight. In contrast, sampling in May 2006 was carried out under moderate discharge conditions that resulted in a characteristic southward flowing coastal current. Metals in both phytoplankton and zooplankton were generally enriched closer to the Hudson River, where dissolved metal concentrations were also highest. In contrast, however, silver and inorganic mercury in zooplankton were highest, further south in the plume, particularly near large sewage outfalls along coastal NJ. For some metals, concentrations in zooplankton were correlated with those in phytoplankton and model calculations indicate that trophic transfer was an important pathway of metal accumulation in plume zooplankton.
but mainly in the north and northwest of the subpolar North Atlantic. A sustained 30 to 40°Ftening trend of the late half of the 20th century in the subpolar North Atlantic and the recent trends in hydrographic properties. We demonstrate the possible impact of the one-big-loop circulation regime and a detached two-small-loop regime resulting in heat and salt transport. 

This paper presents a mechanism for interconnection and variability between the Arctic/Pacific through the wind-evaporation-SST (WES) feedback. The global response to a shutdown of the Atlantic meridional overturning circulation (AMOC) is investigated by conducting a water-hosing experiment with a coupled model. Our results show that in both shelf (DFe 3.5 nM) and deep basin (DFe 2 nM) waters, Fe-organic ligands in seawater samples collected during the Spring 2007 BEST cruise. Our measurements suggest that Fe-organic ligands are in excess of total dissolved Fe by 1-2 nM, suggesting that the organic ligands may help maintain the high concentrations of DFe in the water. Our error correction using the iteration procedure makes a substantial difference in the modeled ligand concentrations and stability constants.

The continuing thinning of the Antarctic ozone layer deems it necessary to study the effects of UV-B radiation on the marine microphytobenthos, a previously neglected group. The results of these studies offer new insight into timing and discriminating paleo-tsunami events in geological records and differentiating these from storm deposits, tsunami are one of the major natural hazards in the Caribbean; recent studies reveal that they strongly affect the coastal environment of even remote sites like the Islands of Curacao, Aruba and Bonaire (Lesser Antilles, Caribbean). Identifying paleo-tsunami events in geological records and differentiating these from storm deposits, however, remains a challenge. Here, we use sediment cores from distal coastal-marine and lacustrine sites to place better constraints on a known submarine slide that likely generated a ~15-m tsunami along the southwest coast of the Island of Curacao ca 14,000 years ago. A detailed core description, magnetic susceptibility and grain size measurements revealed a succession of storm deposits in marine sediments in the partial open bay areas, and tsunami deposits in lacustrine sediments in the rather storm protected Lagoon. The results of these studies offer new insight into timing and discriminating between distal paleo-tsunami and storm deposits in a paleoclimatic context.
group of primary producers. In the intertidal, recruitment of benthic marine diatoms was observed to increase at 0.6µm UV-B and PAR+UV-B (PAR=UV-A+PAR; PAR+UV-B=UV-A+UV-B) for 14 months. No UV effects were observed. In the laboratory, mechanistic effects of enhanced UV-B were studied. Diatoms were exposed to different time treatments of PAR and PAR+UV-A. PAR+UV-B was not compared due to the effect of changes in pH on the concentration and dynamics of PAR. PAR, we conducted a series of experimental studies in the Baltic Sea in summer 2007 within the frame of the SOPRAN (Surface Ocean PRocesses in the ANthropocene) project. At this time diazotrophs were the main primary producers. Thus, the relation between autotrophic N2-fixation and heterotrophic activity (uptake of radiolabeled Leucine) was determined and compared with PAR+UV-B concentration measurements to elucidate how production and fate of PAR may be altered due to short term responses to acidification. We observed that the amount of PAR as well as PAR+microbial activities were sensitive to changes in pH. Our results indicate a decrease of PAR concentration with increasing pCO2 under net heterotrophic conditions. Furthermore, significant correlations between PAR concentration and bacterial abundance suggest a tight coupling between the dynamics of acidic carbohydrates and bacteria dynamics. This study shows that manipulations of pH can affect microbial carbon turn-over and, hence, organic matter cycling.

THE INFLUENCE OF ANTHROPOGENIC MARINE SUBSIDIES ON TROPHIC DYNAMICS IN A LOW-PRODUCTIVE TERRESTRIAL ENVIRONMENT

Ecological perturbations can have strong influences on food web dynamics by altering the source, abundance, and temporal availability of resources. This in turn may disrupt nutrient pathways by varying controls for top-down and bottom-up interactions. The beaches of Isla Magdalena (Baja California, Mexico) are littered with discarded catch (bycatch) of local artisanal fisherman every summer. This marine nutrient input could be supporting excess densities of apex predators (coyotes, Canis latrans). Our objectives are to understand the effects of marine nutrient inputs on the island's coyote population and identify any cascading effects on lower trophic levels. To do so we are using a combination of mark-recapture techniques and stable isotope (13C, 14N, D) analysis of coyote tissue, their prey, and primary producers. Abundance indices suggest spatial differences in coyote and prey density that likely correspond to variations in bycatch biomass across the island. Isotopic results show that a high proportion (>50%) of most coyotes' diets consist of bycatch during the summer. This interdisciplinary study will illustrate how anthropogenic activities in marine ecosystems can have dramatic affects on adjacent terrestrial environments.

LIGHT-INDUCED FORMATION OF CARBON MONOXIDE FROM PARTICLES IN SEAWATER: PRELIMINARY RESULTS

Carbon monoxide (CO) formation from particle photoprocesses was determined on seawater samples collected from one open-ocean (BATS) and two coastal (Vineyard Sound and St. Lawrence estuary) sites. Particles were concentrated using cross-flow filtration with 0.2-micron filter pore size. Samples containing varying levels of particles were irradiated under solar or solar-simulated radiation. CO formation rate increased linearly with particle concentration. Particles contributed to 20-40% of the CO formation in the original samples. Although this increase in CO formation was in part due to light scattering by particles, our results demonstrate that CO formation by particle-involved photoprocesses could be significant compared to CO production from dissolved organic matter photochemistry.

MIXING INDUCED BY EDDY IN NORTHERN PART OF SOUTH CHINA SEA

An intensive and comprehensive experiment was newly performed in northern part of South China Sea (SCS) in June/August, 2007. Conductivity-Temperature-Depth (CTD), Lower Acoustic Doppler Current Profile (LADCP) and TurboMAP-II were used in observation. The geostrophic calculation shows that a subsurface cyclonic circulation exists in a depth range from 50m to 200m with maximum scales of 18°-20°N and 115°-118°E at about 100m, and a deeper anticyclonic eddy becomes evident at 17.5°-19.5°N, 114°-116°E below 50m down to 2000m. The dissipation rate and eddy diffusivity in the eddies are investigated from microstructure observation. Vertical velocities in the eddies are also calculated from ω-equation and microstructure observation, respectively.

NORTH ATLANTIC INFLUENCES ON TROPICAL AMERICAS: RAINFALL AND CROSS-CENTRAL AMERICAN MOISTURE TRANSPORT

Palaeoclimatic observations suggest that during Heinrich events, precipitation decreases on both sides of the Central American Isthmus. A high resolution coupled ocean-atmospheric model simulates this suppression of tropical American rainfall in response to a cooling over the tropical North Atlantic, the latter being typical of Heinrich events. The simulation reveals a surprising analogy to the so-called mid-summer drought of Central America. With increasing solar radiation, wet precipitation over Central America and southern Mexico increases from April to June but then mysteriously decreases in the mid-summer during July-August. The simulation suggests that suppressed convection over the tropical Atlantic warm pool is a cause of the mid-summer drought over Central America and the far eastern tropical North Pacific by exciting subsidence Rossby waves that propagate through the Isthmus. The moisture transport from the Atlantic to Pacific across Central America favors the North Atlantic for the sinking branch of the global meridional overturning circulation (MOC). The mid-summer drought is associated with the development of northeasterly winds across Central America, which are responsible for much of the Atlantic-to-Pacific moisture transport. In response to a North Atlantic cooling as during Heinrich events, the intensified northeast trade winds increase the moisture transport from the Atlantic to Pacific, suggesting a negative feedback to MOC variability.

TSUNAMI INCISIONS PRODUCED BY THE DECEMBER 2004 EARTHQUAKE ALONG THE COASTS OF THAILAND, INDONESIA, AND STRAITS

Field observations and satellite images indicate that tsunami waves select specific patterns of incision in the coastal landscape. To study these incisions we analyze high resolution remote sensing images of the coastline of Indonesia, Thailand, and Sri Lanka impacted by the tsunami of December 26, 2004. The analysis sheds light on the different mechanisms by which currents scour incisions during the flooding and receding phase of a tsunami. During flooding the high velocity flow indents the levels of existing tidal channels and bays, leaving short flood scours. During the receding flood water dissects the coastline with equally spaced return channels widening toward the coast.

ASLO/AGU/TOS/ERF

The Advanced Circulation (ADCIRC) model is employed to simulate barotropic tides and wave conditions over a tidal cycle in the Gulf of Mexico, southwest of the Mississippi River mouth. The two-dimensional version of ADCIRC has been used to simulate the mean and residual currents, and the associated transport of suspended sediments, nutrients, and dissolved oxygen in the area of the Mississippi River Delta. The model results indicate that the Mississippi River discharge plays a significant role in the development of estuarine circulation and sediment transport in the area. The model results are in good agreement with observational data from the Mississippi River Delta.

NUMERICAL STUDY OF LAGRANGIAN TRANSPORT PROCESS IN A MARGOCITAL BASIN

Mixing and transport in a tidal basin or estuary is not only an interesting scientific problem but also an important processes which control the fate and distribution of nutrients, suspended sediment, pollutants and other planktonic waterborne biota in coastal oceans. Two basic mechanisms of horizontal advection, dispersion and chaotic advection have been proposed, but quantifying and predicting the Lagrangian transport of marine particles in the ocean remains a challenge. In a marginal basin like Cobico Bay, particle trajectories show a great deal of sensitivity to location and time. Chaotic advection is traditionally thought as the principal influence to Lagrangian transport due to interaction of significant tidal currents and complex geographic features. A kinematic model of Cobico Bay is also constructed to investigate Lagrangian behavior based on the residual current from the dynamical ocean model. Numerical particles are released at different tidal phase and tracked through time-depended tidal currents with different amplitudes and spatially varying phase lags. Lagrangian coherent structures are distinguished to evaluate the flushing and resident time of different part of tidal channel. The results suggest chaotic advection happens when spatial phase lag of tidal current is great enough and particles may be transported to quite different regions though they were initially released very closely.

Xu, E., Stony Brook University, Stony Brook, USA, fanxu@sunysb.edu; Wang, D. P., Stony Brook University, Stony Brook, USA, DongPing.Wang@stonybrook.edu; Riemer, N., Stony Brook University, Stony Brook, USA, Nicole.Riemer@stonybrook.edu

A SIZE-RESOLVED METHOD FOR FLOCCULATION PROCESSES OF FINE-GRAINED PARTICLES

The transport of fine-grained particles in estuarine and coastal waters is influenced by flocculation processes (aggregation and floc breakup). Aggregation is caused by collision and subsequent adherence between particles, and breakup is mainly due to turbulent stress. As a consequence, the particle size and settling velocity vary with time in the water column, and can be orders of magnitude larger than those of primary particles. In this study the variations in floc size and settling velocity are simulated via a size-resolved method, which approximates the real size distribution of particles in different size bins and solves for each bin a mass balance equation. The zero- (0-D) and one-dimensional (1-D) simulations have been carried out. In 0-D study the median floc size (D50) is proportional to the ratio of initial concentration and Kolmogorov microscale. In the 1-D simulation, on the other hand, the floc size distribution and settling velocity not only are influenced by turbulence-induced flocculation but also by competition between diffusion and settling. Simulation over a tidal cycle shows that floc sizes during high water slack are greater than those during maximum flood or ebb currents.

MODELING TIDAL DYNAMICS AND TIDAL DATUMS IN THE PACIFIC NORTHWEST REGION

A tide model has been developed for the Pacific Northwest region in support of developing a vertical datum transformation tool. VDatum. The model domain extends from Pt. Buchon, California, to north of the Juan De Fuca Strait. The two-dimensional version of the Advanced Circulation (ADCIRC) model is employed to simulate barotropic tides and depth-integrated tidal currents. A high-resolution unstructured grid was created to better represent the complex shoreline and fine bathymetric features. The generated tidal dynamics and elevation data in this region will be used to generate tidal datums, including mean lower low water (MLLW), mean low water (MLW), mean high water (MHW) and mean higher high water (MHHW), as well as tidal constituents, are derived based on the simulated tidal water levels and validated against available observations at various tidal gauges obtained from NOAA’s Center for Oceanographic Product and Services. The results of water discharge on the tidal dynamics and datums in the river/estuarine system will also be discussed.

