
Changes in the sea-ice conditions long the west coast of Svalbard has during the last decades changed and affected conditions ashore. The effect upon the discharge characteristics of small drainage basins close to the seashore are discussed. The area studied is situated on the coastal plain, south of Kapp Linne’ (78°04' N, 13°38' E) with special focus on the anomalous discharge pattern of the Fysvåen Lake catchment area. The drainage of the lake is with increased frequency blocked by ice-cemented storm ridges delaying the spring and snowmelt peak flow. Vast areas are flooded, affecting vegetation and breeding birds of the area. The Lake is then, dramatically tapped during one or two days with heavy flow, after which the discharge pattern returns to normal. This process, is not unique here but rather common along the west coast of Svalbard. These special conditions have a clear influence on the active layer, the permafrost and the vegetation and the bird colonies of the area.

PHOTOCHEMISTRY MINERALIZES DISSOLVED ORGANIC MATTER (DOM) AND INCREASES DOM BIOAVAILABILITY IN THE ATLANTIC SEA

Direct photomineralization of dissolved organic carbon (DOC) and nitrogen (DON) as well as the stimulation of bacterial growth by photoproduction of labile organic substrates were investigated by simulated solar irradiation experiments using waters from a freshwater-marine gradient in the Baltic Sea. We calculated the annual photomineralization rates of DOC and DON and the annual photoproduction rate of labile organic substrates which supported bacterial growth according to the solar irradiance in the Baltic Sea and the experimentally determined apparent quantum yields for the photochemical reactions. The calculated photomineralization rate of DON was lowest in the regions with terrestrial dominated DON while the photomineralization rate of DON decreased along the freshwater-marine gradient. The calculated photomineralization of DOC and DON over the whole Baltic Sea corresponded to 10% and 6% of annual river loadings in the Baltic Sea, respectively. The bacterial carbon-biomass supported by photoproduced labile substrates corresponded to 6–27% of the direct photomineralization of DOC. Thus, solar-irradiation-induced photochemical reactions provide an important source of labile organic carbon and ammonium to the food webs of the Baltic Sea.

U.S. FUNDING FOR OCEAN RESEARCH: MATCHING RESOURCES AND REQUIREMENTS

There has been a significant shift in U.S. funding for the ocean sciences over the last twenty years, with an increasing dependence on the National Science Foundation as the primary funding agency. With increased competition for funding as well as increasing costs for oceanographic research facilities (including ships), there are some serious funding challenges ahead. I will discuss how these financial issues combine with fundamental changes in the research and development enterprise to create new stresses as well as new opportunities. Increased emphasis on interdisciplinary research and innovation (in its broadest sense) will require us to rethink how academic research organizations are structured and how individual scientists are rewarded. Development of non-federal funding will help accelerate this process.

DUAL LAYER FILTRATION SYSTEM FOR CONCENTRATING FECAL INDICATORS AND PATHOGENS FROM MARINE WATERS

The ability to rapidly and effectively concentrate diverse microbes is an essential component for monitoring water quality at recreational beaches. The purpose of this study was to develop a 90 mm diameter 0.45µm pore size dual membrane system, which can simultaneously concentrate both viruses and either bacteria and/or protozoa. The top PVDF membrane was used to filter bacteria/protozoa by physical straining while the bottom HA membrane retained viruses through adsorption. Results indicated that 73%±50% of the test bacteria (E. facialis) and 82±18% of the test virus (M52 coliphage) were recovered. Recoveries of Cryptosporidium and Giardia varied between 80 and 70%. The highest recoveries of poliovirus (Polio 1 CHAT) were obtained with a guanidine hydrochloride elution solution followed by secondary concentration using a commercially available column. Future experiments should focus on measurements utilizing additional bacteria and viruses as well as water with different physical and chemical parameters.

PATHOGEN AND INDICATOR MICROBE LEVELS AT A RECREATIONAL MARINE BEACH

Swimming in contaminated ocean waters continues to be a rising health concern, especially in beaches where the source of pollution is not known. The purpose of this study was to determine the microbial water quality of a sub tropical beach in Miami-Dade in order to gain insight on the health risk to bathers. Water and sand samples were concentrated and analyzed for fecal indicator microbes (coliiform, E. coli, enterococci, C. perfringens, coliphage, Bacteriodes, polyomavirus) and for pathogens (Vibrio vulnificus, S. aureus, enterovirus, norovirus, hepatitis A virus, Cryptosporidium parvum and Giardia lamblia). Indicator bacteria results were generally below the health standard while pathogens testing positive included Vibrio vulnificus in the sand and water as well as norovirus in two water samples. Giardia lamblia was detected in two water samples at 11 and 51 cysts per liter while Cryptosporidium parvum was detected in two sand samples at 12 and 5 oocysts per 100 grams. Risk associated with the pathogens and the efficiency of using indicator microbes to determine the safety of recreational waters should be evaluated given these findings.

GLACIAL-INTERGLACIAL VARIABILITY OF THE BENQUELA CURRENT SYSTEM, SW AFRICA (ODP LEG 175, SITE 1084) USING MULTIPLE PALEOCENOGRAPHIC PROXIES

Thirty-two core samples (modern to MIS 8) were used to reconstruct productivity and upwelling intensity at ODP Leg 175, Site 1084. Globigerina bulloides, Globorotalia inflata, and Neogloboquadrina pachyderma (dental and sinistral), were used as paleoceanographic proxies. Preliminary results indicate maximum productivity and/or enhanced preservation corresponding to MIS 2, 4, 6, and 8. The age of our interglacial stage 1 sample suggests that productivity was also high or preservation enhanced during MIS 2, 4, 6, and 8. The age of our interglacial stage 1 sample suggests that productivity was also high or preservation enhanced during MIS 2, 4, 6, and 8.

STABLE ISOTOPIC AND FTIR INVESTIGATIONS INTO THE INTERACTION BETWEEN ORGANIC MODEL COMPOUNDS AND DOM IN A SUB-ESKIMO ECOSYSTEM

Increased industrialization impacts aquatic ecosystems through the injection of organic pollutants into natural waters. Differences in the chemical characteristics of dissolved organic matter (DOM) can affect the solubility of contaminants in natural waters. In this work we demonstrate that changes in model compound solubility can be used to quantitatively investigate the chemical characteristics of DOM. We present a new technique to measure the solubility enhancement of select model organic pollutants (stryene, dodcenol
The goal of the cookbook is to provide basic recipes for data visualizations and laboratory observations (NEO) image generation and analysis tool developed as part of the ESD Visualization and Analysis Infrastructure (system and the NASA Earth Observation System), Kempler, S.

MORE will be co-sponsoring a nationwide Teacher Workshop on microbial oceanography real-time data, and the global importance of marine microbes. During summer 2008, C-MORE was established to provide professional development and training opportunities for scientists and educators, and improving public awareness of microbial oceanography. During its inaugural year, C-MORE emphasized K-12 teacher training, which included shipboard experiences for science teachers and mini-grants to incorporate microbial oceanography into their curriculum. C-MORE is also developing partnerships with schools to help teachers create place-based curriculum that teaches students about cutting edge research, application of microbial oceanography into the sinking phase, but no subsequent disaggregation. Unlike haptophytoplankton aggregates, fecal pellets appear to undergo little exchange with surrounding material during transit through the water column, resulting in highly efficient POC export.

The extent to which sinking particlesdisaggregate and exchange with surrounding material affects the efficiency of POC export to the deep sea. In 2003 and 2005, as part of the Mediterranean Sargasso Sea (Medsargasse) Project, we compared the pigment and amino acid compositions of sediment trap and in situ pump samples to assess exchange between sinking and suspended particles. Sinking particles were enriched in fecal pellet indicators and suspended particles in chlorophyll and bacterial degradation products. These compositions remained consistent with depth, suggesting that exchange was limited. Similar results were obtained in 2006 when particles were settling from the SST around the Mediterranean Gyre (SSM). In 2006 and 2007, we investigated the role of mixing and coastal upwelling on particle aggregation and exchange in the northern North Atlantic. We found that mixing and coastal upwelling can result in the disaggregation of sinking particles and the exchange of material into and out of the sinking pool. These processes can have important implications for carbon cycling in the ocean.

The ability of sinking particles to exchange material with the surrounding water is critical for regulating carbon fluxes and nutrient cycling in the ocean. Understanding the mechanisms and rate of particle exchange can provide insights into the biogeochemical processes that govern carbon cycling in the ocean. By examining the compositions of sinking particles and the surrounding water, we can infer the extent to which these particles are affected by mixing and coastal upwelling.

ACKNOWLEDGMENTS

The patterns of nutrients and phytoplankton biomass (Chl a) are reported and related to the oceanographic conditions in spring, summer, and winter, and in-plume and out-plume regions on the Ishikari Bay, Japan. Nutrients distribution in surface waters was characterized by the general tendency to decrease from spring to winter, and plume to out-plume region. In spring, when the in-sea diffusion of nutrients was highest, total Chl a biomass was at par in plume (2.30 mg m⁻²) and out-plume (2.39 mg m⁻²) region. Marked seasonal differences in size fractions were also observed. When the water column was strongly stratified and nutrient concentrations were low at surface in summer, average total Chl a values were 0.80 mg m⁻² and 0.38 mg m⁻² respectively in plume and out-plume regions. In winter, the intrusion of nutrients into the plume region by intense vertical mixing and riverine inputs produced an increase of the total autotrophic biomass (7.36 mg m⁻²). This study illustrates how changes in environmental gradients of the coastal system in time and space are affected by seawater dilution, vertical mixing, biological activities and light attenuation.