ORIGINS OF LARGE WAVE-SHAPED BEDFORMS ON THE FLOOR OF MONTEREY SUBMARINE CANYON

Multibeam surveys and ROV dives revealed a field of bedforms from the headdown to ~1000m depth along the axis of Monterey Submarine Canyon. These bedforms range from 20–70m in wavelength and 1–3m in height. The asymmetry of these bedforms suggests that wave-driven canyon migration. Current measurements show tidal oscillations of up to 80 cm/s, with down-canyon current dominant. Empirical models show that flows of these magnitudes are capable of generating sandwaves of the observed sizes. However, variations of the local and flanks of the bedforms showed sequences of strong or moderate clay-clasts firing upward into sand - a stratigraphy typical of gravity-flow deposits. Moreover, three boulder-sized monuments buried 40cm in the bedforms at different locations were translated ~150m down-canyon within a 3-day period, suggesting forces other than tidal currents as the cause. A multi-faceted investigation is underway that includes mapping and geophysical surveys, sediment coring, and ADCP mooring and STED (Self Triggered Event Detector) deployment. In this paper, we present the latest data and analyses that characterize possible mechanisms for forming the observed bedforms and their spatial variation.

SEDIMENT TRANSPORT FROM THE MISSISSIPPI AND ATCHAFLAYA RIVERS TO THE LOUISIANA/TEXAS SHELF

Fluvial sediment dispersal strongly impacts temporal and spatial variations of turbidity and nutrients in estuaries and continental shelves. This has motivated the development of a three-dimensional coupled hydrodynamic and sediment transport model for the Louisiana/Texas (LaTex) shelf. The model, implemented within the Regional Ocean Modeling System (ROMS), included delivery of sediment from the Mississippi and Atchafalaya Rivers, seabed resuspension, and suspended sediment transport by ambient currents. Waves were calculated using the SWAN (Shallow WAves Nearshore) model. The calculations represented a year, 1993, that included large storms and significant river discharge. Additionally, data from the LaTex field program provided measurements of bottom boundary layer conditions for May–June, 1993. Model results indicated that on the LaTex shelf both wind-driven currents and storm waves cause sediment resuspension. While much material from the Mississippi was delivered to deep water, a large amount was transported westward to mix with Atchafalaya sediment in the vicinity of the Dead Zone. This model will later be linked to a biochemical model and evaluated using data from the MCH2 (Mechanisms Controlling Hypoxia, 2) experiment.

THE MEDITERRANEAN OUTFLOW IN A NORTH ATLANTIC SIMULATION

Output from a high resolution, basin scale, North Atlantic simulation is used to study the circulation of the Mediterranean outflow water (MOW) in the Gulf of Cadiz and in the Northeast Atlantic ocean. The model is based upon the hybrid coordinate ocean model (HYCOM) and includes the Richardson number-dependent entrainment parameterization of Xu et al. (2006). As observed, the simulated MOW flows transform from a bottom-trapped gravity current out of the Strait of Gibraltar into a well-bounded, downstream in the Gulf of Cadiz. When the plume spreads further west beyond the Cape of St. Vincent, the inshore, upper part of the plume turns around the Cape and flows northward along the western coast of Iberian Peninsula; the offshore, lower part of the plume continues westward into the northeast Atlantic Ocean. This spreading pattern agrees in general with the scenario described by Danailut et al. (1994). The simulation also suggests that the eddies play a bigger role in carrying MOW westward than northward.
nonlinearity affects not only the profile of individual wave components but also broad-band irregular ocean waves, the spatial and temporal spectra and correlations of the waves. This is illustrated for regular (Airy vs. Stokes) waves, nonlinearity affects the focusing and variations of light fields beneath a dynamic ocean. The codes are optimized by variance reduction techniques. Even with a supercomputer and massively parallel computations, it would be impossible to simulate all the relevant processes with reasonable accuracy. Yue, K. P.

We conducted an analysis of historical satellite imagery to characterize the seasonal and inter-annual variability of SST (14 years) and chlorophyll-a (9 years) in the New Zealand. Our analysis shows that SST and chlorophyll-a remain high in winter months with a secondary peak in the late winter. Surface chlorophyll-a decreased dramatically in early spring as the water column stratified. The winter bloom, when light levels are low and mixing is high, suggests that phytoplankton populations are not constrained by low light (Sverdrup) which we hypothesize may be typical on shallow broad shelves. In addition, inter-annual variability in SST and chlorophyll-a are evident and appear to be set by conditions during the winter months.

Chant, R. J.

We have developed a model of the Maine Coastal Current in response to local forcing as the hindcast is forced by a climatological monthly mean at the open boundaries. In addition, the hindcast in the Gulf of Maine Ocean Observing System (GoMOOS) nowcast/forecast system. The surface forcing is derived from the North American Regional Reanalysis, and satellite derived sea surface temperature is assimilated in the model to constrain the heat budget. The hindcast is compared with the historical database of Fisheries and Ocean Canada and National Marine Fisheries Service. Preliminary analysis focuses on the interannual variability of the Maine Coastal Current in response to local forcing as the hindcast is forced by a climatological monthly mean at the open boundaries. According to Yue and Chant (2016), the hindcast in the last 5 years is compared with the GoMOOS nowcast of 2002-2006 that uses a daily open boundary condition derived from the NCEP Regional Ocean Forecast System.

Laboratory experiments simulating ocean CO$_2$ sequestration by acidifying bathypelagic seawater with CO$_2$ gas or buffer solutions were conducted to examine the influence on bacterial activity. Here, bacterial production (H-leucine incorporation rate) and the proportion of viable cells (elongated cells under the inhibitor of cell division) were measured. It was observed that moderate acidification (−0.6 in pH unit) increased both parameters. Further acidification over −1.0 in pH unit, on the other hand, depressed both. Bacterial activity was supposed to be quite sensitive to the degree of acidification. Also, the results strongly indicates the presence of some bacterial species in the bathypelagic layer which can be activated with moderate acidification as the consequence of CO$_2$ sequestration.

VARIABILITY OF FRESHWATER DISTRIBUTION IN THE CANADA BASIN OF THE ARCTIC OCEAN IN 2000S

Freshwater inventories of surface and halocline waters in the Canada Basin are comprised of inputs from rivers, sea-ice melt and low salinity Pacific water and removal due to sea-surface evaporation. To assess interannual variability of these freshwater inputs, a suite of geochemical tracers were collected from 2000 to 2007: oxygen isotope ratio and alkalinity are used to distinguish sea ice meltwater/brine rejection from other freshwater inputs and nutrients are used to identify Pacific water distributions. Horizontal maps show that the relative contribution of these components vary significantly according to regional sources. Shelf-basin exchange is shown by the lateral transport of freshwater and brine from the continental shelves into the Canada Basin. Substantial inter-annual differences are found in both horizontal and vertical distributions of freshwater components.

MIXED LAYER HEAT BALANCE ON SEASONAL TO INTERANNUAL TIMESCALES IN THE WESTERN TROPICAL PACIFIC: AN OGCM STUDY

We examined the mixed layer heat balance, using an ocean general circulation model, on seasonal to interannual timescales in the western tropical Pacific, where variations in the relatively high SST are closely related to the East Asian climate through atmospheric convective activities. On the seasonal timescale, the SST is dominated by the surface heat flux and subsurface processes, such as entrainment, during summer, while by the surface heat flux and the meridional heat advection due to the enhancement of the Mindanao Dome during winter. On interannual timescales, the mixed layer heat balance in the western tropical Pacific exhibits a seasonal dependency: the SST variability is mainly influenced by the surface heat flux during summer and by the oceanic interior process during winter. This well explains the seasonal relationship between the local SST and precipitation anomalies in the western tropical Pacific: their correlation shows negative values in summer, while positive in winter.

ASSESSMENT OF DYNAMICS OF CHROMOPHORIC DISSOLVED ORGANIC MATTER IN COASTAL ENVIRONMENTS BY EEM-PARAFAC

Excitation-emission matrix (EEM) fluorescence techniques have been widely used to characterize chromophoric dissolved organic matter (CDOM) in coastal environments. However, since the EEMs are often composed of various types of overlapping fluorophores, it may be difficult to properly evaluate CDOM dynamics in coastal based solely using the EEM “peak picking” technique. In the present study, parallel factor analysis (PARAFAC) was applied to decompose EEMs into individual fluorophore components for samples collected at Ise Bay, Japan. Four humic-like and three non humic-like fluorescent components were identified by PARAFAC and the dynamics of each of the fluorescent components was evaluated separately. The spatial distribution of the three non humic-like fluorophores suggests an autochthonous, estuarine origin for these components. The linear relationships between salinity and abundance of two of the four humic-like components observed in the bay area, suggests a terrestrial origin, probably riverine as conservative behavior for these components was observed. In contrast, non-conservative mixings of the other two humic-like components were found in the bay area, suggesting sources other than riverine inputs.

RING AND WESTERN BOUNDARY CURRENT INTERACTIONS - TWO SCENARIOS

More than two decades ago, one of us proposed two scenarios for the interaction of a cold core ring and a western boundary current (the Gulf stream): 1) the ring coalesces completely with the stream; 2) the ring exchanges mass and pressure energy with the stream but is then reorganized to form a ring free from the stream. The first scenario was successfully proved in series of papers, particularly Olsen (1980). However, the second one had lack of sufficient evidence to demonstrate this scenario really takes place. In February 2007, we made a direct observation of a cold core ring collision with the Kuroshio making use of Moving Vessel Profiler (MVP). We cut through the ring and the Kuroshio. The data demonstrate that the mass and the energy of ring were exchanged with those of the Kuroshio. According to the satellite altimeter data, the ring reorganized and increased in size. Clearly, this new data set demonstrates the second scenario is real. We present the detail of our data set and the data analysis. Examples of ring interactions in both the Kuroshio and Gulf Stream are summarized.

A SYSTEMATIC OBSERVATION OF METHANE PLUME BEHAVIOUR AROUND SEAFOAM COLD SEEPAGE

Cold seepages are characterized as rapid upward transports of methane from deeper part to the sea surface. Prior to reach the sea surface, methane meets downwards diffusing seawater sulfate, it is oxidized anaerobically by a consortium of microorganisms that use sulfate as an oxidant. A significant portion of the bicarbonate produced after the sulfate reduction near the seafloor. When the methane fluxes are much, direct methane bubbling occurs and the bubble jet blows up in the water column due to the buoyancy. Then the diffusive and dispersal processes will be enhanced. The methane bubbles and the dissolution and dispersion process have been numerically studied by the authors. The results suggest that the behavior of methane plume is susceptible to current profile among the several factors. In the previous studies, however, there are few cases that methane concentration in the water column and current profile were simultaneously measured in the same area. In order to obtain the both data and reconstruct the numerical model, the R/V Tansei-maru cruise KT-06-26 including CTD-cast with seawater sampling and ADCP mooring were carried out at the Umitaka Spur off Joesu region, eastern Japan Sea. Magnificent methane flare has been reported at the Spur. The mooring system composed of three ADCP with two 3-D current vector instruments was deployed for ca 58 hours. During the deployment, 24 CTD-casts with seawater sampling were conducted.

REMOTE SENSING STUDIES OF MERIDIONAL OVERTURNING CIRCULATION IN NORTH ATLANTIC OCEAN

Although satellite remote sensing measurements are commonly used in oceanographic research, very few of these studies address deep ocean convection (DOC) as it relates to Meridional Overting Circulation (MOC). The major limitation of using remote sensing measurements directly results from their poor temporal and spatial resolution, with respect to the characteristic features of deep water convection. However, features associated with prior and post deep water formation have much larger spatial and longer time scales compared to the convective plumes. This talk will focus on detecting and monitoring the preconditioned flow and lateral exchange features resulting from prior and post deep convection, respectively. Using several sources of data, including heat and vapor exchange, and horizontal and vertical flow fields, we have created a composite data set that allows the analysis of horizontal flow fields and the vertical water column structure that are associated with DOC. The improved understanding of DOC and MOC results from this study will allow us to better access its impact on climate change and thus help to detect the early onset of rapid climate change. Preliminary results will be discussed in this presentation.

temperature and salinity observations with three kinds of background error covariances: (1) a Gaussian-type, (2) a hybrid-type that augments (1) with flow-dependent BV structures and (3) a hybrid-type that augments (1) with flow-independent EOF structure. Our results show that the analyses derived from the multivariate, hybrid background error covariances have the improvement over the one derived from the Gaussian background error covariance. The improvement can be found in both the temperature and salinity fields, especially in tropical Atlantic. Among them, the analysis incorporated with BV information has the significant impact in the salinity field, which encourages the CGCM to predict a warm anomaly in 2006.