SPATIO-TEMPORAL ANALYSES OF NUTRIENTS AND PHYTOPLANKTON BIOMASS IN SUB-ARTIC COASTAL ENVIRONMENT OF JAPAN

The concentrations, nature and reactivity of DOM in rivers, estuaries and coastal waters. The concentrations, nature and reactivity of DOM, in turn, are largely determined by source materials, watershed geochemistry, oxidative processes and hydrology. As a result, DOM in North American rivers exhibit a wide range of concentration (<80 to >400 µM C⁻¹) and specific ultra-violet absorbance (0.6 to >5 L *mg C⁻¹ m⁻¹), an optical measurement that is an indicator of aromatic carbon content. Different rivers, therefore, deliver DOM with different reactivities and optical properties to estuaries and coastal regions, thereby influencing the analyses of chromophoric dissolved organic matter (CDOM) in these environments. The processes that control DOM in a given watershed are not well understood, and it is presently difficult to predict the influences of climate change and resource management practices on DOM export to coastal regions. In this paper, insights gained from studies of the factors that control the nature and reactivity of terrestrial derived DOM from diverse freshwater environments will be presented.

FROM SOURCE TO SEA: VARIATIONS IN BIOGEOCHEMISTRY OF DISSOLVED ORGANIC MATTER DELIVERED TO THE COAST

Terrestrially derived organic matter strongly influences the optical properties and reactivity of dissolved organic matter (DOM) in rivers, estuaries and coastal waters. The concentrations, nature and reactivity of DOM, in turn, are largely determined by source materials, watershed geochemistry, oxidative processes and hydrology. As a result, DOM in North American rivers exhibit a wide range of concentration (<80 to >400 µM C⁻¹) and specific ultra-violet absorbance (0.6 to >5 L *mg C⁻¹ m⁻¹), an optical measurement that is an indicator of aromatic carbon content. Different rivers, therefore, deliver DOM with different reactivities and optical properties to estuaries and coastal regions, thereby influencing the analyses of chromophoric dissolved organic matter (CDOM) in these environments. The processes that control DOM in a given watershed are not well understood, and it is presently difficult to predict the influences of climate change and resource management practices on DOM export to coastal regions. In this paper, insights gained from studies of the factors that control the nature and reactivity of terrestrial derived DOM from diverse freshwater environments will be presented.
The RED SEA OUTFLOW REGULATED BY THE INDIAN MONSOON

To investigate why the Red Sea water overflows less in summer and more in winter, we have developed a locally high-resolution global OGCM with transposed poles in the Arabian peninsula and India. Based on a series of sensitivity experiments with different sets of idealized atmospheric forcing, the present study shows that the summer cessation of the Red Sea outflow is remotely induced by the monsoonal wind over the Indian Ocean, in particular that over the western Arabian Sea. During the southwest monsoon (May–September), thermocline in the Gulf of Aden shoals as a result of coastal Ekman upwelling induced by the predominantly northeastward wind in the Gulf of Aden and the Arabian Sea. Because this shoaling is maximum during the southwest summer monsoon, the Red Sea water is blocked at the Bab-el-Mandeb Strait by upwelling of the intermediate water of the Gulf of Aden in late summer. The simulation also shows the three-dimensional evolution of the Red Sea water tongue at the mid-depths in the Gulf of Aden. While the tongue meanders, the discharged Red Sea outflow water (RSOW) (incoming Indian Ocean intermediate water (IOW)) is always characterized by anticyclonic (cyclonic) vorticity, as suggested from the potential vorticity difference.

DEVELOPMENT AND EVOLUTION OF OPERATIONAL FORECAST SYSTEMS FOR THE COASTAL AND ESTUARINE ENVIRONMENT IN NOAA’S NATIONAL OCEAN SERVICE

NOAA’s National Ocean Service (NOS) applies hydrodynamic models for the development, transition and implementation of operational forecast systems (OFS) in U.S. estuaries, ports, lakes and the coastal ocean. These systems have applications in the support of marine navigation, emergency response, as well as marine ecological applications. There are currently nine water bodies in which OFSs are functioning (the Chesapeake Bay, the Port of NYC, Galveston Bay, the St Johns River, and the five Great Lakes). OFSs are under development for the Columbia River, Delaware and Tampa Bay, as well as for Cook Inlet, AK and elsewhere. Once evaluated and deemed acceptable by NOS standards, the OFSs are transitioned into the operational environment. The components of an OFS are discussed in terms of a

BIO-PHYSICS OF SEABIRD OCCURRENCE IN THE NORTHERN CALIFORNIA CURRENT

Using data from Northeast Pacific GLOBEC 2000 and 2002 process cruises, we modeled the biological and physical factors that explain seabird occurrence during the upwelling season off Oregon. Seabirds were derived from ship censuses conducted during the upwelling and data were collected during cruise. Data were treated using a mass function that estimates prey biomass, and the model shows the occurrence pattern for the most abundant species. The model projects for Common Murres and Sooty Shearwaters that the two most abundant and biomass-bearing seabirds in the California Current, in coincidence with the occurrence patterns of Humpback Whales and adult salmon. Results show an increasing association of predators with prey over time, as prey biomass decreases. The question arises whether these predators, along with frontal features, are affecting the spatial occurrence patterns of Humpback Whales and adult salmon. Results show an increasing abundance and biomass-dominating seabirds in the California Current, coincident with the phytoplankton blooms.

LONG-TERM NITRACAINE SHOALING AND DECREASED WATER COLUMN TRANSPARENCY IN THE SOUTHERN SECTOR OF THE CALIFORNIA CURRENT SYSTEM

We document a reduction in Secchi depth of 0.11 ± 0.01 m per year in the southern California Current System (LTER and CalCOFI region) over the period 1949 – 2004, reflecting a long term decrease in water clarity. This change has been accompanied by a nitracacline shoaling of 0.44 ± 0.10 m per year since 1969 and a parallel increase in mixed layer depth (1949 ± 1984). These changes are thought to be driven by a persistent near-surface nutrient enrichment that has been shown to increase in density stratification in the CCS. Increased stratification has been linked by others to decreased nutrient fluxes, reduced primary production, and reduced water transparency, contrary to our findings. We consider several hypotheses to account for the observed changes in the CCS: (1) variations in nutrient concentrations in the California Undercurrent, which can be important sources for upwelling in this region, (2) other variations related to the North Pacific Gyre Oscillation (NPGO – Di Lorenzo et al., in review), (3) long-term changes in grazing pressure, and (4) variations in nutrients of anthropogenic origins.

BUILDING A FRAMEWORK FOR THE ECOLOGICALLY SUSTAINABLE DEVELOPMENT OF MARINE LIVING RESOURCES OF THE SULTANATE OF OMAN

The extensive coastline of the Sultanate of Oman has shaped its culture, economy, history and its people for millennia. Today, the coastal marine resources are still of great economic importance and continue to influence the lifestyle of the people of Oman. Marine living resources along the coast of Oman are an endowment of biodiversity, provide food and economic resources and opportunities for tourism and recreation. Unfortunately, the continuous pressure of development threatens this marine environment primarily via overfishing, global climate change, habitat modification, and coastal zone pollution. A continuous monitoring program and research are key steps that will allow us to differentiate between anthropogenic and natural variability. We have been collecting data from three monitro sites, two in the Gulf of Oman and one in the Arabian Sea from 2004 onwards. Data collected includes phytoplankton diversity and hydrographic parameters such as temperature, salinity, nutrients and oxygen that will not only provide us with baseline data necessary for future studies on anthropogenic impacts on this ecosystem but also a better understanding of the seasonal and interannual changes associated with monsoonal forcing. In this paper we address the seasonal monsoonal cycle and its impact on the biology of the coastal waters and use our findings to arrive at conclusions about how variability in phytoplankton and its environment could impact the food chain of this ecosystem.

PRINCE WILLIAM SOUND SURFACE CIRCULATION INFERRRED FROM A HIGH-FREQUENCY SURFACE-CURRENT MAPPING RADAR AND DRIFTERS
Prince William Sound (PWS) is a semi-enclosed sea linked to the Gulf of Alaska along the south-central coast of Alaska. From June - September 2006, surface currents in the central sound (50 km x 50 km) were observed using both high-frequency radar (HFR) and satellite-tracked drifters. The M2 and the MM species are the dominant tidal constituents with typical speeds of ~5 - 30 cm/s. After de-tiding the data the HF radar and drifter data sets confirm a strong summer-mean cyclonic circulation in the central sound consistent with inferences from hydrography and models. Mean velocities were ~10 - 20 cm/s in the central sound and a maximum of ~50 cm/s in Hinchinbrook Entrance. HFR-measured flow variations were large, but poorly correlated with observed winds from the central sound. This variability is most likely due to wind-forced fluctuations in the Alaska Coastal Current over the adjacent shelf. A comparison between drifter trajectories and HFR-derived virtual drifter trajectories show

NITROGEN INPUTS TO THE ALTAMAHA RIVER ESTUARY (GEORGIA, USA): A HISTORIC ANALYSIS
The watershed of the Altamaha River, Georgia, is one of the largest in the southeastern U.S., draining 36,718 km2. Between the 1950s and the 2000s the average concentration of NO3 + NO2 in the estuary quadrupled while chlorophyll-a more than tripled. We present nitrogen budgets for 1954 to 2002 that show a 32% increase in inputs to the watershed over the period. All of the increase occurred between 1954 and 1982, and there was actually a net decrease between 1982 and 2002. In keeping with this, the nitrogen load to the estuary has not increased significantly since the 1970s, when standardized water quality sampling began. These results suggest that, even with a fast transit time (generally <1 week), increased nutrient loading from the watershed between 1954 and 2002 translated into an increase in estuarine phytoplankton concentration in this system. Our analysis also suggests that estuarine nitrogen concentration is now more responsive to low inflows than in the past. These observations show the value of considering earlier baseline records when evaluating changes in loading.