LARGE-SCALE EDGE WAVES GENERATED BY HURRICANE WILMA’S LANDFALL

Direct observations of the storm surge induced by Hurricane Wilma’s landfall on the West Coast of Florida on October 24, 2005 revealed a formation of a wave pulse propagating alongshore as Wilma moved inland and the surge was no longer sustained by wind forcing. The height of the wave pulse exceeded 1.5 m in detailed sea level data but its magnitude was obscured in direct surge measurements because it propagated during the stage of low tide. The duration of this wave pulse was ~6 hrs and the propagation speed varied in the range of 10-25 m/s indicating some dispersion of the initial disturbance. The wave pulse was followed by a train of much weaker oscillations during the next 24 hrs. The observed wave is identified as an edge wave of large spatial and temporal scales. Preliminary model calculations demonstrate a generation of edge waves with large spatial and temporal scales by a fast-moving circular storm system crossing the shelf at a close-to-normal angle. The pulse structure forms when the shelf width is comparable with the storm’s spatial scale.

WATER MASS FORMATION AND CIRCULATION IN THE PERSIAN GULF

The circulation and water mass transformation processes in the Persian Gulf and the water exchange with the Indian Ocean through the Strait of Hormuz are studied using the HYbrid Coordinate Ocean Model (HYCOM). The Persian Gulf is a shallow, semi-enclosed marginal sea where the Persian Gulf Water (PGW), one of the most saline water masses in the world, is produced due to the arid climate. The PGW flushes out of the Persian Gulf as a deep outflow through the Strait of Hormuz and induces a surface inflow from the Indian Ocean, driving an inverse-estuarine type water exchange. The model results compare favorably with observed features, particularly with the measurements in the strait. The model suggests that deep waters are formed both in the northern gulf and in the southern gulf during wintertime and contribute with different seasonal cycle to the total deep outflow through the strait. The circulation in the gulf exhibits strong seasonal signal, and the annual cooling/heating cycle of the surface heat flux is identified as responsible for the seasonal variability by changing the vertical mixing.

CENSUS OF MARINE LIFE: TECHNOLOGIES FOR BIOLOGICAL RESEARCH THROUGH OCEAN OBSERVATORIES

The Census of Marine Life is an international research program that studies the diversity, distribution and abundance of marine life. As part of this mission, Census projects are developing and demonstrating technologies to collect information, in an automated way in situ, about marine animals and their migratory patterns. In addition, Census scientists have advanced tag technologies enabling them to employ marine life as platforms for sensors. Tags on marine predators have gathered more physical oceanographic information than any conventional system, including the Argo float system, and can transmit those data to satellites. Many of the technologies used within Census research - tags, sensors and receivers - can be integrated in ocean observatories, thus providing a major biological component to these systems. The goal of the Ocean Biogeographic Information System, which houses all Census data, is to become interoperable with the data infrastructure of the Global Ocean Observing System to better address ecosystem concerns associated with global change, fisheries and pollution.

RECENT THERMOHALINE CHANGES IN THE NORTHERN NORTH ATLANTIC

The coupled breeding, implemented in the NASA GMAO coupled general circulation model (CGCM), is designed to capture the growing errors related to the atmosphere- ocean coupled instability in an interannual time scale (e.g. ENSO). The derived coupled bred vectors (BV) are originally used as the initial ensemble perturbations for the purpose of improving season-to-interannual ensemble forecast skill. In this study, we incorporate the oceanic component of the BVs into the data assimilation (DA) procedure to explore the possibility of improving the DA performance through the background error structures. The potential impact is investigated through the DA experiments, which assimilate
Combining hydrographic (CTD), moored, profiling ARGO-float and expendable bathythermograph (XBT) measurements in the central North Atlantic, we document significant changes in its upper, intermediate (Labrador Sea), deep (Iceland-Scotland Overflow/ Northeast Atlantic) and bottom (Denmark Strait Overflow) waters that have occurred during the past two decades. Affected by vertical and lateral mixing, these waters evolve along their spreading pathways. The similar seasonal-to-decadal scale signals in the thermocline characterize different adjacent major basins in the North Atlantic, implying that there is a persistent inter-basin advective exchange pattern which contributes to the large-scale connections and interactions in the Atlantic climate and eco-systems. The moored and ARGO measurements were used to fill both spatial and temporal gaps in the CTD data. Continuous time series constructed from the ARGO data for the Labrador, Fringer and Greenland basins supported the warming that was apparent in the temporarily sparse CTD & XBT data. Other questions addressed are: Does the recent warming occur in a steady/continuous way or in jumps? What is the contribution of the seasonal changes to the multyear trends? What is the rate of deep convection?

OBSERVED DIAPYCNAL INJECTION OF SALINITY ANOMALIES

Temperature and salinity profiles from the global array of ARGO floats reveal a large amplitude seasonal cycle of density offshore of the deep western boundary currents in the sub-tropics of each ocean basin. This seasonal cycle is quantified by the summer to winter change in a bulk vertical Turner angle computed from the ARGO profiles. The injection of salinity anomalies onto previously subducted isopycnals is quantified by comparing pairs of measurements from the same profiles. Distributions of global Turner angle and basin-scale diapycnal injection metrics, such as the average overturning salinity increase and depth of penetration into stratification, are presented. These ARGO results are consistent with a conceptual model of perturbative convective mixing of a highly density compensated water column and with previous results from an OGCM hindcast. The model results are used to relate interannual variations in isopycnal salinity to sea surface salinity (SSS) and to discover the generation mechanisms for the SSS anomalies.

DEPTH ZONATION OF DEEP-SEA MEGAFANAL SCAVNGERS OF THE HAWAIIAN ISLANDS

The deep-sea demersal and benthopelagic scavenging communities of Oahu and the Northwestern Hawaiian Islands were explored with the use of baited time-lapse free-vehi- cles cameras. Our aim was to identify scavenger assemblages and investigate depth related trends in community composition, species richness, and scavenging abundance. Twenty-one deployments ranging in depth from 250-4783 m yielded 37 taxa attracted to bait, including records of 5 fish species previously unknown to the Hawaiian Islands and the first occurrence of the family Zoarcidae. Cluster analysis of Bray-Curtis similarity of species peak abundance revealed 4 main depth groupings (250-500, 1000-1500, 3000-4000m) with significant separation between designated groups. A major faunal break was identified at the 500-1000m transition, where species turnover was greatest. A linear de- cline with depth was observed in scavenger relative abundance while no relationship was observed for species richness. Significant size differences (TL) with depth were found for 2 of the 4 fish species examined. Evidence of competition and predator-prey interactions between scavenging species was observed, indicating the need for caution when using baited cameras to index abundance.

ATMOSPHERIC WEATHER NOISE AND THE TROPICAL PACIFIC SST VARIABILITY IN A CGCM

The interactive ensemble coupling strategy has been developed specifically to determine how noise impacts climate variability within context of coupled general circulation model (CGCM). This study examines the impacts of local versus non-local noise on the tropical Pacific sea surface temperature anomaly (SSTA) variability using three CGCM simulations. The control run uses the standard coupling strategy. In the first experiment, the interactive ensemble strategy is applied globally thereby reducing the noise at the air-sea interface at each grid point. In the second experiment, the interactive ensemble strategy is applied locally in the tropics only. By directly comparing the three CGCM simulations we investigate a role of local versus non-local noise on the ENSO statistics. Preliminary result indicates that a non-local noise in the North Pacific has a minor impact on the ENSO statistics including the frequency and amplitude.

FOLLOWING A LAMINAR CHEMICAL TRAIL: STAYING ON TRACK AND BEING ON TIME

Both Tenora longicornis, a coastal marine copepod, and Hesperodiaptomus shoshone, a high- algal freshwater lake copepod, exhibit chemically-mediated mate-tracking of laminar trails designed to mimic the scent trails of their conspecific females. After trail discovery, initiated by the female the copepod precisely follows the 3-dimensional path taken seconds earlier by the female copepod mate. High-speed videography coupled with high-magnification Schlieren optics enabled us to visualize both the deformation of the odor signal and the movement of the male copepod in this behavioral assay. Males happily followed the trails we made and our observations show clear differences between the larval and adult-sized species. Tracking by the copepod around the scent trail with transport of the copepod along the path allows the aquatic micro-crustacean to have one or numerous sensors in the trail and others outside of it to facilitate edge detection using spatial sampling. We will discuss results of our 3-dimensional analyses to examine the orientation of the sensor with respect to the signal and body position to understand edge detection and error-correcting mechanisms of copepods.

It has been suggested that coastal rivers deposit iron-rich sediments along the continental
which can later provide a source of bioavailable iron for coastal primary productivity.
Here we examine iron concentrations in sediments which were deposited along the northern California shelf following a major Eel River flood event in winter 2006. Concentrations of bioavailable and non-bioavailable iron were measured in sediment
cores collected shortly after the event in May 2006 and one year later in June 2007. Total
bioavailable iron in the 2006 flood layer was about 9.4±10g kg⁻¹ based on the average concen-
tration of samples and the flood layer depositional area. This represented roughly 24% of
the bioavailable iron required to support average annual productivity along the continental
shelf between the Eel and Klamath Rivers. Between 2006 and 2007 about 2.3×10⁶ g of this
bioavailable Fe was lost, suggesting that only 6% of average annual productivity could have
been supported. These results indicate that major flood deposits may only be a minor
source of bioavailable iron along California’s north coast.

WHAT IS THE NEW ‘NEW’?
Much recent work has centred on quantifying how processes such as nitrogen fixation, mesoscale physics and dust deposition affect new nitrogen supply to the oligotrophic ocean. But how certain are we what ‘new’ nitrogen actually means? We are happy that organic material is recycled into nitrate at depth, but how can we define or measure the new nitrogen supply given the growing realisation that this nitrification happens in the euphotic zone too? We present modelling results demonstrating the significance of nitrification in surface waters: much nitrate taken up by phytoplankton in the oligotrophic gyres can be recycled in situ. We discuss the implications of this work for future observational and modelling approaches to ‘new’ production.

WHAT DOES INFERRED OXYGEN UTILISATION RATE TELL US ABOUT OCEAN VENTILATION?
The oxygen utilisation rate (OUR) of biological activity in the ocean interior is relevant for studies over a range of oceanographic disciplines. As well as informing biogeochemical processes such as primary production and nitrogen fixation, physical processes such as ocean circulation and ventilation can be inferred from the distribution and use of oxygen. In our work, we use a full biogeochemical simulation of a medium-resolution GCM, OCCAM, to provide relevant tracer fields for the recent historical period. In conjunction with both real (CFCS, radiotracters) and idealised (ventilation, dye) age tracers, we then use the simulated biogeochemical fields to compare the inferred OUR along isopycnals with the actual modelled OUR. The region studied corresponds to Jenkins (1987)

TEMPORAL AND SPATIAL VARIATIONS OF PHYTEPLANKTON PHOTOSYNTHETIC PHYSIOLOGY DURING THE SPRING DIATOM BLOOM IN THE WESTERN SUBARCTIC PACIFIC

Variations in photosynthetic parameters of phytoplankton during the spring bloom were investigated in the western subarctic Pacific. Photosynthetic parameters normalized by Chl. a concentration were drastically changed with development of the bloom. Light-saturated maximum photosynthesis rate ($P_{\text{max}}$) and light-limited slope ($a$) were almost constant in the first half of the bloom and then concurrently increased in the latter half of the bloom with a constant light-saturation index ($E_{\text{Ssat}}$). Maximum quantum yield showed similar temporal change. In contrast, maximum photochemical quantum efficiency of photosystem II ($\Phi_{\text{PSII}}$) increased in the first half and thereafter decreased. This difference means that the processes downstream of the photosystem II (destinations of redoxants, activities of enzymes, etc.) might control both $E_{\text{Ssat}}$ and $a^*$ during the bloom. It seems that the parallel increase in $P_{\text{max}}$ and $a^*$ resulted in massive spring bloom in the subarctic western Pacific. In general, ecosystem model uses constant $a^*$ regardless of environmental conditions and physiological state. Parallel change in $P_{\text{max}}$ and $a^*$ should be taken into account for the models reproducing ecosystem dynamics during spring diatom blooms.

GEOPHYSICAL DISTRIBUTION OF THE FEEDBACK BETWEEN FUTURE CLIMATE CHANGE AND THE CARBON CYCLE

We examined climate–carbon cycle feedback by performing a global warming experiment using a coupled climate–carbon cycle model. The model showed that by the end of the 21st century, warming leads to a further increase in CO$_2$ level of 125ppmv. This positive feedback can mostly be attributed to land-based soil-carbon dynamics. On a regional scale, Siberia and Amazonia had intense positive feedback resulting from accelerated microbial respiration. Some regions, such as western and central North America and South Australia, experienced negative feedback, because enhanced litterfall balances the loss in soil carbon. The oceanic contribution to the feedback was much weaker than the land contribution, but the positive feedback in the northern North Atlantic was as strong as those in Amazonia and Siberia in our model. In the northern North Atlantic, the weakening of winter mixing due to warming causes a reduction of CO$_2$ absorption at the surface. Moreover, weakening of the formation of North Atlantic Deep Water causes reduced CO$_2$ subduction to the deep water. Thus, the mechanism of carbon-cycle contribution to climate–carbon cycle feedback varies by region.

SURFACE CURRENT MEASUREMENT AND INTERIOR CURRENT ESTIMATION USING HF RADAR IN THE TSUSHIMA STRAIT

HF radar in the Tsushima strait shows large seasonal variations of a geostrophic Tsushima Warm Current (TWC) and wind driven flow (WDF). WDF is as large as TWC in some region to mask seasonal TWC variations of our interest. To reveal the TWC variation, WDF was investigated using moored ADCPs and HF radar in the strait. Despite a short (2 weeks) observation period of relatively calm and variable wind, a clockwise velocity spiral similar to a theoretical Ekman spiral was detected as the first mode of PCA. Monthly WDF and TWC at HF radar range was estimated using wind speed and bearing angle obtained from the detected spiral, and monthly geostrophic TWC was inferred by subtracting the estimated WDF from currents measured with HF radar. The inferred TWC shows clear seasonal variation: it is uniform in winter while it accompanies current counters on both sides of TWC in summer as a result of lee-side eddy generation behind large islands.

CHANGES IN SIZE AND LIPID CLASS COMPOSITION IN EARLY DIAGENETIC PHYTEPLANKTON PHOTOSYNTHETIC PRODUCTS

Phytoplankton populations were incubated with NaHCO$_3$ under light for 1 day, followed by incubation in the dark for 29 days. The changes in the concentration of photosynthetic organic carbon (P-OC), lipid carbon (P-LC) and fractionated lipid carbon (P-LFC) were followed by mass spectrometer combined with an elemental analyzer. Changes in the P-LFC on the particulate fraction (>0.7μm) showed that PL degraded more slowly than TG, resulting in the higher remaining ratio of PL than TG. This result suggests that structural lipids are more stable than storage lipid. The contribution of dissolved fraction in P-OC, and P-LC increased with the progress of diagenesis, and the accumulation of stable lipid materials increased. The decomposition was confirmed. Although the size composition in P-OC readily approximated to that of OC in the ocean surface water, the contribution of dissolved fraction in P-LC on day 30 was obviously lower than that of LC in marine environments.

These results indicate that size compositions of LC are established by diagenesis of photosynthetic lipid with longer term and/or existence of lipid originated from other sources.

ROLE OF FRESHWATER AND WATERWAY ON SALINITY REGIME AND TURBIDITY MAXIMUM ZONE IN LOWER HAN RIVER ESTUARY, KOREA

Environmental Fluid Dynamics Code (EFDC) is used to simulate an effect of major water ways and freshwater discharge on salinity features of the macro-tidal Han River Estuary in Kyunggi Bay, located in the middle of the western coast of Yellow Sea. Two-layer flow in the Yeonma Waterway and its corresponding salinity regimes are successfully illustrated. Compared with Yeomma Waterway, Gyodong and Seokme Waterways are proved to play an important role in draining freshwater into the Kyunggi Bay. Through Yeomma Waterway, less saline water in summer reaches into the Kyunggi Bay, and draws back in winter. This feature is well simulated by the model. Particularly in summer (July – September), the salinity at the Yeonma entrance shows a high gradient in salinity ranging from 15.0–25.0 psu, which is evaluated a well-balanced zone between the discharged freshwater and tidal forcings. On the other hand, the 20psu isohaline occupies the upper reach of the Yeonma Waterway in January, February and March, and starts growing from April to the Yeonma entrance. From September the 20psu isohaline ceases back to the location of January. Similar salinity profile of residual circulation in August shows the nation is drawn just above the Incheon Harbor, where is coincidently near the spoil ground. The predicted null point is expected to play a role in suspended sediment convergence, resulting in a Turbidity Maximum Zone. It is anticipated to expedite a negative effect of Incheon Harbor siltation.

MERGING MOLECULAR AND OCEANOGRAPHIC PROCESSES IN THE SCOTIA SEA AND BEYOND

Although marine organisms with pelagic larvae are generally assumed to experience high larval retention and low levels of population connectivity, the majority of dispersal and effective gene flow is frequently unclear. Our research examines the influence of oceanographic and life history variation on gene flow in two species of Antarctic fish: Champsoscyphus gunnari and Nototenia rossii. These species are broadly sympatric in their distribution, but differ in aspects of life history that are expected to strongly affect their dispersal capabilities. We are employing two oceanographic models: a low-resolution global model to predict larval transport at the circumpolar scale, and a high-resolution regional model to investigate finer scale cross-shelf transport and retention around South Georgia. To compare predictions from the oceanographic models with patterns of population differentiation at both circumpolar and regional geographic scales, we are using mtDNA and microsatellite markers to examine historic and contemporary gene flow. Here we present data from oceanographic models in combination with genetic analyses, including evidence for inter-specific variation in mitochondrial gene flow at the circumpolar level.

THE OBSERVATION EVIDENCE OF YELLOW SEA WATER CURRENT

Yellow Sea Warm Current (YSWC) is the main current in southern yellow sea in winter. This paper uses the data from 3 moorings in the path of the YSWC and the accordingly CTD station in the area to study the 3 dimension structure of YSWC. The results is (1) in the monthly average timescale the YSWC is stable northward from sea surface to bottom. (2) The upper layer of the YSWC bear strong influence of the winter cold surge, the direction of YSWC is often changed when circulation cold surge. (3) The lower layer of YSWC is also bear the influence of morphology but is stable northward and the currents is between 4cm/s to 10 cm/s. (4) The warm water in the bottom layer also indicate that the YSWC is stable near the bottom.
Salinity and the Ocean Water Cycle

One consequence of global warming is that the moisture holding capacity of the atmosphere should go up following the Clausius-Clapeyron relation. If the residence time of water vapor in the atmosphere (~ 9 days) remains unchanged, the stronger evaporation should lead to stronger precipitation and thus, an acceleration of the water cycle. As the oceans are the source of 80% of global evaporation and the sink for 78% of global precipitation, the accelerated water cycle would be important not only for droughts and flood variability, as well as the salinity at the surface. This study establishes a time series of evaporation-minus-precipitation over the oceans from 1979 to present by utilizing the new evaporation dataset from WHOI Objective Analyzed air-sea Fluxes (OAFlux) project and satellite precipitation from NASA Global Precipitation Climatology Project (GPCP).

We present an analysis of the variability and trends of ocean evaporation and precipitation, their response to the change in sea surface temperatures, their connection to the near-surface atmospheric circulation, and their relation to salinity trends in the ocean.

Cross-shelf circulation in the yellow and East China seas

Satellite-ocean color data indicate a significant turbid water plume extending in the southeast direction from the southeast coasts of China to the shelf edge south of Cheju during fall-winter, suggesting significant cross-shelf currents in the Yellow Sea/East China Sea in winter that transport suspended sediments from the area of the old Huanghe mouth into the Okinawa Trough. Part of the turbid plume joins the Yellow Sea Warm Current to enter the northern Yellow Sea trough in winter. The turbid plume grows in fall, reaches its maximum expansion and intensity in winter-spring, and begins to decrease in summer. The cross-shelf currents are suggested to be associated with (1) the convergence of the Yellow Sea Coastal Current and the Taiwan Warm Current off the Changjiang mouth and (2) the time-dependent forcing of the northerly wind bursts that drives the intrusion of the Yellow Sea Warm Current.

Sulfur Speciation in the Black Sea Anoxic Basin Sediments

We report solid phase sulfur speciation of four cores from anoxic basin sediments of the Black Sea. Cores were retrieved in April 2003 on board R/V Knorr and pyrite, acid volatile sulfides, zerovalent sulfur, organic polysulfides, humic sulfur and dithionite extractable iron content were determined. One major result is that pyrite - sulfur was the major phase in all cores (200-400 mmol/g dry), however zerovalent sulfur and humic sulfur were the second and third largest sulfur species and their concentrations reached up to about 100 mmol/g dry. Another major result is the anomalous enrichment of dithionite extractable iron and zerovalent sulfur in the central western basin core, and porewaters of this core were relatively depleted in dissolved sulfide. We hypothesize that the 1999 earthquakes in southwestern Turkey (magnitudes 7.2 and 7.4) triggered massive transpor of metal-oxide rich shelf sediments to the deep basin western, enriching the upper sediments in reactive iron minerals and causing subsequent oxidation of porewater sulfide. This process may affect the overall sulfur budget of the sea via preventing the build-up of sulfide over longer timescales.

Mud Volcanoes in the South Caspian Basin

The locations of mud volcanoes have been mapped in the South Caspian Basin, offshore Azerbaijan. Most of the mud volcanoes are situated above anticlines that are complicated by faults. Those that develop on the flanks of structures are clustered in the southern portion of the study area. Syncline mud volcanoes are also concentrated in the south. More than 30% of the mud volcanoes have a distinctive collapse structure associated with them. Those with low relief and great areal extent are observed in the northeast. Four types have been recognized: concave, convex, flat and buried. These differences in morphology may result from the relationship between driving force (pressure) and material supply, width of conduit or could represent different stages in mud volcano evolution. Mud volcano formation is only the offshore Caspian is mainly controlled by tectonic forces and overpressured sediments. The volcanism is associated with high fluid pressure gradients (di-stresses) in the subsurface and not with diapirism as observed onshore. The mud volcano development commenced in the Lower Pliocene with the greatest activity during the Upper Pleistocene. The cycles of mud volcano activity coincides with time of high sedimentation rate, a regional contraction episode, and a major stage for hydrogen generation.

HFCs and Other Halocarbons in the Deep Western Boundary Current

In the spring of 2007, we made measurements of HFC-22 and HFC-142b along with CFC-11 and CFC-12 on the Western Boundary Time Series (WBTIS) cruise. The CFC-11 and CFC-12 data showed elevated concentrations in the core of the upper DWBC between 1200m and 1800m that are only slightly higher than concentrations observed in 1997. This is consistent with the fact that the atmospheric concentrations of CFC-11 and CFC-12 leveled off and began to decline in the troposphere in the early 1990s. CFC concentrations cannot be used to date this young deep water current anymore. The HFC-22 data clearly shows elevated concentrations in the Deep Western Boundary Current. These concentrations are higher than the concentrations of the older deep waters of the North Atlantic, and they are substantially lower than any concentrations found near the surface. It will be possible to monitor the ages (ventilation times) for this current well into the next decade using the HFC tracers. By using the younger HFC tracers along with the older CFC-11 and CFC-12 tracers, we can extend ventilation ages to younger water masses.