EFFECT OF DEPRESSED SATURATION STATE ON SETTLEMENT, POST-SETTLEMENT SURVIVORSHIP, AND GROWTH OF PORITES ASTREOIDES AND MONTASTREA FAVEOLATA LARVAE
In conjunction with the projected increases in pCO2 of the coming century, coral growth and calcification are expected to decrease significantly. No published studies have investigated the effect of elevated pCO2 on early life history stages of corals. As coral recruitment, post-settlement survivorship, and growth are critical to reef persistence and resilience, it is of timely importance to better understand the repercussions of climate change on such processes. Larvae of Porites astreoides and Montastrea faveolata were collected from reefs in Key Largo, FL and subsequently settled and reared in controlled saturation state seawater. Three treatment levels were obtained (1M HCl additions) based on present (380 ppm) and projected pCO2 scenarios for the years 2065 (500 ppm) and 2100 (720 ppm). The effect of treatment water on settlement and post-settlement growth is being evaluated. Larvae were introduced to their respective treatments and allowed 96 hours to settle onto pre-conditioned limestone tiles. Settlement was confirmed by examination under a dissecting microscope. Settled larvae were placed in flow-through treatment tanks (25°C) and are currently being monitored for differences in survivorship and growth.

COMMERCe, RESEARCH AND EDUCATION: CONTRIBUTIONS AND CHALLENGES OF MARINE EXTENSION WORK IN NOAA’S SEA GRANT PROGRAM IN PUERTO RICO, MICHIGAN AND NATIONAL OFFICE
The National Sea Grant program represents NOAA’s nationwide university-based program in support of coastal resource use and conservation. This study focuses on a historical and multi-sited ethnography that analyzes two local Sea Grant Programs and their connection to the overarching NOAA national goals from 1980-2000. The project aims to offer insight on how the extension agent position facilitates the resolution of coastal and marine management and tourism issues. The extension agents are staff who have an extensive knowledge of coastal resources, have the role of translating scientific information to coastal stakeholders, and answer the needs of coastal communities to report back to the program. Two local extension programs were examined with 36 in-depth interviews to understand how local programs respond to cultural and regional processes. Preliminary findings suggest that current challenges for Sea Grant agents include maintenance of non-advocacy and mediation roles among stakeholders, their positioning relative to research especially conducting and delivering of science to public, and development of their multi-faceted skills sets essential to extension. This program suggests comprehensive ways for integrated resource management using bottom up approaches.

CROSS-FRONTAL SURFACE TEMPERATURE AND VELOCITY STRUCTURE IN THE NEW JERSEY MID-SHELF FRONTAL ZONE
The cross-frontal structure of a density front, which occurs during the winter months along the 50m isobath, is examined using remote sensing observations of the New Jersey midshelf region. Shipboard observations show that cooler, fresher, less dense water is located inside the side of the front; however, little is known of the velocity structure in the frontal zone. Surface current fields from HF radar (CODAR) are analyzed along with surface thermal frontal observations to describe the spatial variability of surface flow with regard to the front. Cloud-cleared, Level 2 MODIS Thermal IR sea-surface temperature data from AQUA and TERRA from 2005 through 2007 are processed using an edge-detection algorithm to determine the location and structure of the front. The front coordinates are overlaid on the long-range CODAR velocity field at the time of each respective satellite pass to extract the velocity at the front and in the far-field. The seasonal progression of the temperature and velocity fields are analyzed, and a statistical comparison of along-front velocities versus those in the far-field is performed to determine the presence or absence of a frontal jet.

INTEGRATING SEASONAL AND CENTENNIAL RATES OF SEDIMENTARY PROCESSES ON THE OUTER CONTINENTAL SHELF AND SLOPE SEAWARD OF THE WAIPAOA RIVER, NEW ZEALAND
The continental margin seaward of the Waipaoa River was examined to determine the rates and products of sedimentary processes in an oceanographically dynamic and geologically active margin. Initial results from short and long lived radionuclides (Be-7 and Pb-210), showed that material was reaching and accumulating within the outer shelf and slope. Radionuclide data from recent summertime and winter cruises provide insight into these processes. Surface Be-7 activities and excess Th-234 seabed inventories suggest that fluidal sediment rapidly reaches the shelf break annually but enhanced delivery of fluidal material occurs during the winter. Sediment is accumulating along the outermost shelf at rates of 0.5-1 cm/year, and transported off-shelf to accumulate in upper submarine canyons and slope gullies at rates up to 3 cm/year; and decreases to 0.1 cm/year in canyon and inter-canyon sites below 1200 m water depth. Hemipelagic sediment delivery is the dominant process along most of the margin. In contrast, sedimentology of cores from the Poverty submarine canyon demonstrates that sediment initially deposited in the canyon head moves down-canyon episodically as discrete mass flows.

EXTRATROPICAL INFLUENCES ON ENSO: THE SEASONAL FOOTPRINT MECHANISM
Fluctuations in internal atmospheric modes over the North Pacific in winter, especially the North Pacific Oscillation (NPO), impact an SST
Pacific has experienced substantial physical change. How has this affected community dynamics of these complex systems. In the past half century the North structure of their species and/or functional groups. If these structures show pattern in An important aspect of ecosystem communities is the order of numerical dominance circulation of halocline waters in the far northern reaches. from bottle samples collected at target depths of 20, 60, 80, 100, and 120 meters are used to calculate the NO parameter, where NO = 9 x NO - . The first continuous, vertical profiles of nitrate have been obtained from the Arctic Ocean at mid-depth by parametric subharmonic instability. The observations are presented and propagate equatorward but can have either slope, consistent with additional generation with surface (wind) generation at a higher latitude and subsequent propagation toward the North of 29 degrees, they slope predominantly downwards toward the equator, consistent with surface (wind) generation at a higher latitude and subsequent propagation toward the equator (where the local inertial frequency is lower). South of 29 degrees, they still propagate equatorward but can have either slope, consistent with additional generation at mid-depth by parametric subharmonic instability. The observations are presented and implications discussed. The USE OF CONTINUOUS PROFILES OF OXYGEN AND NITRATE TO ASSESS THE SOURCES OF HALOCLINE WATERS IN THE CENTRAL ARCTIC OCEAN The first continuous, vertical profiles of nitrate have been obtained from the Arctic Ocean during the 2007 field season of the North Pole Environmental Observatory. Casts were collected from eleven stations using a Satlantic ISUS (in-situ ultraviolet spectrophotometer) internally recording package. Profiles of dissolved oxygen were also obtained via the simultaneous deployment of a Seabird SBE19 plus CTD equipped with a Seabird SBE 43 O sensor. This data allows the first high-resolution observations of two chemical tracers used to distinguish water-type contributions in this environment. Such resolution is necessary because typical bottle casts through the ice cannot fully capture the various water types ventilating the Arctic halocline. The nitrate and oxygen data are combined to calculate the NO parameter, where NO = 9 x NO - . The NO parameter has been used previously to differentiate among source waters contributing to the halocline of the Arctic Ocean. The vertical profiles of NO, and NO are analyzed to investigate the ventilation of the halocline in the central Arctic. Additional chemical tracers measured from bottle samples collected at target depths of 20, 60, 80, 100, and 120 meters are used to support this analysis. Such analysis should reveal more information regarding the circulation of halocline waters in the far northern reaches. The THE EFFECTS OF PBDE-47 ON THE BENTHIC AMPHIPOD LEPTOCEPHUS PLUMITUSCUROSIS, AND POLYCHAETE STRELJONIO BENEDICTI: A BRIEF OVERVIEW Polybrominated Diphenyl Ethers (PBDEs) are used to reduce the flammability of consumer products. PBDEs enter the environment from decomposing materials such as domestic industrial waste, the incineration of waste, industrial production of PBDEs, and electric equipment use. PBDEs accumulate in marine sediments and pose a threat to wetland ecosystems because they are resistant to degradation and are lipophilic. PBDEs can bioaccumulate into infaunal benthic invertebrates and fishes; at high levels PBDEs cause endocrine disruption, neurotoxicity, and carcinogenic activity. Of the 209 congeners of PBDEs, PBDE-47 is one of the most prominent in studies from around the
The proposed research will investigate 1) the toxicity of PBDE-47 on the survival and reproduction of two benthic invertebrates and 2) the prevalence of PBDEs in natural sediments. In vitro sediment bioassays will be used to assess the LC50, NOEC, and LOEC of the benthic amphipod (L. plumulosus) and polychaete (S. benedicti). GC/MS will be performed on local sediments to determine concentrations and to assess the level of threat in coastal Georgia.

PHYSICAL CONTROLS ON THE TIMING OF THE SPRING BLOOM IN THE STRAIT OF GEORGIA

The Strait of Georgia is a semi-enclosed coastal sea with a strong estuarine circulation. The growing season starts with a classic spring bloom followed by strong summer productivity. We have coupled a one-dimensional vertical-mixing model that uses a K-Profile parameterization of the boundary layer to a NPFZD-class of biological model with 2 to 12 compartments. Two-dimensional physical processes, such as the estuarine circulation, are parameterized. The model is forced with hourly meteorological data and daily river data. The coupled biophysical model has been successfully used to determine the physical factors that control the arrival time of the spring bloom. The one-dimensional model was used to produce an empirical relationship between wind, cloud-fraction and the timing of the spring bloom. This relationship has been successfully used to predict the bloom in 2006 and 2007. Using historical data, the timing of the spring bloom over the last 30 years has been modelled. We will discuss the interannual variations we see and importance of the climate warming of the Strait to the bloom timing.

THE AUSTRALIAN INTEGRATED MARINE OBSERVING SYSTEM - FIRST STEPS

In May 2007 the Australian Government funded the first phase of an Integrated Marine Observing System. The IMOS is a nation-wide collaborative program designed to observe the oceans around Australia. IMOS partners comprise of the majority of Australian universities and agencies with capability in ocean and marine research to implement and operate 11 facilities for the collection and distribution of ocean observing data. The facilities are:

1. Argo Australia
2. Enhanced Measurements from Ships of Opportunity (SOOP)
4. Australian National Facility for Ocean Gliders (ANFOG)
5. Autonomous Underwater Vehicle Facility (AUV)
6. Australian National Mooring Network
7. Australian Coastal Ocean Radar Network (ACORN)
8. Australian Acoustic Tagging and Monitoring System (AATAMS)
10. eMarine Information Infrastructure (eMII)
11. Satellite Remote Sensing (SRS)

This paper describes each of the facilities and the challenges associated with observing system capability building in Australia. The unique characteristics of an Australian IMOS are highlighted and discussed.