DYNAMICS OF CARBON DIOXIDE IN A MANGROVE-DOMINATED MARINE ENVIRONMENT

The importance of the coastal ocean in the regulation of anthropogenic carbon dioxide creates a need for a more robust understanding of the carbon dioxide dynamics of its constituent ecosystems. Despite their ubiquity in the tropics and subtropics, the carbon dioxide dynamics of mangrove dominated coastal environments are not well understood. A model of a mangrove dominated coastal environment was developed from diurnal studies of carbon dioxide exchanges conducted in Bermuda. Net ecosystem exchange, calcification, and air-sea gas exchange on a diurnal timescale were determined from spatially and temporally resolved measurements of carbon dioxide parameters including, temperature (T), salinity (S), total alkalinity (TA), total dissolved inorganic carbon (DIC), dissolved oxygen (DO), pCO2, and pH, in the bay system. The absence of riparian inputs and tidal creeks as relieved allowed for simpler modeling of the mangrove system itself. Previous data from Mangrove Bay along with the present study provides a time series of data to provide enhanced modeling and a richer understanding of the role of mangrove forests in subtropical and tropical coastal carbon regulation.

PHOTobiOGEoCHEmISTRY, OR PROBING THE IMPACTS OF SUNLIGHT-INDUCED CHANGES IN NON-LIVING MATTER: EVOLVING QUESTIONS, RELEVANCE, APPROACHES, AND ANSWERS

Born in nitrogen cycle studies, photobiogeochemistry expanded in the 60s and 70s mainly by characterizing direct photolyses of known solutes (xenobiotics; nitrite, nitrate). Hybrid chemical-ecosystem model scientists began to appear. Sophisticated techniques (hplc, flash photolysis, pulse radiolysis) were first applied. Watershed 1977’s “firsts” included a thesis, a photobiogeochemistry review, and a report of singlet oxygen. The 80’s saw studies of CDOM, particles, and reactive intermediates (radicals, singlet oxygen). An interdisciplin-
ary, international conference (1983) facilitated networking and widened perspectives.

New insights sprung from systematic fieldwork (CO2, HOOC, CDOM fluorescence, surveys), in-situ experiments, and modeling. The late 80s and 90s brought a broader, deeper understanding of marine optics, the nature of CDOM, and of marine vs. river-

derived CDOM. CDOM photobleaching and photo-remineralization studies com-

mented on photobiogeochemical-microalgae connections and roles in the C cycle (DOC bioavailability, CO2, CO2) became fact. Particle studies proliferated. Now, despite its complexity, particle photochemistry appears poised for takeoff. Progress in molecular-
level studies of CDOM (structure, photophysics, bleaching) is accelerating. Constraining ocean-atmosphere connections involving DMS, COS, and CS2 seems feasible. Metal photobiogeochemistry is hot; iodine’s active photo-cycle bookmarks. Happy hunting!

OCEANOGRAPHIC PROCESSES GENERATED BY HURRICANE IVAN

The Hybrid Coordinate Ocean Model (HYCOM) has been configured for the Gulf of Mexico (GOM) at 1/25th horizontal grid resolution and has been nested inside a basin-scale 1/12th Atlantic version of HYCOM. The nested GOM model is used to study tem-
perature variations, current patterns, transport variations, and two coastal-trapped waves (CTW).\n
Current meter data, hydrography and numerical simulations are analyzed in order to identify the circulation patterns in the Veracruz Coral Reef System (Sistema Arrecifal Veracru-

ano) in Veracruz, Mexico. Results show that the main forcing in the region is the Madden-Julian Oscillation (MJO). Statistical validation with observations consistently reveals improvement of the models as ones moves from unstable (chaotic or stochastically-
forced limit cycle), to neutral, to stable dynamical regimes. Motivated by this result, in the second part of this talk we will discuss the role played by the different components of the SF (such as westery wind bursts and the MJO) using hybrid and a fully coupled GCM.

Zavala-Garay, J., IMCS, Rutgers the state University of New Jersey, New Brunswick, USA, jzavala@marine.rutgers.edu; Zhang, C., RMSAS, University of Miami, Miami, USA, zhanchg@rsmas.miami.edu; Kapur, A., RMSAS, University of Miami, Miami, kapur@rsmas.miami.edu

ON THE ORIGIN OF THE OBSERVED ENSO VARIABILITY

Three popular and controversial hypotheses that have been proposed to explain ENSO variability (EV) are H1: EV originates from deterministic low order chaos; H2: EV origi-

nates from the effect of stochastic forcing (SF) acting on a self-sustaining system; and H3: EV and variability originates from a stable system maintained by SF. In the first part of this talk we evaluate these hypotheses in a parallel way of thinking by deriving two stochastic models (SM1 and SM2) from the most outstanding example of a chaotic ENSO system: the Cane and Zebiak (CZ) model. In contrast with previous studies using the CZ model, SM1 and SM2 can admit SF that decorrelates as fast as the observed SF does (down to 3 days). The SF used in the models is estimated from observations and syn-

thetic time series are derived using a method that preserves key characteristics of the SF as its seasonality, spatial and temporal scales, and the structure and eastward propagation of the Madden-Julian Oscillation (MJO). Statistical validation with observations consistently reveals improvement of the models as ones moves from unstable (chaotic or stochastically-
forced limit cycle), to neutral, to stable dynamical regimes. Motivated by this result, in the second part of this talk we will discuss the role played by the different components of the SF (such as westery wind bursts and the MJO) using hybrid and a fully coupled GCM.

FORAGING LEACH’S STORM-PETREL (OCEANOGRAMA LEUCORHA) DO NOT REQUIRE VOCALIZATIONS TO RELOCATE THEIR UNDERGROUND BURROW

Leach’s Storm-Petrels, Oceanograma leucorha, are burrow-nesting seabirds that breed on remote islands. Each pair of Storm-Petrels incubates one egg, each bird taking turns on the egg while its partner forages at sea. Foraging trips take approximately four days and always begin and end at night. Exactly how the seabirds are able to distinguish their burrow from thousands of others is not well-known. Some species of Storm-Petrels are thought to be aided by highly characteristic vocalizations that can clearly be heard at night, emitted both by birds flying around the colony and birds underground (Taoda and Okumura 1990). We recorded behavior in one nest and focused on analyzing calling behavior. Chatter calls and Purr-calls, inside and outside the burrow and the movements of the incubating Storm-Petrel. We observed the incubating bird take ~60+ breaks for short periods on most nights while its partner was foraging. When the foraging bird returned, during three out of four changeover events, there were no vocalizations heard from the incubating partner, indicating that the returning bird did not necessarily require vocalizations to locate its burrow.

CIRCULATION ON THE VERACRUZ CORAL REEF SYSTEM DURING AUTUMN-WINTER 2006-2007

Current meter data, hydrography and numerical simulations are analyzed in order to identify the circulation patterns in the Veracruz Coral Reef System (Sistema Arrecifal Veracruzano) in Veracruz, Mexico. Results show that the main forcing in the region is the along coast wind stress. Tides contribution is one order of magnitude smaller and the contribution of eddies next to the shelf break seems to be negligible. Strong currents ~ 1 m/s are observed during strong wind events associated with norther.
sargassum is photodegraded under simulated sunlight with half-lives of 25–30 hours, and the spectral slope coefficients of its UV-visible absorption spectra (α ~ 16–35 nm) are in the range of 5-values generally observed in ocean water. Sargassum derived CDOM thus likely contributes significantly to remotely sensed observations of ocean color and to attenuation of solar UV radiation in the upper ocean. (Although this work was reviewed by EPA and approved for publication, it may not necessarily reflect official Agency policy).

CARBONATE SYSTEM AND SEA-AIR CO2 FLUXES IN SPRING IN THE YELLOW SEA

The Yellow Sea (YS), along with the East China Sea (ECS) to its south represents an important continental shelf region of the Northwest Pacific Ocean. Two world major rivers (Yangtze and Yellow Rivers) discharge into the region. It is also one of the 64 most productive large marine ecosystems of the world, and has received substantial attention in the international research community. However, information regarding the distribution of carbonate system in the YS, which allows us to better evaluate the regional air-sea CO2 fluxes in the YS is limited. This study thus implies that multiple processes may be responsible for the air-sea CO2 exchange in these two neighboring coastal seas. We emphasize that a better spatial coverage is still needed to better constrain the air-sea CO2 fluxes in the two important coastal seas, and in global continental shelves at large.

DECLADAL AND MULTI-DECLADAL VARIABILITY OF ATLANTIC SUBTROPICAL CELLS AND THE THERMALINE CIRCULATION

The tropical Atlantic is a crossroad of the Thermohaline Circulation (THC) and Subtropical Cells (STCs). It has been hypothesized that part of the THC return flow and STC upwelling in tropical Atlantic perturb the sea surface temperature (SST), which has important controls on the regional air-sea CO2 exchanges in these two neighboring coastal seas. We emphasize that a better spatial coverage is still needed to better constrain the air-sea CO2 fluxes in the two important coastal seas, and in global continental shelves at large.

Zhang, D., NOAA/PMEL and JISAO/OCEAN, Seattle, USA, dengxiao.zhang@noaa.gov; McPhaden, M.I., NOAA/PMEL, Seattle, USA, michael.mcmphaden@noaa.gov.
the western boundary STC of the Southern Hemisphere. It is found that the Northern and Southern interior STCs are generally in phase with those related to the deep oceanic variations of the Atlantic Niño. The western boundary STC, which we define as the NBC/NBUC flow within STC density classes, is weaker than and coherent with variability in the deeper flows, suggesting that the variability associated with wind-driven STC is overshadowed by the deep meridional overturning circulation at this latitude. A possible role of the mid- tidewater current variability of the NBC/NBUC in the tropical Atlantic meridional SST gradient mode and the Atlantic Multidecadal Oscillation (AMO) will be discussed.

COOPERATIVE KALMAN FILTER FOR OCEAN FUNCTION TRACKING USING AUTONOMOUS UNDERWATER VEHICLES

Ocean features below the surface are typically time varying and difficult to locate. We develop a method that combines measurements from multiple autonomous underwater vehicles to localize various ocean features. Vehicle movements are coordinated to track the features for in-situ observation. We design a cooperative Kalman filter to reduce measurement noise and spatial variations in sensor data to achieve results suitable for data assimilation. The motion coordination algorithm is able to take advantage of the nowcast or forecast made by ocean models to effectively navigate the vehicles. Simulation results are presented to demonstrate the effectiveness of our method in revealing structures of underwater temperature or salinity fields.

ON THE CURRENT-WAVE WIND INTERACTION IN THE SHOALING WAVE EXPERIMENT

This study presents two cases of the wave-current-wind interaction during the Shoaling Waves Experiment (SHOWEX). Wind, wind stress flux and wave data were obtained from Air Sea Interaction Spar (ASIS) buoys. Surface currents were measured by a High-Frequency Ocean Surface Current Radar. Two distinct types of wave-current-wind interaction were observed in the presence of the strong along-coast current from Chesapeake Bay. Current results in waves at the peak of wind-sea spectra shifting away from the wind direction; furthermore the buoyancy current front was also found to steer the stress away from the mean wind direction. As the strong along-coast current moved toward coast, the whole experiment domain was under uniform current. The wind stress and high frequency waves were observed to be steered away from the mean wind direction by the current. This effect has also been confirmed by data from the SeaWind scatterometer on board the QuikSCAT satellite. The above findings have been compared with the wave-current theories. The wind refraction under both shear current and uniform current cannot be explained by existing theories completely; therefore more work need to be done in wave-current interaction. The wind stress shifting observed from ASIS and QuikSCAT shows the wind direction retrieved from scatterometer lies between true wind direction and current direction, which is in agreement with the results from some recent studies.

ASSESSMENT OF THE ECCO2 HIGH RESOLUTION GLOBAL-OCEAN AND SEA-ICE DATA SYNTHESIS USING THE CLIVAR/GODEA GLOBAL SYNTHESIS AND OBSERVATIONS PANEL METRICS

The Estimating the Circulation and Climate of the Ocean, Phase II (ECO2) project aims to produce an increasingly accurate global ocean and sea-ice data synthesis at resolutions that start to resolve ocean eddies and other narrow current systems, which transport heat, carbon, and other properties within the ocean. ECCO2 data synthoses are obtained by least squares fit of a global full-depth-ocean and sea-ice configuration of the Massachusetts Institute of Technology general circulation model (MITgcm) to the available satellite and in-situ data. This presentation assesses the first ECCO2 data synthesis versus a series of metrics established by the CLIVAR/GODAE Global Synthesis and Observations Panel. These metrics include misfits from sea surface height observations, climatological and in situ temperature and salinity profiles, meridional transports, heat and salt content, sea level changes, transports through key regions, water masses, sea surface temperature and transport indices, and surface fluxes.

MULTI-SATELLITE BLENDED SURFACE MARINE PRODUCTS AND THEIR APPLICATIONS

Multi-satellite blended products of sea water surface (SWW) and temperature (SST) and their applications are presented. In addition to the traditional ship and buoy observations, SWW and SST have been operationally observed from multiple long-term satellites. Satellite observations provide superior spatial-temporal coverage, while in-situ observations provide the ground-truth for satellite bias correction. Blended products from all these resources increase both global coverage and resolution and reduce bias and analysis errors. Global 0.25° gridded products are available: 6-hourly sea winds from July 1987, and daily SST from Jan 1985 onward. In addition to their general use in physical oceanography, these products have applications include users in climate monitoring, tritium-based indices for fisheries/ecosystem, ocean natural mineral slick monitoring, and other areas such as marine aviation and transportation incident investigations, wind/wave power generation research, and education/outreach. The products are accessible through ftp, as well via inter-operable web-based data servers that provide for easy data access, visualization, subsetting and downloading in user-preferred formats, which increases the user community that can benefit from these products. Details can be found at http://www.ncdc.noaa.gov/oa/satellite.html.

IMPACT OF THE ATLANTIC MULTIDEcadAL OSCILLATION ON NORTH PACIFIC CLIMATE VARIABILITY

Large-scale multidecadal climate variability in the North Pacific, such as the Pacific Decadal Oscillation (PDO), has been observed during the 20th century. Using a hybrid version of the GFDL coupled climate model, we show that the Atlantic Multidecadal Oscillation (AMO) provides a source of multidecadal variability to the North Pacific, and needs to be considered along with other forcings for North Pacific climate variability and change. The North Pacific response, which lags the North Atlantic forcing by several years, is generated through atmospheric teleconnections originating in the Atlantic. Oceanic dynamics and positive air-sea feedback over the North Pacific enhance the response. The results indicate that a North Pacific regime shift, opposite to the 1976-77 shift, might occur now a decade after the switch of the observed AMO to a positive phase around 1995. The origin of the AMO is highly debated. Some suggest that it is driven by Atlantic meridional overturning circulation (AMOC) variations, while others think it is induced by changes in radiative forcing. Here the mechanism, attribution and various climate impacts of the AMO will also be discussed.

IMPACTS OF FRESHWATER FLUX FORCING ON SALINITY AND INTERANNUAL VARIABILITY IN A HYBRID COUPLED MODEL OF THE TROPICAL PACIFIC

In the tropical Pacific, ocean salinity has been proved to be important to the tropical dynamics and El Niño-Southern Oscillation (ENSO). Previously, most modeling studies have focused on the roles of forcing components of atmospheric winds and heat flux; the effect of freshwater flux (FWF) forcing and its related feedback have been examined mostly in ocean-alone models. Here we use a hybrid coupled model (HCM) of the tropical Pacific climate system, constructed from an oceanic general circulation (OGCM) and a simple atmospheric model. Interannual anomalies of evaporation minus precipitation, (E-P)anom, are constructed statistically by a SVD analysis, relating the FWF variability to SST anomalies. The constructed HCM can well reproduce interannual variability associated with ENSO in the tropical Pacific. Coupled sensitivity experiments are performed with different representations of FWF forcing within the simplified atmospheric model, consisting of climatological and anomalous FWF fields both [i.e., (E-P)clim+(E-P)anom], the climatological field and precipitation anomalies [i.e., (E-P)clim-Panom], the climatological field and evaporation anomalies [i.e., (E-P)clim+Eanom], and the climatological field only [i.e., (E-P)clim], respectively. It is demonstrated that FWF forcing can have a significant modulating impact on ENSO, with more realistic simulations of interannual SST variability in the eastern tropical Pacific (e.g., the amplitude and structure).

IMPACT OF AN ENSEMBLE CIRCULATION-DEPENDENT INFLATION FILTER ON OCEANIC CLIMATE DETECTION WITHIN ‘BIASED’ COUPLED GCMs

This study serves as the first step of our efforts for discovering the impacts of fully-coupled GCMs’s biases on Oceanic Data Assimilation. We design first an ‘imperfect twin’ experiment using two coupled GCMs that are biased with respect to each other, in which, based on the 2005 ARGO network, observations are drawn from one coupled GCM and assimilated into the other. Using a standard ensemble filter, the assimilating imperfect model successfully recovers the upper-ocean temperature and salinity from observations, but fails to converge in the deep ocean, where model bias is relatively large compared to the ocean’s intrinsic variability represented by the ensemble spread. The inconsistency between the
well-constrained upper and poorly-constrained deep oceans generates spurious currents throughout the water column. To relax this problem, we introduce an ensemble circulation-dependent inflation filter (ECdF) which uses a pre-computed anomaly’s variance to inflate the covariance whenever a small ensemble spread would otherwise make the model “over-confident.” The ECdF greatly improves filtering performance, reducing global deep-ocean RMS errors by 30–40% for temperature, 40–50% for salinity, 70% for horizontal currents and 80% for vertical velocity. Consistently, the estimate accuracy on meridional overturning circulation, pycnocline depth and ENSO variability is dramatically enhanced.

APPLICATION OF CROSS FLOW ULTRAFILTRATION FOR ISOLATING EXOPOLYMERIC SUBSTANCES (EPS) FROM MARINE DIATOMS

Three techniques, i.e., 1) ethanol precipitation, 2) stirred cell ultrafiltration, or 3) cross-flow ultrafiltration, both 2) and 3) followed by stirred cell diafiltration were compared for their effectiveness of quantitatively isolating exopolymeric substances (EPS) from the marine diatom Amphora sp. The results showed that ethanol precipitation was not effective in isolating and concentrating EPS from the seawater medium. Stirred ultrafiltration appeared best for harvesting EPS from this diatom. However, because of its limitations in terms of time and volume, cross-flow ultrafiltration was further improved by stirred cell diafiltration and a three-step cartridge soaking. Thus, the yield of the two ultrafiltration methods (3.0 mg-glucuronic acid/l) became comparable, and no EPS was found in the permeate. Two extracellular polysaccharides with similar molecular weights of 1000 kDa could be isolated from Amphora sp. These results are important for investigations of the gel-formation capacity of microbially produced EPS in marine environments.

MODELING OF FRESHWATER PATHWAYS IN NEW YORK BIGHT

This study is to investigate the dispersal process of Hudson River plume on New Jersey shelf which is crucial for the local biogeochemical processes. We used ROMS with three major forces (atmospheric forcing, ambient current, and tides) to study the mean dynamics and freshwater dispersal on the mid- and outer-shelf. The model was verified through comparison with field data and CODAR observations. Comparison of simulations driven by various combinations of the three forces quantified the influence of the forces on the freshwater spreading. Ekman transport and geostrophy were identified as the two major processes in shaping the surface mean circulation, while it is the ambient current that drove the mean circulation in deep. We found three freshwater pathways, and the mid-shelf pathway explained the spread of the freshwater from the Hudson Valley. The comparison identified wind as the primary force to push the freshwater onto mid- and outer-shelf. Hudson Valley was showed to be a barrier for the freshwater transport and its role was magnified by the ambient current. Tides had minor impact on both mean circulation pattern and freshwater dispersal.

SOUTHWARD TRANSPORT THROUGH THE TAIWAN STRAIT DUE TO TYPHOONS

As is well known, the northward transport through the Taiwan Strait is weak or even reversed in winter due to strong northeasterly monsoon while the northward transport is very strong during summer and early autumn before the northeasterly monsoon bursts. This paper is focused on the transport caused by typhoons in the Taiwan Strait. Numerical studies, using a two-way nested coupled tide-surge model (NCTSM), show that the transports caused by typhoons moving along the four devised routes, which are representative of most typhoons affecting the Taiwan Strait, direct southward. The southward transports due to typhoons were confirmed by the buoy observing data during the period from 27 Aug. to 5 Oct. 2005 when five typhoons separately affected the Taiwan Strait and they were related to local effect and/or remote effect of the wind fields of typhoons. These results indicate that the typhoon, affecting the Taiwan Strait, could induce southward transport through the Taiwan Strait, which might weaken or even reverse the well-known northward transport.

RETRIEVE SIZE DISTRIBUTIONS OF PHYTOPLANKTON SUSPENDED PARTICLES AND DETRITUS FROM VOLUME SCATTERING FUNCTIONS IN A COASTAL WATER OFF NEW JERSEY

Phytoplankton, suspended particles, and detritus are major particulate components in a coastal environment and knowledge of spatial and temporal variations of their size distributions will provide important insight into understanding coastal dynamics of physical, chemical and biological processes. Traditional particle sizing and counting devices, such as Coulter counter or an infrasound system, while each has their own limitations, cannot differentiate among different particles and can only provide a bulk estimate of the overall size distribution. Volume scattering function measures the angular variation of light scattered by a water volume, within which each component contributes additively. The contribution by each component, in turn, is a function of their size distribution, concentration, and refractive index. Here we report an inverse modeling approach using the measured volume scattering functions to derive the number densities and size distributions of major optically important water constituents simultaneously. The method will be evaluated by comparing the results with the estimated by other instruments.

EXCHANGE FLOW BETWEEN OPEN WATER AND AN AQUATIC CANOPY

Convective exchange produced by spatial heterogeneity in water temperature plays an important role in the transport of nutrients and other substances, in particular, between the littoral and pelagic regions of surface water bodies. During the daytime, the emergent portion of aquatic plants blocks the solar radiation from entering the water beneath them. A temperature difference is established due to the uneven distribution of the solar energy between an open and vegetated region. The temperature difference can generate density difference that can drive exchange flows between the open and the vegetated regions. A series of experiments has been conducted to investigate the exchange flow between an open and vegetated region of water, in which a random array of cylinders was used to simulate an emergent canopy. The flow pattern was captured using a CCD camera. It has been found that the open velocity entering the open region maintains a constant speed while flow into the vegetated region decelerates gradually due to additional drag. The discharge rate is controlled by the canopy region and decreases over time and with increasing drag.

EASTERN PACIFIC FORCING OF ENSO SEA SURFACE TEMPERATURE ANOMALIES

Previous studies have described the impacts of wind stress variations in the eastern Pacific on sea surface temperature (SST) anomalies associated with the El Niño/Southern Oscillation (ENSO) phenomenon. However, these studies have usually focused on individual El Niño events and have not considered impacts on La Niña—the cold phase of the ENSO cycle. In this paper we examine effects of wind stress and heat flux forcing on interannual and interdecadal variability of ENSO and tropical Pacific from sensitivity tests using ocean general circulation model over the period from 1980 to 2002. Results indicate that in the Niño-3 region (5°N-5°S, 90°-150°W) a zonal wind stress anomaly of 0.01 N m-2 leads to about 1°C SST anomaly and that air-sea heat fluxes tend to damp interannual SST anomalies generated by other physical processes with a rate of about 40 W m-2 per 1°C. These results systematically quantitatively confirm the expectations from previous event-specific numerical model studies that local forcing in the eastern Pacific can significantly affect the evolution of both warm and cold phases of the ENSO cycle. The results are also consistent with a strictly empirical analysis that indicates a wind stress anomaly of 0.01 N m-2 leads to about 1°C SST anomaly in the Niño-3 region.

SEA BREEZE DRIVEN OCEAN RESPONSE ON A STRATIFIED CONTINENTAL SHELF AT THE CRITICAL LATITUDE

The coastal ocean response to sea breeze forcing in the northwest Gulf of Mexico is investigated using observations and numerical simulation. The response depends significantly on a number of factors including the characteristics of sea breeze, river-associated stratification, latitude, and coastal and bathymetric curvature. The observations indicate that the river-associated stratification can significantly alter the oceanic response and this varies interannually and spatially. The maximum diurnal oceanic response usually occurs in June when there is a shallow mixed layer, strong stratification, and an approximately 2-week period of continuous sea breeze forcing. Freshwater events like, “the Great Flood” of the Mississippi River in 1993, deepen the summer mixed layer and reduce oceanic sea breeze response during that year. Numerical experiments indicate that offshore freshwater flux associated with sea breeze forcing depends significantly not only on stratification and latitude, but also the curvature of the coast and topography. Basin wide near inertial response in the form of propagating Poincare waves occurs in the numerical simulations but is limited to latitudes below 30°N, making the Gulf of Mexico unique in this regard.