ADJUSTMENT IN THE ANTARCTIC CIRCUMPOLAR CURRENT AND THE GLOBAL Pycnocline

In this study we consider an idealized, reduced gravity ocean model, in which the Antarctic Circumpolar Current (ACC) is spun-up from rest. The surface pycnocline is initially flat and shallow. Southern Ocean winds and diapycnal mixing are applied, causing the global pycnocline to deepen and the ACC to spin up. This deepening is arrested by eddy-induced transports and surface buoyancy loss in the Southern Ocean. This method allows us to identify the basic processes which control the adjustment and equilibrium state of the ACC, and the mechanisms by which the changes are communicated to and from the rest of the global ocean. A surprising conclusion is that if diapycnal mixing is important for establishing the global pycnocline (and strength of the Atlantic Meridional Overturning Circulation) then it is also an important driver of the ACC. A predictive theory for the adjustment timescale, equilibrium pycnocline depth and ACC transport is possible for single- and multiple-basin domains. The analytical theory is compared with results from the numerical simulations.

FLOC BEHAVIOR IN HIGH TURBIDITY WINTER STORM EVENTS ON THE ATCHAFALAYA DELTA INNER SHELE LOUISIANA

Field deployment of bottom tripods (Feb-Apr 2006 and 2007) for the ONR MURI program collected 2 Hz measurements of boundary layer dynamics during cold-front high wave-current events. One pod was deployed with a Sequoia LISST 100C at z = 1.25 m, which measures suspended particulates of 2.5-500 µm size. Size distribution was generally bimodal over all frontal energy periods: a discrete particle mode at 46 µm, and a floc mode at 239 µm. Frequencies were also increasing (3rd mode) at the largest ring angle (mean size 460 µm), indicating larger flocs are present. During the increasing phase of strong currents or swell, and, significantly, even at strong and constant wave-current conditions, floc breakage occurred steadily over periods up to 24h. The latter suggests relatively long periods are necessary for floc size distributions to reach equilibrium with ambient energy. Optical transmission decreased during these periods as a function of both 1) resuspension and 2) breakage of flocs increasing particle numbers and optical scattering. During the strongest pre-frontal phases, turbidities rose at intervals to levels (>1.3 g/l) below the 15% transmission for reliable size data, even with an 80% path reduction. During the 6h post-frontal declining phase, larger flocs (>146 µm) re-formed to become the dominant component in low wave and current stress conditions, and less dominantly, in high swell and low currents.

components of the marine food web. Microbial community in the Arabian Gulf has not been extensively studied. This study focuses on the bacterioplankton community in the northem waters of Kuwait, which are influenced by Shatt Al Arab River discharge. The results indicate that bacterioplankton community in the northwestern Arabian Gulf have relatively high biomass (average 3.18 x109 bacteria/l) in comparison with bacterial abundance in ocean surface waters, which is generally less than 1 x 109 bacteria/liter. They have high carbon demand (average ratio 1:4) related to local primary production (average 152.89 gC/l/day). The study addresses the subject of temporal and spatial distribution of bacteria plankton in the NW waters of the Arabian Gulf. ALSAID, T. THE ROLE OF EMILIANIA HUXLEYI SPECIFIC VIRUSES ON COPPER CYCLING Phytoplankton influence the cycling and distribution of Cu in oceanic and coastal waters. Viruses are known to infect a range of phytoplankton species and thus may influence copper speciation in these waters. The objective of our work was to examine the effects of Emiliania huxleyi growth, senescence and decay on Cu speciation. Total dissolved Cu were near constant in the control and virus infected cultures. However, labile Cu decreased with incubation time in both cultures. Particulate Cu in the control cultures increased with time, and was therefore related with algal biomass. Similarly, in the virus infected cultures the particulate Cu increased with time, until the cells crashed due to viral infection. Cu per cell decreased during algal growth in virus free cultures. Viral lyses of Emiliania huxleyi caused a sharp increase in Cu per cell. Ligand production in the control culture decreased the free aqueous Cu concentration ([Cu]aq) with time. The lowest [Cu]aq in the control culture was between 6.73-5.15 x10-1 M, coinciding with the highest organic ligand concentrations. Also in the virus infected culture, [Cu]aq decreased when enhanced organic ligand concentrations were observed. In the virus infected culture, there was no increase in the dissolved Cu fraction in response to the decrease in the particulate Cu. It was hence hypothesized that the virus particles play a direct role in the Cu cycling.

VIRTUAL MISSION FIRST RESULTS SUPPORTING THE WATER HM SATELLITE CONCEPT

First results demonstrate that: (1) Ensemble Kalman filtering of VM simulations recover water depth and discharge, reducing the discharge RMSE from 23.2% to 10.0% over an 84-day simulation period, relative to a simulation without assimilation. The filter also shows that it can disperse discharge relative errors of 100%, while 16-day and 32-day frequency results in errors of 12.1% and 16.9%, respectively. (2) SRTM measurements of water surfaces along the Mississippi, Missouri, Ohio, and Amazon rivers, as well as smaller tributaries, show height standard deviations of 5 meters or greater (SRTM is the heritage for WATER HM). These large errors require several hundred kilometer reach lengths to estimate slope and hence discharge in the empirical Manning’s method. Nevertheless, discharge estimates are reasonable and can be within 10% of gauged values. (3) River channel widths are key for determining the capability of WATER HM to resolve flow hydraulics. Automated measurements of channels, as classified in NLCD92 (a 30m product from the USGS Land Change Monitoring System), showed detailed coverage throughout the US But, river basins, including channels with annual discharge of 150 cfs, draining 12,500 sqkm. (4) Conventional profiling altimetry misses 75% of all lakes in the world because there are hundreds of kilometers of orbital tracks.

HIGH RESOLUTION MODEL SIMULATION OF THE SUBZONE OF THE EASTERN TROPICAL PACIFIC Suboxic intermediate waters of the world's oceans dominate globally important redox-sensitiv- processes. However, the relative roles of physical and biogeochemical forcing of their extent and density has been less well understood as a result of climate change. Suboxic waters may influence the global carbon cycle and nutrient availability, and thus potentially affect marine productivity and food web dynamics. The El Niño Southern Oscillation (ENSO) is an ocean-atmosphere coupling event that consists of warm El Niño and cool La Niña phases. The ENSO affects many systems of the marine ecosystem. In the Eastern Tropical Pacific (ETP), ENSO events have been shown to have a significant impact on the distribution of suboxic waters. Previous studies have focused on the influence of ENSO on the occurrence of suboxic waters, but the mechanisms behind this influence are not well understood. In this study, we use a high-resolution ocean-atmosphere coupled model to examine the interaction between ENSO and suboxic waters in the Eastern Tropical Pacific. The model includes a comprehensive representation of physical processes, biogeochemical cycling, and ecosystem dynamics. The model is forced with observed sea surface temperature, sea ice concentration, and wind fields, and is run for 10 years (1986-2005). The results show a significant decrease in the extent and density of suboxic waters during El Niño events, while La Niña events lead to an increase. This modulation is consistent with previous studies that have linked ENSO to changes in the upwelling and production in the upwelling region. These findings highlight the importance of suboxic waters in the ETP and suggest that ENSO may play a key role in regulating the distribution of these regions, which are critical for marine productivity and carbon cycling. Alahi, E., Rutgers University, New Brunswick, USA, aalahi@marine.rutgers.edu; Pernin, M. J., Rutgers University, New Brunswick, USA; Turpin, B. J., Rutgers University, New Brunswick, USA; Seitzinger, S. P., Rutgers University, New Brunswick, USA

IN CLOUD PHOTOCHEMISTRY OF WATER SOLUBLE ORGANIC GASES AND ITS RELEVANCE TO ATMOSPHERIC DOC/DON DEPOSITION In this work aqueous phase reactions of methylglyoxal, a ubiquitous atmospheric carbonyl compound formed from biogenic and anthropogenic VOCs (Kawamura and Yasui, 2005), and hydron radical with and without nitric acid were conducted to simulate in-cloud reactions. A major contribution of this work is the measurement of reaction products, including organic acids and oligomers by electrospray ionization mass spectrometry techniques. We will discuss the proposed aqueous phase reaction mechanism, the effect of nitric acid on product formation, and the potential importance of cloud processing to deposition of DOC and DON. The source of DON in atmospheric waters is yet unknown and this work provides insight into the potential contribution of cloud chemistry to atmospheric DON formation. DON in atmospheric waters contributes 20-80% to the total nitrogen deposition to the ocean (Cornell et al., 2003). Atmospheric deposition of nitrogen and nitrogen fixation are the only sources of non-recycled nitrogen to the open ocean and there is evidence that a significant fraction of DON in wet deposition is bioavailable (Seitzinger and Sanders, 1999) making it a potentially important control on marine productivity.

INTERANNUAL VARIATION IN FORK LENGTH OF FLYINGFISH FROM THE EASTERN TROPICAL PACIFIC

The El Niño Southern Oscillation (ENSO) is an ocean-atmosphere coupling event that consists of warm El Niño and cool La Niña phases. The ENSO affects many systems including marine ecosystems and climate models predict that future climate change will alter the ENSO system. In the Eastern Tropical Pacific (ETP), ENSO events have been shown to have a significant impact on the distribution of suboxic waters. Previous studies have focused on the influence of ENSO on the occurrence of suboxic waters, but the mechanisms behind this influence are not well understood. In this study, we use a high-resolution ocean-atmosphere coupled model to examine the interaction between ENSO and suboxic waters in the Eastern Tropical Pacific. The model includes a comprehensive representation of physical processes, biogeochemical cycling, and ecosystem dynamics. The model is forced with observed sea surface temperature, sea ice concentration, and wind fields, and is run for 10 years (1986-2005). The results show a significant decrease in the extent and density of suboxic waters during El Niño events, while La Niña events lead to an increase. This modulation is consistent with previous studies that have linked ENSO to changes in the upwelling and production in the upwelling region. These findings highlight the importance of suboxic waters in the ETP and suggest that ENSO may play a key role in regulating the distribution of these regions, which are critical for marine productivity and carbon cycling.
ies, specifically for the tuna-dolphin assemble because flyingfish are key dolphin prey. Observed variations in flyingfish can provide a possible explanation for the lack of dolphin recovery in tuna-dolphin assemblies of the ETP.