INTERACTION OF EDDIES WITH SHELF WATER IN A PARTIALLY ENCLOSED BAY

Interactions of point vortices with a step-like topography are examined through the use of a barotropic, quasi-geostrophy, f-plane, contour dynamics model and within a domain

Zhang, X., Massachusetts Institute of Technology, Cambridge, USA, xzhang@mit.edu; Nepf, H. M., Massachusetts Institute of Technology, Cambridge, USA, hnm@mit.edu

2008 Ocean Sciences Meeting
where the shallow region, as bounded by the topography on the north and indented coastlines on the south, has the shape of a bay. Anticyclone- and cyclone-induced interactions show remarkable differences in phenomena such as formation of topographic eddies, cross-shelf water exchanges and motion of vortices, etc. Two basic mechanisms, especially their relative importance, control the process: one is the advection of the potential vorticity front by the vortex and the other one is the propagation of topographic Rossby waves along the shelf-break. When the vortex is an anticyclone, the two mechanisms counteract each other as they force frontal deformations into opposite directions; while for a cyclone, the two work together pushing deformations eastward. This asymmetry is responsible for quite different behaviors between anticyclone- and cyclone-involved interactions.

HURRICANE GENERATED WAVE AND WAVE-INDUCED LOADING ON COASTAL BRIDGES DURING HURRICANE IVAN(2004)

Hurricane Ivan (2004) caused significant property damage and loss of lives as it passed through the Caribbean Sea and Southeastern US. Maximum storm surge reached 6m along the Florida coast, while waves reached 20m in height and 17s in period offshore, and 1.6m in height and 4s in period inside the shallow Escambia Bay where the I-10 Bridge collapsed, apparently due to the high surge which reached the bridge deck and the wave force exceeded the connection force of the bridge. In this study, a high-resolution storm surge modeling system CHIS-SMMS is applied to simulate the waves, currents, and storm surge during Hurricane Ivan (2004). Simulated storm surge and waves are successfully validated by comparison with observed data of wave, water level, and high water mark. With validated surge and wave force, the wave loading on the I-10 Bridge is calculated during Hurricane Ivan. The results reveal that the total wave force on top of surge is 334 tons, sufficient to overcome span weight and its bolted connection and push bridge deck into water. Significant 3D flow features are simulated.

TSUNAMI INUNDATION STUDY WITH UNSTRUCTURED GRIDS: BENCHMARKING AND APPLICATION TO THE CASCADIA SUBDUCTION ZONE

Existing inundation models for assessing tsunami hazards predominantly use structured grid techniques. For realistic applications, models based on unstructured grids have distinct advantages over structured grid models because they resolve the effects of complex geometries and bathymetry more efficiently. Here we present an efficient, robust and accurate inundation model based on unstructured grids. The model, SELF, uses a hybrid finite-element and finite-volume method and semi-implicit time stepping. The advection in the momentum equations is treated with the Eulerian-Lagrangian method (ELM). The use of the semi-implicit time stepping and ELM eliminates most numerical stability constraints, and results in greater efficiency. The wetting and drying process is incorporated in the model in a straightforward way, thus making it suitable for tsunami inundation studies. The model has been benchmarked with the first two problems published on the 3rd International Workshop on Longwave Runup Models. Recently we have applied it to assessing tsunami hazards along and off the California coast. Oregon using inputs from source models that explore the variability of Cascadia Subduction Zone earthquakes. Here we present preliminary comparisons with field mapping of the extent of paleotsunami deposits. The ultimate goal is to design a new generation of digital inundation maps for coastal communities in Oregon using state-of-the-art technology.

NUMERICAL SIMULATION OF THE GENERATION OF NONLINEAR INTERNAL GRAVITY WAVES IN THE SOUTH CHINA SEA

When barotropic tides interact with topography, internal tidal beams form when the ratio of large-amplitude internal tidal beams or if they emerge from nonlinear waves. Two basic mechanisms lead to the formation of nonlinear wave trains, particularly during strong spring tides. While numerous observations indicate the presence of nonlinear wave trains that appear to emerge from the Luzon Strait on the eastern side of the South China Sea, it is not clear from these observations whether the waves evolve from large-amplitude internal tidal beams or if they emerge from nonlinear waves of deformation. We present results of both two- and three-dimensional simulations of nonlinear internal gravity waves in the South China Sea using the nonhydrostatic model SUNTANS in order to highlight different regimes under which the different waves can form. Results are compared with in-situ and remotely-sensed data for verification and to aid in understanding of the governing physical processes. This work was supported by ONR Award N00014-05-1-0294.

THE BARRIER LAYER IN THE EAST CHINA SEA IN SUMMER

In summer, in the East China Sea where the temperature is roughly homogeneous in the upper layer, vertical variations of salinity may be responsible for significant density stratifications. In this paper, based on the high resolution CTD data from 1980 to 2006, we show that the fresh surface water from Yangtze River discharge play an important role in determining the density structure. Moreover, water mass with high salinity carried by the Taiwan Warm Current and Kuroshio also influence the density structure. The meeting of these fresh water and salty water may induce a strong halocline in the upper layer. This halocline induces a pycnocline that acts as a barrier layer for mixing between the surface water and the subsurface water. The barrier layer occurrence is strongly related with the Yangtze River discharge. When the discharge is large or small, the barrier layer is wide and thick or is thin and only occurs in limited area.

A HANDS-ON PRIMARY SCHOOL ACTIVITY THAT SHOWS PHOTOBLEACHING OF CDOM AND THE USE OF REPlicATES AND CONTROLS, AND RELATES PHOTOBLEACHING TO THE WATER CYCLE

Chromophoric Dissolved Organic Matter (CDOM) is an important component in freshwater and marine ecosystems that plays multiple roles in biogeochemical cycles. Photobleaching of CDOM (reduced absorption of incoming solar radiation caused by CDOM photodegradation) increases the penetration of UV and visible radiation in the water column, with important consequences for the biotic community. We designed an intuitive, quick, and safe hands-on experiment to help primary school students visualize and understand photobleaching by using commercially available colored drinks as CDOM analogs. The class reviews the water cycle, emphasizing inputs of color from soil to rivers and then to the ocean. Students then see samples of various drinks in transparent plastic bags (some leak, making need for replicates obvious) and sit them in sunshine for several hours on a sunny day. By comparing the colors of samples exposed to sunshine with controls without exposure, students easily see the photobleaching of some chromophores. We tested this activity multiple times in a local elementary school. The school enrichment teacher’s evaluation of its educational suitability, requirements, and pluses and minuses will be presented.

INTEGRATING SATELLITE IMAGERY AND NUMERICAL MODELS FOR COASTAL SEDIMENT TRANSPORT STUDY

Mobile Bay located on the north Gulf Coast is a broad and shallow estuary. Its bottom sediments are highly sensitive to winds because of the shallow water depth. The objective of our study is to quantify the re-suspension and transport of fine sediments in a shallow estuary by integrating numerical models with satellite imagery. We have employed the Moderate Resolution Imaging Spectroradiometer (MODIS) product that has 250-m spatial resolution and 12-bit spectral resolution. The total suspended sediment solid (TSS) is inferred from the satellite imagery according to a new relationship between MODIS red-channel data and in-situ measurements. However, the effectiveness of the inferred TSS is limited to the sea surface and the temporal resolution is also limited by the satellite scanning frequency and cloud contamination. Therefore, output from numerical models is utilized to fill the gaps in time and space. A sediment transport model has been integrated with a 3D circulation model and a spectral wave model as well as satellite imagery to gain insight into the temporal and spatial variability of suspended sediments. The methodology for combining remote sensing and numerical models can be used to study sediment dynamics in areas with limited access.

LONG-RANGE PROPAGATION OF THE SEMIDIURNAL INTERNAL TIDE NORTHWARD FROM THE HAWAIIAN RIDGE

In the experimental Internal Waves Across the Pacific (IWAP) Spring 2006, six moorings were deployed along a 1400-km-long section from 25-37°N, while simultaneous spatial surveys were conducted in two northbound and two southbound transits. The section was selected to follow an internal-tide beam emanating from French Frigate Shoals. At each mooring, the internal tide had a spring-neap cycle, consistent with the barotropic tidal forcing at the Hawaiian ridge lagged by the expected travel time for a mode-1 wave. The

Zhao, Z., University of Washington/Physical Oceanography Laboratory, Qingdao, China, zhaoz@poul.washington.edu;
energy flux decreased from ~4 kW/m at MP1 to ~1 kW/m at MP6. Dissipation estimates indicate ~24% of the internal-tide flux was removed within 100 km of the critical latitude, an enhancement that we attribute to PSI. The flux was also estimated using a new phase-adjustment method and an extended T/P altimeter dataset. The altimetric and moored fluxes were in good agreement. The coherent and incoherent internal tides were calculated from historical and IWAP moorings, revealing the influence of the mesoscale eddy field on internal tide propagation. The Doppler compressed expanded internal tide was observed from shipboard measurements in the southbound/northward transits.

MODELING OF AGULHAS RING INJECTION INTO THE SOUTH ATLANTIC DURING GLACIALS AND INTERGLACIALS

Recent proxies suggest that, at the end of the last glacial, there was a significant increase in the injection of Agulhas rings into the South Atlantic (SA). This event brought about a dramatic increase in the salt influx from the Indian Ocean into the SA helping to re-start convection in the North Atlantic and leading to the termination of the Younger Dryas. We propose a mechanism through which large variations in ring production take place. We develop a semi-analytical non-linear 1½-layer model of current retroreflection from non-zonal coastline on the β-plane, supposing the outflow to be zonal. Based on this model, we define a critical value of the coastline slant γ, implying restricted possibilities for ring detachment from the retroreflection area in the 'supercritical' range of y. In the case of Agulhas rings, region rings can produce only if the retroreflection occurs beyond specific latitude where the angle is critical.

A MECHANISM FOR THE BIFURCATION OF THE TSUSHIMA WARM CURRENT IN THE JAPAN/EAST ASIA

By using POM, we investigate the mechanisms of two branch currents associated with the Tsushima Warm Current (TWC) in the Japan/East Sea (IES). The results from model simulations reveal that these two branch currents are both forced by the Kuroshio Current (KC) along Japan's east coast. The friction exerted by the KC induces a considerably pressure

SEASONAL INFLUENCE OF INDONESIAN THROUGHFLOW IN THE SOUTHWESTERN INDIAN OCEAN

The influence of the Indonesian Throughflow (ITF) on the dynamics and the thermodynamics in the southwestern Indian Ocean (SWIO) is studied by analyzing a forced ocean model simulation for the Indo-Pacific region. The warm ITF waters reach the southwestern Indian Ocean from August to early December, with a detectable influence on weakening the vertical stratification and reducing the stability of the water column. As a dynamical consequence, baroclinic instabilities and oceanic intraseasonal variabilities (OISVs) are enhanced. The temporal and spatial scales of the OISVs are determined by the ITF-modified stratification. Thermodynamically, the ITF waters influence the subtle balance between the stratification and mixing in the SWIO. As a result, from October to early December, an unusual warm entrainment occurs and the SSTs warm faster than just net surface heat flux driven warming. In late December and January, signature of the ITF is seen as a relatively slower warming of SSTs. Finally, a conceptual model for the processes by which the ITF impacts the SWIO is proposed.

M., University of Massachusetts Boston, Boston, USA, allen.gontz@umb.edu; Olsen, C. R., University of Massachusetts Boston, Boston, USA, curtis.olsen@umb.edu;
fuller use with better time resolution. A microbial water quality model is constructed by coupling a coastal circulation and transport model (CACE3D) with a microbe fate model. The modeling domain is a bayside beach in Miami, Florida. The hydrodynamic model results are compared with current velocity measurements. For the microbe fate model, our work shows that human shedding, dog feces and rainwater runoff are major sources; also die-off rate is extracted from experiment and literature. However, there are some modeling issues (e.g., time term such as location and number of sources plus dog and runoff). We approach this problem by performing Monte Carlo simulation: define location and number of source terms as random variables, determine their probability distribution by analyzing high resolution camera images of the beach, run the model using random input terms and analyze the results.