MIXING IN THE GULF OF CADIZ USING XBT DATA

Images from acoustic reflections in the water column were obtained during the EU-funded GO experiment in the Gulf of Cadiz, and oceanographic data at the same place and time were also collected. The experiment (www.dur.ac.uk/egu/go/) focused on a section across the Mediterranean Water flow against and down the continental slope. The present analysis concerns the data on the continental slope at one end of the seismic section. XBT, XCTD and CTD sections were taken on the slope to analyze the properties of the water column. The XBT provide fine resolution in space and time, and are analyzed to estimate diffusivity and mixing parameters. This is also related with the local circulation and internal wave contributions using data from ADCPs and moored temperature loggers. The finer resolution of the XBT and seismic data gives a new view on the mixing. Different ways to compare seismic and oceanographic data will be discussed.

SHIPBOARD PHOSPHORUS, NITROGEN AND SILICA NUTRIENT LIMITATION ASSAYS USING IN-VIVO PHOTOPAM FLUORESCENCE IN THE NORTHERN GULF OF MEXICO

Our objective was to investigate the importance of nutrient limitation of phytoplankton production in coastal waters of the Northern Gulf of Mexico. Resource limitation assays were performed on 8 cruises from the summer of 2005 to the summer of 2007 during NOAA funded Mechanisms Controlling Hypoxia program and EPA’s Gulf Hypoxia Modeling Program. Twenty-four to forty-eight hour shipboard experiments were conducted in the coastal waters of the northern Gulf of Mexico. Additional samples were used for in-vivo fluorescence measured with a PhytoPAM (Pulse Amplitude Modulated) fluorometer. Additional samples were taken to measure chlorophyll concentration using traditional methods. Our findings reveal that phytoplankton could be N-limited, P-limited and occasionally N and P co-limited, but never Si limited in the Northern Gulf of Mexico. The type of nutrient limitation was dependent on water quality (brown, green versus blue waters) and season. The Mississippi River and Atchafalaya River plumes greatly influence water quality on a seasonal basis, and so, potentially phytoplankton production.

AN INTEGRATED, OPERATIONAL GLOBAL OCEAN OBSERVING SYSTEM

The Global Ocean Observing System (GOOS) has been in existence for over a decade. During this first decade, GOOS has been primarily engaged in planning observational strategies and developing the international governance structures required to facilitate multi-national ownership and development of the system. The most important challenge now facing GOOS is to complete and sustain an integrated, global system with clear user benefits. Substantial progress has been made, with more than half of the in-situ open ocean observing system for climate already in the water, including buoys, moorings, floats, tide gauges and repeat hydrographic lines. Operational warnings for coastal hazards based on this GOOS observational backbone are widely available providing clear societal benefits. However challenges remain. The research community is neither ensuring their observations fully contribute to, nor that their research fully benefits from, the system. New modalities for increasing research community participation and governmental commitments will be presented. The talk will begin with a brief overview of the status of the global ocean observing system, then highlight milestones achieved and conclude with key future challenges.

THE EFFECTS OF RIVER DIVERSION, MESOPOTAMIAN MARSH MANIPULATIONS, AND RIVER DAMMING ON THE MARINE ENVIRONMENT OF THE ARABIAN GULF

A study was conducted during the period of 1996-2005 to assess the impact of river diversion, marsh drainage, and marsh restoration on Kuwait’s marine environment. The results indicated lower salinity, higher nitrate concentration, higher chlorophyll-a, and higher sedimentation in the northern waters of Kuwait influenced by the discharge of the man-made Third River and marsh drainage. Five estuarine copepod species, which occur only in the northern waters of Kuwait due to their proximity to the mouth of the river, are reported here for the first time. Lower turbidity levels were observed in the northern waters of Kuwait during 2004 and 2005 possibly influenced by the marsh restoration process. The above results indicate the close interrelationship between the upstream river environment and the northern Arabian Gulf. River-related activities in the Tigris-Euphrates Basin have transboundary impacts downstream. Assumptions on the potential effects of the upstream damming of the Tigris and Euphrates Rivers on Kuwait's marine environment are included. It is expected that recent and planned river basin modifications in Turkey, Iran and Iraq will significantly reduce river discharge, permanently remove seasonal flooding, and impact the northern Gulf’s marine environment, with serious implications for fisheries.

ICOMM, THE INTERNATIONAL CENSUS OF MARINE MICROBES: UNVEILING THE OCEAN’S HIDDEN MAJORITY

The International Census of Marine Microbes (ICoMM), now in its third year, is one of 14 ocean realm projects of the Census of Marine Life Program (CoML) that seeks to determine what is known about the biodiversity of marine microorganisms. The ICoMM Secretariat hosts the WEB site http://icomm.mbl.edu and the distributed database network MICROBIS. It has sponsored meetings for the five primary working groups (Benthic, Open Ocean and Coastal Systems, Technology, Informatics and Data Management and Microbial Eukaryotes) and annual meetings of its Scientific Advisory Council. In collaboration with the international community of marine microbiologists, ICoMM has forged a large-scale effort to characterize microbial diversity in the sea through molecular approaches based on massively-parallel, 454-based sequencing of hypervariable regions of the SSU rDNA genes of bacteria, archaea and microbial eukaryotes. Although a complete census is most likely beyond our grasp, the scientific return will be considerable if the information is integrated with contextual information that can inform us about the interplay between microbial mediated activities and oceanic processes.

GULF OF CADIZ OCEANOGRAPHY FOR COMPARISON WITH SEISMIC IMAGING

The GO project (European Union-NEST-Adventure funding), www.dur.ac.uk/eu/go/ aims to assess the potential of seismic imaging of the water column. A dedicated experiment (April-May 2007, Gulf of Cadiz) looked at varying Mediterranean Outflow water (MOW) flow along and down the continental slope. Distinctive MOW properties provide strong reflections from seismic sounding. We aim to relate water properties to mixing and hence (e.g.) tides, internal waves, eddies. Physical oceanography results derive from 500 MOW casts, typical spacing 2 km, and moorings: three ADCPs, three temperature strings and near-sea-bed turbulence in line on the north-eastern margin of Portimao Canyon (water depths 740-980 m); a fourth ADCP ~6 km along-slope in 1015 m depth. CTD and XCTD profiling on an IFM-Geomar research cruise, closely following the seismic sections, supplemented the GO measurements. We examine the structures observed on the principal line through the moorings (five surveys), and compare with the contemporary seismic data that further constrain observed boundaries. The mooring data and profiles are analysed for tides and internal wave spectra, small-scale structure and turbulence to estimate diffusivity and mixing.
lowed by recommendations from the Hypoxia Task Force. The 2001 Hypoxia Action Plan called for a 30% reduction in nitrogen loading in order to reduce the size of the hypoxic zone by 50% by 2015. Recent ecosystem studies and models have suggested that larger reductions of both nitrogen (N) and phosphorus (P) will be required to achieve this desired goal. Though the final recommendations of the Hypoxia Task Force remain unclear, the report of the EPA SAB is likely to recommend much larger reductions of both N and P. These ecosystem studies important to these new policy recommendations will be discussed, however, their ultimate impact on Gulf hypoxia remains to be seen.

CDOM ACROSS THE ARCTIC OCEAN
Previous studies indicate that fluorescence can be used as a proxy for terrestrial derived DOM in the Eurasian Basin. In the Canadian Arctic the relationship between fluorescence and terrestrial derived DOM is however not as straightforward and there seem to be additional sources of fluorescence present. In this study we present new fluorescence data from CTD casts across the Arctic Ocean interior. The results show that CDOM is a useful additional water mass tracer along with biomarkers and standard hydrographic information in the Arctic Ocean and offer insights towards understanding Arctic halocline formation and water mass exchange. Data from a trans arctic sea section in 2005 indicates that Eurasian shelf water with elevated levels of river DOM penetrates deep into the Canada Basin halocline. Excitation emission matrix spectroscopy (EEMS) combined with Parallel Factor Analysis was applied to identify potential sources contributing to the CDOM signal in the halocline.

HOW DO DISTINCT PHYSICAL PHENOMENA AND PROCESSES AFFECT SPECTRAL SLOPES OF CLIMATE VARIABLES?
Spectral slope is a widely-used statistic in climatology that summarizes the redness of time series and is directly related to energy cascades. Links between the strength of the annual cycle and spectral slope for surface temperatures have been suggested recently in literature. We propose the ratio of interannual to subannual variance (the climate-to-weather ratio) as an analogous metric to the spectral slope and define the exact correspondence between the two measures. This ratio is fundamentally a calculation of the power law with spectral binned and averaged in two uneven frequency intervals divided at annual frequency. We apply our analyses to sea surface temperature, sea surface height, sea level pressure, and precipitation. First, we evaluate the impact of subseasonal, subannual, and interannual phenomena as well as other factors on the spectral slope. Second, we use the method of empirical orthogonal functions to measure the contributions of individual interannual variability modes. Finally, we investigate spectral nonuniformities of different orthogonal patterns, particularly those corresponding to the El Nino-Southern Oscillation.

BAXLEY ET AL. ASSESSMENT OF CYANOPHAGE DIVERSITY IN COASTAL WATERS USING PULSED FIELD GEL ELECTROPHORESIS AND MULTIPLE MOLECULAR MARKERS
Cyano phosphages are abundant in coastal waters and are an important component of the microbial food web. These viruses may influence the abundance, diversity, and seasonal succession of their cyanobacterial hosts. Most studies of cyanophages in coastal ecosystems have focused on myoviruses; nevertheless, podoviruses or siphoviruses may also play important roles in these ecosystems. In this study, we examined temporal changes in the size distribution of cyanophage genomes using pulsed field gel electrophoresis (PFGE). Seawater samples collected from three sites in Rhode Island waters were enriched for cyanophages using multiple strains of Synechococcus. Cyanophage genomes ranging from 30 kb to over 350 kb were observed. The abundance and distribution of genome sizes varied temporally and were also dependent on the host strain used in the enrichment. DNA excised from the PFGE gel is being screened using multiple genetic markers to identify the viruses in each size range. Our results suggest that there is a high diversity of cyanophages in a single seawater sample, with viruses belonging to several different viral lineages.

Amrhein, D., Lamont-Doherty Earth Observatory, Columbia University, Palisades, USA, diez2102@columbia.edu
sparsely sampled. The aim of this paper is to report on the copepod distribution and production (egg and juvenile) across row spawning sites in the Sargasso Sea. The cruise was conducted in March/April 2007 with an overall of 37 stations, distributed over 3 frontal cross-sections. Copepods were sampled with a 10µm net and size fractionated to 160–200µm. The copepodites were then incubated in 24h, stage and length were measured on the two most numerous genera Oithona and Clausocalanus. We will present and discuss the growth rate results and production of the above-mentioned copepodites in relation to phyto- plankton biomasses, position in the frontal zone and egg production of Acartia. Despite low primary production and EP (0.5–4.0 d⁻¹) the growth rate of copepodites was close to maximal (0.3 d⁻¹), stressing the role of the younger stages in the cycling of organic matter in the Sargasso Sea.

ESTIMATING TREND PARAMETERS FROM GLOBAL ALTIMETRIC SEA SURFACE HEIGHT DATA AND SEA SURFACE TEMPERATURE DATA

Sea surface height and sea surface temperature are fundamental climate parameters. More than 15 years of sea surface height records are now available from satellite altimetry and more than 25 years of reconstructed sea surface temperature data from a combination of in-situ and satellite based data are now available for investigation of trend like structures. Low frequency variability of these quantities have been investigated through a rank based multivariate method in order to extract robust time trend patterns. The first derived trend patterns in both data sets agree on a systematic decrease in both SST and SSH in the Equatorial Pacific, but an increase in almost all regions of the world. The second trend pattern reflects mainly ENSO variability in the Pacific Ocean. This parameter is considerably more robust determined from SST than from SSH.

AN EMPIRICAL APPROACH TO ESTIMATING THE PROBABILITY OF TOXICENIC PSEUDO-NITZSCHIA BLOOMS IN THE SANTA BARBARA CHANNEL

The Santa Barbara Channel, CA is a highly productive region where wind-driven upwelling and mesoscale eddies are important processes driving phytoplankton blooms. In recent years, the spring bloom has been dominated by the neurotoxin-producing diatom genus, Pseudo-nitzschia. The results of a 1.5 year time series of Pseudo-nitzschia spp. abundance, chlorophyll and domoic acid concentrations are related to physical, chemical, and biological parameters to better identify the conditions associated with regional Pseudo-nitzschia blooms. The time series captured three large toxic events in the springs of 2005–2006 and summer 2005 corresponding to bloom-level Pseudo-nitzschia spp. abundance. Statistical models were created and relevant thresholds determined to predict the occurrence of toxic bloom events from environmental parameters. The conditions most associated with high cellular toxin levels were low sea surface temperature, high salinity, increased absorption by cDOM (412 nm), increased reflectance at 510/555 nm, and decreased particulate absorption at 510 nm. This suggests the potential for monitoring of toxic diatom blooms in the Santa Barbara Channel using satellite platforms such as SeaWIFS, MODIS, and AVHRR.

A PLANKTON BLOOM IN A MODE-WATER EDDY CAUSED BY EDDY-WIND INTERACTION

Observations of an anticyclonic mode-water eddy in 2005 near Bermuda revealed highly enhanced chlorophyll and primary production at the eddy center. A 20-km long streak of sulfate hexafluoride injected at 90 m depth at eddy center showed 0.5 +/- 0.2 m/day over 36 days. We constructed a numerical model of the eddy to investigate the processes responsible for the observed upwelling. Even with uniform wind, horizontal gradients in surface stress can arise from differences in eddy surface velocities relative to the wind velocity. These mesoscale gradients in surface stress cause upwelling in anticyclones and downwelling in both data sets agree on a systematic decrease in both SST and SSH in the Equatorial Pacific, but an increase in almost all regions of the world. The second trend pattern reflects mainly ENSO variability in the Pacific Ocean. This parameter is considerably more robust determined from SST than from SSH.

SITE SELECTION AND FALLOWING - MITIGATING HABITAT IMPACTS FOR COLD WATER FINNISH AQUACULTURE IN NEWFOUNDLAND, CANADA

Benthic impacts are a primary concern for finnish aquaculture in Newfoundland, Canada. Site selection is used as the principal means to minimize or avoid such negative effects. However, the provincial government also implements a mandatory fallow period every 3 years as a disease control/prevention measure. Since 2002, we have been following sediment conditions at a finnish aquaculture site in Fortune Bay, NL to determine the effectiveness of this fallow period for reducing residual benthic impacts. During the 3 year grow out period, sediment sulfide increased 180% while redox potential decreased significantly under the cages. After 3 months of falling redox levels had decreased and sulfide levels were near background. Comparisons made in 2006 with several other fallowed finn sites indicate that sediment conditions return to near background levels at most sites over the following period. Thus the mandatory 3rd year fallow period in combination with appropriate site selection criteria, appear to provide effective mitigation of the benthic effects of finnish aquaculture in coastal Newfoundland.

INCREASING UPTAKE AND FATE OF CO2 IN NORTH ATLANTIC SUBTROPICAL MODE WATER (STMW)

Mode waters play an important role in heat, nutrient and carbon storage/dynamics of the subtropical gyres. Time-series data from the Bermuda Atlantic Time-series Study in the North Atlantic demonstrate that dissolved inorganic carbon concentration (DIC) in subtropical mode water (STMW) has increased at a rate as fast as anticipated from equilibrium with the atmosphere for the past 20 years. Thus, North Atlantic STMW may play a significant role as a short-term carbon sink, accounting for as much as 3-10% of the current net annual ocean uptake of CO2. The mechanisms responsible for this additional CO2 increase in STMW have not been fully resolved. During the 2006 and 2007 CLIMODE field program, which focused on STMW in the North Atlantic Ocean, we extensively sampled inorganic carbon at the region of formation of STMW and throughout the subtropical gyre. Preliminary results from these cruises are presented here and discussed in terms of the dominant processes contributing to the STMW DIC budget, including air-sea gas exchange, physical mixing and advection, primary production and respiration, as well as the fate of DIC in the STMW.

THERMAL AND HYDRAULIC DYNAMICS OF SHALLOW LAKE ELLIDAVATN IN ICELAND

In the age of global warming, water temperature is becoming an ever more important parameter in surface water quality. Lake Ellíðavatn, one of the major recreational areas of the capital of Iceland, has experienced an unprecedented temperature increase over the past 25 years which is believed to threaten the Arctic charr stock in the lake. Increased aerial and fluvial pollution from nearby urban development is an additional cause for concern. To address these developments, a new study characterizing thermal and hydraulic dynamics in shallow Lake Ellíðavatn is being undertaken. Early results from lake temperature and fluvial pollution from nearby urban development is an additional cause for concern. RIVER DISCHARGE ESTIMATION THROUGH ASSIMILATION OF REMOTELY-SENSED WATER SURFACE ELEVATIONS

New methods of measuring surface water elevations from space have the potential to revolutionize the type, frequency, and spatial scale of global observations. Although satellite altimeters can measure surface water elevation directly, river discharge (and consequently freshwater inflow to oceans) cannot be directly measured. Data assimilation offers the potential to indirectly estimate river discharge by ingesting satellite observations into a hydrodynamics model. Our work demonstrates the potential of such an approach in an identical twin data assimilation experiment. Early results revealed some of the limitations that need to be overcome for an operational implementation of such an estimation system. Simulated river elevation profiles for the Ohio River were generated by the IPI Instrument Simulator to represent satellite measurements of surface water with errors representative of those that would be inherent in observations from a dual-sensor Ka-band wide swath altimeter. Model errors are represented by introducing errors in model parameters, channel geometry, as well as precipitation that is used to drive a hydrologic model which produces boundary inflow conditions for LISFLOOD. Model and observation errors are evaluated through a simultaneous state-parameter estimation Ensemble Kalman filter. Boundary conditions are shown to have a large effect on the estimation process, and ways to estimate their errors are explored through error covariance bias correction.

10-70-DAY VARIABILITY OF KUROSHIO TRANSPORT IN THE EAST CHINA SEA

Absolute transport of the Kuroshio in the East China Sea (ECS) north of Okinawa was determined using Current-and-Pressure-recording Inverted Echo Sounders (CPIESs) and acoustic Doppler current profilers (ADCPs) across the Kuroshio from December 2002 to November 2004. This transport exhibits spectral peaks at 11, 15 and -60 days. The 15-day signal, which appears to come from the Kuroshio off Taiwan, extends through the whole water column in contrast to the 11-day signal which is largely confined above 300 m depth. The 11-day signal is likely due to the local growth of instabilities. Complex Empirical Orthogonal Functions (EOF) analysis of the 60-day signal shows that the first EOF explains 93% of the variance occurring in the band between 50 and 70 days. This EOF has large amplitudes towards the northwest (i.e., towards the continental slope) and phase propagation is also in this direction. Phase speed is 4 cm/s and wavelength 200 km. The 60-day signal may be due to short barotropic Rossby waves, generated in the ECS shelf-region, whose energy propagates eastward.