META-TRANSCRIPTOME OF A EUKARYOTIC MARINE PLANKTON COMMUNITY IN TAMPAA BAY, FL

A cDNA library from mRNAs isolated after a Peridinium quinquecorne bloom in Tampa Bay, FL surface waters was constructed. Our specific objective was to develop a procedure to identify protein-encoding open reading frames from eukaryotic plankton without prior cultivation or identification. The phyltoplankton population based on RbcL COI identities consisted of organisms closely related to Skeletonema diatoms, Peridinium quinquecorne dinoflagellates, several types of chlorophytes, and a number of type-A Synechococcus. The cDNA clones from the meta-transcriptome were sequenced (aver-age size 360 bp). BLAST analysis (NCBI Genbank) revealed good homology to previously identified sequences, several of these transcripts being closely related to those of the prasinophyte Ostreococcus lucimarinus and other unicellular eukaryotes. Predicted protein homologues included genes associated with phyltoplankton growth and photosynthesis (NDH, COII, Cytb; NR, ribulose-5-phosphate carboxylase, rbcL), coi (Salamen adenoylsynthesise (converts inactive coxalins to metabolically active B), N-acetyl-γ-glutamyl-phosphate reductase (arginine biosynthetic pathway), a G-pro- tein-coupled receptor induced protein and several photosynthetic-pigment related pro- teins. Since less than 10% of the RNA sequences were RNA, the enrichment techniques for mRNAs were fairly successful.

ENZYMIC HYDROLYSIS OF POLYSACCHARIDES IN SURFACE AND BOTTOM WATERS IN THE DELAWARE BAY ESTUARY AFFECTED BY ELEVATED (MINERAL) PARTICLE LOAD

Extracellular enzymes play a key role in global DOM cycle. They operate outside the cell where they may become associated with organic or mineral phases. This study shows evidence that elevated (inorganic) particle load in the water column affect hydrolysis of high molecular weight polysaccharides. Surface and bottom water samples, taken at three sites in Delaware Bay in December 2006, were incubated with six distinct fluorescently- labeled polysaccharides. Changes in molecular weight were monitored over time using gel permeation chromatography. At two sites, hydrolysis rates of four polysaccharides were higher in bottom than surface waters, and one substrate (pullulan) was almost exclusively hydrolyzed in bottom waters. Results of particulate-organic carbon and nitrogen as well as bacterial cell counts indicate that bottom water suspended matter was mostly inorganic and likely of benthic origin. The results propose that resuspended bacteria and/or enzymes associated to minerals increase enzymatic activities in bottom waters, and broaden the spectrum of enzyme activity in the water column with consequences on organic matter degradation in highly dynamic aquatic environments such as estuaries and coastal waters.

THE EXPLORER OF THE SEAS OBSERVATORY: FOUR YEARS OF REGIONAL MARINE SURFACE WATER MEASUREMENTS IN THE CARIBBEAN SEA

The 31m cruise liner, Explorer of the Seas, operated by Royal Caribbean Cruises, Ltd. (RCCL), cruised from Miami, Florida through both the Eastern and Western Caribbean age each year in the Caribbean Sea and surrounding waters. Since May 2001, the flowing seawater system has operated continuously and been maintained by the two onboard technology. Lessons learned from the over five years of continuous operation will be presented along with a summary of environmental sensor data time series and seasonal averages. Instrument maintenance issues, design modifications and instrument calibration histories will be discussed. A first look at the resultant searchable database will be shown.

TIME-VARIABLE CONVERSION OF BAROTROPIC TO BAROCLINIC M2 TIDAL ENERGY AT THE KAENA RIDGE, HAWAII

The temporal variability of internal tide generation is examined for the Kaena Ridge, the site of the near-field component of the Hawaii Ocean Mixing Experiment. Barotropic to baroclinic energy conversion for the dominant M2 tidal constituent is obtained using moored observations of currents, temperature and salinity over a six-month deployment (December 2002 - May 2003). The energy conversion exhibits low frequency variability with amplitudes ranging by a factor of two (0.5 to 1.6 W/m2) over the record. Similar amplitude variations are found for the M2 energy density at the ridge and just off the ridge as the internal tide radiates to the southwest. The observed energy conversion correlates with stratification variations near the bottom, suggesting that deep stratification over the ridge flank modulates the internal tide generation. Comparisons of numerical model simulations with the observed energy conversion will be presented.

HYDROGEN PYROLYSIS/LIPID COMPOUND ANALYSIS OF BLACK CARBON COMPOSITION AND SOURCE IN GANGES-BRAHMAPUTRA RIVER SEDIMENTS

Though recent work shows that black carbon (BC) represents significant portions of the organic carbon (OC) exported to the ocean, our understanding of its sources and fate remains relatively poor. Catalytic hydrocracking (Hy-Py) provides information on refractory aquatic OC composition, structure and source, not available through other methods. Materials are heated at high H2 pressure with a molybdate-catalyst. Volatilized compounds produced at low temperatures (50-350°C), representing loosely bound organic components, and those produced at high temperatures (350-520°C), representing molecular ‘back-bone’, are captured downstream and analyzed for lipid biomarker composition. BC in Ganges-Brahmaputra (GB) floodplain sediments constitute 12 to 85% of the TOC and have d13C of -22 to -24‰, distinct from that of TOC -19 to -27‰. Comparison of lipid compounds in the Hy-Py products of GB sediments to that of reference materials including Chestnut wood, Franciscan mélange and Devonian Shale, together with lignin and conventional lipid biomarker data, indicate a mixture of sources for GB-BC including terrestrial plant and fossil carbon.

SEAGRASS RESPONSE TO OCEAN ACIDIFICATION: FROM INDIVIDUAL LEAVES TO POPULATIONS

Seagrasses, a polyphyletic group of aquatic angiosperms form the bases of highly produc- tive ecosystems ranging from tropical to polar seas that support diverse assemblages of marine organisms. Despite their evolutionary and ecological success, seagrasses have high light requirements that make them vulnerable to eutrophication, sediment loading and coastal modification. Unlike most marine autrophs, the high light requirements result from CO2 limited photosynthesis because the capacity for bicarbonate utilization cannot saturate the CO2 requirements of Rubisco. Despite clear evidence for carbon limitation of photosynthesis, seagrasses thrive in high light environments, and show little evidence of light-induced photoinhibition. Increasing the availability of dissolved aqueous CO2 can increase instantaneous rates of light saturated photosynthesis by up to 4 fold. Prolonged exposure to elevated CO2 concentrations increases the concentrations of non-structural carbohydrates (sucrose and starch), rates of vegetative shoot proliferation, and flowering, and reduces light requirements for plant survival. Consequently, seagrass populations are likely to respond positively to CO2 induced acidification of the coastal ocean, which may have significant implications for carbon dynamics in shallow water habitats and for the restoration/preservation of seagrass populations.

PROMOTING AND RESEARCHING SUSTAINABLE OCEAN SCIENTIST-EDUCATOR PARTNERSHIPS: THE COSEE-CA COSIA MODEL

COSEE California’s Communicating Ocean Sciences to Informal Audiences (COSEA) is an NSF-funded program promoting effective, sustainable scientist-educator partner- ships. COSEA (http://www.lawrencelabochscience.org/cosia) is a consortium of 6 core partnerships between ocean sciences research institutions and informal science education institutions (e.g., science centers, aquaria). COSEA’s first goal is to provide a model for establishing substantive, long-term partnerships between scientists and informal science education institutions to meet their respective educational outreach needs. To promote the development of effective partnerships, COSEA scientists and educators collaborate- ly developed and co-teach an upper division college course for undergraduate and graduate students in ocean sciences-related degree programs. The course teaching theory
that the students practice while communicating ocean sciences concepts to the public. COSIA-CA is developing dissemination models to share our "best practices and materials with non-COSIA institutions and organizations (e.g., the National Marine Sanctuaries). COSIA researchers are tracking the formation and evolution of COSIA partnerships to derive principles for developing and sustaining future scientist-educator partnerships. In this presentation, we share our partnership development strategies, mechanisms for promoting future partnerships, our dissemination model, and some preliminary research results.

THE ELBE ESTUARY UNDER THE PRESSURE OF CLIMATE CHANGE - IMPACTS ON THE TRANSITION ZONE BETWEEN RIVER AND SEA

The Elbe is one of the largest rivers in Europe – it is 1092 km long and has a catchment area of 148,268 km². It has a funnel-shaped river mouth and its estuarine part which exhibits a remarkable salinity and turbidity gradient extends over nearly 100 km. The load of nutrients coupled with the energy from tidal action intensifies the stirring-up and cycling of nutrients from shallow sediments, making the Elbe, like other estuaries, one of the most productive systems of (acoustic) system. Anthropogenic changes in the upper and lower part of the River Elbe as well as changes in climate, caused by an increase in temperature with higher evaporation and lower precipitation, have remarkable impacts on the matter flux of this system. An internal fertilization effect leads to an unexpected increase in nutrients and particulate organic matter, which because of their long residence times in the estuarine part of the river cause summer oxygen concentrations of about 2 mg l-1 and lower.

RADIOCARBON CONTENT OF SOOT AND CHARRED BLACK CARBON USING THE BENZENE POLYCARBOXYLIC ACID METHOD.

Black carbon (BC), a bi-product of combustion processes, is ubiquitous in the environment due to the burning of biomass and fossil fuels. Defined by a continuum from char (e.g. biomass) to soot, the structure of BC is unknown. Soot is composed mostly of condensed aromatic rings whereas char has an abundance of oxidized functional groups. We investigate whether the radiocarbon signatures of the various components of the BC structure differ from that of the bulk BC. Using the benzene polycarboxylic acid (BPCA) method, a chemical oxidation method, we quantify BC as BPCAs and measure the Δ14C values of the resulting BPCAs. The distribution of BPCAs formed provides information about the chemical structure of the bulk BC material. BPCA distributions and their Δ14C values, along with the bulk BC and Δ14C values will be presented for NIST 1649a, a wellstudied urban dust of anthropogenic origin, and wood char prepared for the BC Ring Trial, of modern origin.

LARGE SCALE MODES OF BOTTOM PRESSURE VARIABILITY FROM GRACE AND THE ECCO MODEL - REVISITED

The ECCO baroclinic numerical model (version JPL-kf066) which assimilates altimetry and XBT, shows basin-scale modes in bottom pressure (BP) with most energy at annual, but also shorter periods. The ECCO-II high resolution baroclinic model, without data assimilation, also does. Similar modes were seen by Stepanov and Hughes (2006) in a barotropic model, and explained in terms of a mass exchange between the Pacific and Southern Ocean. We also see these modes in the GRACE monthly data, interpreted as bottom pressure variations. This presentation takes advantage of the latest releases of the GRACE data, with much improved accuracy and corrections, and also seeks to understand weaker interannual components in these signals.

MODELING SEDIMENT DEPOSITION IN THE YELLOW RIVER MOUTH

Yellow River is famous for its high sediment concentration and it carries a huge amount of sediment into Bohai Sea during flood seasons. Recent studies indicated that the local hydrodynamics plays an important role in sediment transport and deposition at the river mouth. To analyze the sediment deposition in the Yellow River mouth, we applied the Community Sediment Transport Model (CSTM) to the whole Bohai Sea with emphasis on the Yellow River mouth. The model couples the third-generation wave model - SWAN, a regional ocean circulation model - ROMS and a suspended sediment transport model. Wave-current interactions are presented by the short wave forcing in currents, the wave effect on bottom-boundary layer, and the current effect on waves. The external driving force includes tidal forcing, wind stress, and river outflow. The sediment discharge from the river was measured at Lijn Station and was taken into account in the numerical model as a sediment source condition. The numerical results of the tidal current velocities and sediment concentration are compared with observations. The simulations show that the sediment concentration in the Yellow River mouth presents a distinctly seasonal variety and most of the suspended sediment deposits around the Yellow River mouth.

MICROBIAL CONTROL OF PHOSPHATE IN THE NORTH ATLANTIC SUBTROPICAL GYRE

Phosphate concentrations fall into the low nanomolar range in several oligotrophic areas of the world oceans, but little is known about its in situ dynamics. Here we have budgeted the uptake of phosphate by the dominant microbial groups using flow cytometric sorting in order to assess the microbial control of this depleted nutrient in the North Atlantic gyre. The bacterioplankton was the main consumer of bioavailable phosphate. Within the bacterioplankton a group of heterotrophic bacteria with low nucleic acid content, 60% comprising of SAR11 clade cells. On the results of fluorescence in situ hybridisation, and Prochlorococcus phototrophic cyanobacteria, were the two major groups taking up phosphate. Each of these two bacterial groups was responsible for an average of 45% of the phosphate uptake, whilst Synechococcus (7%) and picoeukaryotic (0.3%) phytoplankton played minor roles in direct phosphate uptake. Hence phosphate uptake in the oligotrophic gyre is rapid and mainly by the two dominant bacterial groups and not by eukaryotic algae.