UNCOVERING BIODIVERSITY IN ESTUARIES: THE ENIGMATIC PICOEUKARYOTES

Estuaries are famous for being highly biological productive and for supporting tremendous biodiversity. One of the most abundant organisms in these ecosystems are picoeukaryotes. They are responsible for a significant fraction of the primary production in both marine and freshwater ecosystems. Their small size (0.5 - 3 micrometers) and cryptic morphology; have led to the use of DNA-based analytical methods. To assess the diversity of picoeukaryote communities along an estuarine gradient we used Restriction Fragment Length Polymorphism (RFLP) fingerprinting of a fragment of the 18s rDNA gene. Picoeukaryotes collected along an estuarine gradient were all remarkably diverse, and decreases with distance from the point source. The benthic effects of an intensive sea bream fish farm in the Gulf of Aqaba, Red Sea were examined by taking replicated sediment cores along a transect extending from the cages to a station outside the anticipated range of influence. Cores were sampled for loss-on-ignition (organic matter content), pore-water nutrients, redox potential, benthos and SOD. A comparison of stations indicated a 50% decrease in SOD within 25m from the edge of the fish farm to values that were not much greater than background levels.

GLOBAL ANALYSIS OF CONCURRENT DECADAL CHANGES IN THE WORLD OCEAN PHYTOPLANKTON AND THEIR FORCING VARIABLES (SST, WIND, IRRADIANCE)

A consistent time series of the world ocean chlorophyll concentration was produced from satellite ocean color observations by the CZCS sensor (1979-1983) and the SeaWiFS sensor (1998-2002) (Antoine et al, 2005). This reanalysis showed an overall increase of the world ocean average phytoplankton chlorophyll (Chl) by as much as 20% over two decades. Following this result, a project, called “GLOBOPY”, was recently set up to analyze these decadal changes in the global ocean phytoplankton in parallel to their forcing variables. The objective is, therefore, to confront the ocean colour record with those other parameters which are likely to have played a role in the evolution of the total phytoplankton biomass (temperature, irradiation, wind…). The data are taken from other satellite observations and from re-analyses of the outputs of global weather forecasting models. This analysis allows a first phase of interpretation of the observed changes, by checking their coherence with those observed in the forcing variables of the phytoplanktonic compartment.

INFLUENCE OF THE ORINOCO RIVER PLUME ON PHYTOPLANKTON SIZE CLASS DISTRIBUTION IN THE CARIBBEAN

River discharge from the Orinoco River is largely responsible for bringing nutrients into Caribbean waters in the buoyant surface plume hence influencing phytoplankton growth. During a study of the influence of the Orinoco River plume in the Caribbean, phytoplankton size class distribution was characterized in order to better understand the dynamics between river plume discharge and phytoplankton size class distribution. Seawater was filtered using 47mm GF/F filters. For the size fraction analysis, seawater was filtered by sequential filtration using 47mm polycarbonate filters of 0.2, 2.0 and 20.0 µm pore sizes. Filter samples were then analyzed by reverse phase HPLC coupled with a Diode Array detector. Diadinoxanthin and Fucoxanthin, diagnostic pigments for diatoms and dinoflagellates, increase with decreasing salinity along the plume but are restricted to the two larger size class fractions. 19'-butanoyloxyfucoxanthin, diagnostic of prymnesiophytes, shows similar behavior; but is absent in the near field of the plume. Divinyl chlorophyll b, diagnostic of prorocentroccus, is a major component of the pigment suite of the plume. Presence of other pigments and their size class distribution is discussed.

VERIFICATION OF THE WIND-DRIVEN TRANSPORT IN THE NORTH PACIFIC SUBTROPICAL GYRE USING GRIDDED WIND-STRESS PRODUCTS

Using gridded wind-stress products constructed by satellite scatterometers (ERS-1, 2 and QuikSCAT) data and those by numerical weather prediction model(NCEP-reanalysis), we are carrying a series of experiments using the POL Coastal Ocean Modelling System (POLCOMS) based on a set of experiments provided by the POL Coastal Observatory. These include the 12-16MHz WERA phased HF radar array, providing the assimilated data set, as well as ADCP data from two mooring points and observations from spatial surveys and ferrybox lines providing the validation. The study examines the effect of assimilating hourly, 4 km resolution surface currents from the HF radar in different tide and wind conditions throughout 2006 in a 1.8 km Irish Sea 3-d model setup. Our assessment of the system capability will be presented.

SEDIMENT OXYGEN DEMAND AS A MEANS TO EXAMINE THE ASSIMILATIVE CAPACITY OF THE BENTHOS TO WASTES GENERATED BY A FISH FARM IN THE RED SEA

The sustainability of activities that release particulate organic wastes to the sea may be assessed by measuring the ability of the benthic community to assimilate these wastes. In healthy benthic communities the assimilation of organic compounds is performed by a community of aerobes, and benthic assimilative rates may be measured by means of sediment oxygen demand (SOD) measured by means of oxygen consumption. The loading of particulate organic matter to the seafloor is generally greatest below net cage fish farms and decreases with distance from the point source. The benthic effects of an intensive sea bream fish farm in the Gulf of Aqaba, Red Sea were examined by taking replicated sediment cores along a transect extending from below the cages to a station outside the anticipated range of influence. Cores were sampled for loss-on-ignition (organic matter content), pore-water nutrients, redox potential, benthos and SOD. A comparison of stations indicated a 50% decrease in SOD within 25m from the edge of the fish farm to values that were not much greater than background levels.
estimate wind-driven transports of the North Pacific subtropical gyre, and compare them in the central portion of the gyre (around 30N) with geostrophic transports estimated from historical hydrographic data (World Ocean Database 2005). The wind-driven transports for QSCAT and NCEP are both in good agreement with the geostrophic transports within reasonable errors, except for the regional difference in the eastern part of the zone. The difference in the eastern part results from an anti-cyclonic thermohaline flow in the surface. We also examined the consistency of the Sverdrup transports estimated from the products by comparing them with the results of the western boundary current in previous studies. The sum of the Sverdrup transport for QSCAT or NCEP and the thermohaline transport, agrees well with the northward transport of the western boundary current. It is concluded that the Sverdrup balance can hold in the North Pacific subtropical gyre.

In the abundance of heterotrophic microbes and picoeukaryotes, enhanced microbial activity was examined using terminal restriction fragment length polymorphisms of the 16S ribosomal RNA gene. This suite of daily and diurnal measurements documented 2-fold increases in the abundance of heterotrophic microbes and picoeukaryotes, enhanced microbial activity and shifts in the major bacterioplankton groups following the spawning events.

FOLLOWING NUTRIENT LOADING DUE TO CORAL SPAWNING

WAVE-DRIVEN SETUP AND ALONGSHORE FLOWS OBSERVED ONSHORE OF A SUBMARINE CANYON

The effect of alongshore variations in the incident wave field on wave-driven setup and on alongshore flows in the surfzone is investigated using observations collected onshore of a submarine canyon. Wave heights and radiation stresses at the outer edge of the surfzone (water depth < 2.5 m) varied by up to a factor of 4 and 16, respectively, over a 450 m alongshore distance, resulting in setup variations as large as 0.1 m along the shoreline (water depth > 0.3 m). Even with this strong alongshore variability, wave-driven setup was dominated by the cross-shore component of the wave radiation stress tensor, and setup observed in the surfzone is predicted well by a one-dimensional cross-shore momentum balance. Stronger cross-shore and alongshore setup gradients contribute to the alongshore flows observed in the inner surfzone, and a simplified alongshore momentum balance suggests that the large [O (1 m/s)] currents are tidal rectification and density-driven circulation. Stronger circulation of the gyre occurs during the later part of the stratified season (July—August and September—October). The density-driven flow along the gyre is set-up by weak tidal mixing in the deep basin in the central Bay of Fundy and strong tidal mixing on the shallow flanks around Grand Manan Island and western Nova Scotia. Residence times longer than 30 days are predicted for particles released in the proximity of the gyre. A set of climatological runs were conducted to evaluate the relative importance of the different forcing mechanisms affecting the gyre. The main mechanisms are tidal rectification and density-driven circulation. Stronger circulation of the gyre occurs during the later part of the stratified season (July—August and September—October).

MODEL SIMULATIONS OF THE BAY OF FUNDY GYRE

Arbogast, A. L.; CMIMA/CSIC, Barcelona, Spain, alfredo@cmima.csic.es; McGillicuddy, D. J.; WHOI, Woods Hole, MA, USA, dmegill@whoi.edu; Smith, K. W.; WHOI, Woods Hole, MA, USA, kwsmith@whoi.edu; Lynch, D. R.; Dartmouth College, Hanover, NH, USA, Daniel.Lynch@dartmouth.edu

The characteristics of a persistent gyre in the mouth of the Bay of Fundy are studied using model simulations. A set of climatological runs were conducted to evaluate the relative importance of the different forcing mechanisms affecting the gyre. The main mechanisms are tidal rectification and density-driven circulation. Stronger circulation of the gyre occurs during the later part of the stratified season (July—August and September—October). The density-driven flow along the gyre is set-up by weak tidal mixing in the deep basin in the central Bay of Fundy and strong tidal mixing on the shallow flanks around Grand Manan Island and western Nova Scotia. Residence times longer than 30 days are predicted for particles released in the proximity of the gyre. A set of hindcast model simulations were conducted to study both the recent (2005—2007) interannual and intra-annual variability during the stratified season. Data assimilation of ADCP velocity data was used to improve the skill of the simulations. The resulting circulation suggests that during 2005 the strength of the Gyre was reduced which contributed to weaker reten- tion. The strongest flow and retention was estimated for late-spring 2007.

WAVE-CURRENT INTERACTIONS IN THREE DIMENSIONS

A theoretical framework for wave-current interactions based on the Generalized Lagrangian Mean is presented together with some first results obtained with the primitive equations ROMS model forced by a simple wave model (Thornton and Guza 1983). The different forces appearing in the 3D balance are discussed, together with a possible parameter- ization of strong wave nonlinearity.

DISTRIBUTIONS OF STABLE ELEMENTS AND RADIOISOTOPES IN SOME ESTUARINE AREAS OF JAPAN

Variations of the concentrations of chemical compounds in the hydrosphere, such as rivers, estuaries and coastal areas, are caused by changes of the environments and weather conditions. As chemical properties differ between fresh water and seawater, the behaviors of these compounds compositions are different in each environment. It is important for the understanding of the behaviors of these compounds to determine the concentrations of stable elements and radionuclides in these areas. A survey of Japanese rivers was conducted, and then a database was prepared. The concentrations of chemical compounds were investigated in order to clarify the distributions and behaviors of these from the estuarine to coastal areas. Major chemical compounds, i.e. nutrients and salinity, and minor components, i.e. halogen, selenium and heavy metals and POC etc., were determined in estuarine areas. The nutrient concentrations in estuarine areas were higher than in the coastal areas, as there was the diffusion in river water in the surface layer of the estuaries. Furthermore, there were high correlations between the chloride, bromine and iodine concentrations. We will discuss the behaviors on the basis of the concentration distributions of nutrients in some estuarine areas of Japan.
The amount of genomic information available for diatoms is increasing rapidly. In recent years, whole genome sequences have been completed for the centric diatom Thalassiosira pseudonana and the pennate diatom Phaeodactylum tricornutum. Two more pennate diatoms are currently being sequenced—the polar diatom Fragilariaopsis and the toxic diatom Pseudo-nitzschia multiseries. These large-scale sequencing projects have generated new hypotheses about diatom capabilities and thus have laid the foundation for detailed studies into their physiology and ecology. I will provide an update on current diatom genome sequencing projects and will describe new ways that these data are being used to better understand how diatoms transport and process silicon.

Evolutionary Optimization in Marine Biogeochemistry Modeling: An Example from Optimal Foraging

The process of constructing ocean ecosystem models for use in biogeochemistry includes selecting mathematical functions to represent dynamical interactions among state variables. Usually several choices exist among functions that have been used in past models (e.g., multiplicative vs. Liebig vs. Geider/Armstrong descriptions of light-nutrient interaction), and it is often not clear which of them should be used. Here I argue that evolutionary optimization, a staple in the field of evolutionary ecology, can be used to sort among competing mathematical descriptions. Furthermore, in many cases optimality arguments lead to alternative, more powerful functional descriptions, whose parameters may be easier to interpret and measure, leading to a more productive dialogue between empiricists and modellers.

Portuguese Man-O-War (Physalia physalis) is a marine jellyfish, which is an invasive species that cryptically uses the planktonic stages of the crustacean species Bopyrus minor as a means of dispersal to colonize new areas. We tested the efficiency of Bopyrus as a dispersal agent using a newly developed laboratory model that can simulate the dispersal process and evaluate the factors that influence the success of Bopyrus' larval stages. The model incorporates the dynamics of Bopyrus' dispersal and the environmental conditions that affect its survival and recruitment into new areas. We found that Bopyrus' dispersal is influenced by both biological and environmental factors, and that the optimal dispersal strategy varies depending on the environmental conditions. Our results suggest that further research is needed to understand the factors that influence Bopyrus' dispersal and to develop effective strategies for managing its invasive spread.
examples from my own work and that of others, I emphasize the need to apply multiple approaches, specific to the life stage of the larve, to effectively validate and enhance our understanding of these organisms. Application of those approaches, particularly within the framework of an intensive coastal ocean observing system, is a necessary precursor to model acceptance and advancement.

COUPLING SATELLITE BIO-OPTICS, NUMERICAL MODELS AND OBSERVATIONS TO DEFINE A COASTAL ECOSYSTEM

We define a three-dimensional ecosystem of the coastal ocean by assimilation of observations with an ocean model. The 3-D volume of coastal bio-optical/physical properties was determined by coupling surface bio-optical satellite properties, vertical density properties from circulation models and in situ profiles of bio-physical properties. Relationships between density profiles, 1% light level, and profiles of chlorophyll and backscattering coefficients were determined from observations. These physical-bio-optical relationships were constrained by satellite surface properties and used to extend a subsurface profile by incorporating model fields of mixed layer depth, degree of stratification, and 1% light level. The equations used to characterize the profile shape were optimized by in situ profiles from sea-gliders and stations observations and the variability of these optimized coefficients determined. This approach considers surface satellite accurate with uncertainty in the subsurface profile. By exploiting in situ vertical properties to constrain profile shape and extending these relationships both spatially and temporally, we reduce the uncertainty of subsurface shape and define the bio-optical ecosystem. The 3-D bio-optical ecosystem volume is demonstrated in the northern Gulf of Mexico and other regions.

RECENTLY ENHANCED PRIMARY PRODUCTIVITY IN THE ARCTIC OCEAN

In 2007, the Arctic Ocean experienced an unprecedented loss of sea ice, with a summer minimum ice extent that was 23% below the previous low in 2005 and nearly 40% below the mean low for 1979-2000. This loss of sea ice increased the area of the Arctic Ocean exposed to summer solar insolation by 1.3 million square kilometers, or 15%. In addition, an earlier spring melt and later autumn freeze in the Arctic in recent years resulted in a longer phytoplankton growing season. Satellite ocean color data suggest that chlorophyll concentrations in the newly exposed areas of the Arctic Ocean in 2007 range from 0.25 to 0.80 mg m⁻², typical of concentrations found at lower latitudes. These observations, along with satellite-based estimates of sea surface temperature and cloud cover, were used as input to a primary production algorithm to estimate rates of phytoplankton primary production throughout the Arctic Ocean. We will present recent estimates of changes in pan-Arctic productivity, including the contribution by the new and unprecedented area of open water observed in 2007.

THE ROLE OF NUTRIENTS IN LYNGBHYA GROWTH AND CHEMICAL DEFENCE

Benthic cyanobacteria of the genus Lyngbya form harmful algal blooms (HABs) that occur in marine and estuarine environments throughout tropical and subtropical oceans of the world. They are extremely prolific producers of biologically active secondary metabolites, many of which deter grazing by generalist herbivores. Nutrient blooms of Lyngbya occur regularly throughout Florida and may be triggered by terrigenous nutrient inputs. In addition, these blooms may grow unchecked as grazers avoid consuming the filaments. In this study we examine the ecology of Lyngbya blooms in Florida including the effects of nutrient additions and light on Lyngbya growth and toxin production. We use a bioassay approach to assess the role of nitrogen, phosphorus, iron and low light conditions on the growth and secondary metabolite production of Lyngbya spp. from Florida, USA. We also assess how these compounds affect potential grazers and the implications of these blooms for the marine ecosystem.

THE LACAR-ICOMM NETWORK: IDENTIFICATION OF RESEARCH CAPABILITIES AND OPPORTUNITIES FOR ASSESSING MARINE MICROBIAL DIVERSITY IN SOUTH AMERICA AND THE CARIBBEAN

The International Census of Marine Microbes (ICoMM), the South American and the Caribbean Census of Marine Life (CoML) regional committees, launched a regional ICoMM node (LACar-ICoMM). This network aims at promoting discussions on marine microbial studies carried out in both regions in order to identify research capabilities, complementary strengths and possibilities for enhanced collaboration in assessing marine microbial dynamics and diversity. Studies dealing with bacterial, phytoplankton, phytobenthos and/or cyanobacterial ecology and/or taxonomy are carried out in coastal and oceanic marine systems modulated by geographic and seasonal patterns, as well as by the expression of large South American rivers or strong upwelling systems, in tropical and temperate areas. Bacteria capable of degrading pesticides and hydrocarbons are also monitored (activity and diversity) in the Caribbean (Colombian Caribbean, Orinoco Delta), as well as in tropical (Microbial Observatory of Rio de Janeiro, Guanabara Bay, Brazil) and temperate waters and sediments of South American threatened coastal systems. The application of molecular tools in monitoring marine microbe diversity and dynamics represents a common priority for each type of study and a challenge for future research in the area.

A CONTRIBUTION OF WIND FORCE TO A PRIMARY PRODUCTIVITY IN THE PHILIPPINE ARCHIPELAGOS

In June, 2007, a wind driven surface current along the Cuyo East Pass in the Philippine Archipelagoes was observed by the Synthetic Aperture Radar (SAR) on the Advanced Land Observation Satellite (ALOS). Simultaneously, the moored Acoustic Doppler Current Profiler (ADCP) at the west of the Panay Island observed the northward current in the surface to 150 m depth from the middle of June to the beginning of July, 2007, while the south wind was dominant. The Moderate Resolution Imaging Spectroradiometer (MODIS) on the AQUA observed the decrease of the sea surface temperature and chlorophyll a concentration. The MODerate resolution Imaging Spectroradiometer (MODIS) on the AQUA observed the decrease of the sea surface temperature and chlorophyll a concentration. The satellite observations provided the horizontal response of the primary production and the ADCP provide the time series of the vertical distribution of water mass. This study examined the mechanism of the primary production in the Philippine Archipelagoes based on these observations and from the point of response of biological activities to the environmental changes, which could be determined by the seasonal winds.

Elucidating shifts within microbial communities are a prerequisite for gaining a better understanding of organic matter (DOM) availability over a tidal cycle in Apalachicola Bay, FL. Elucidating shifts within microbial communities are a prerequisite for gaining a better understanding of organic matter (DOM) availability over a tidal cycle in Apalachicola Bay, FL. Elucidating shifts within microbial communities are a prerequisite for gaining a better understanding of organic matter (DOM) availability over a tidal cycle in Apalachicola Bay, FL.

To further our understanding of the temporal variability of DOM, we set out to characterize the seasonal and diurnal changes in DOM composition and bioavailability in this estuarine system. Our data suggest that the temporal variability of DOM composition and bioavailability is strongly influenced by the interaction of physical processes with biological activity.

We investigated the diurnal and seasonal variability of DOM composition and bioavailability in the Apalachicola Bay estuary, FL, using a combination of field observations and modeling approaches. Our results show that the temporal variability of DOM composition and bioavailability is strongly influenced by the interaction of physical processes with biological activity. We found that the temporal variability of DOM composition and bioavailability is strongly influenced by the interaction of physical processes with biological activity.

In summary, we found that the temporal variability of DOM composition and bioavailability is strongly influenced by the interaction of physical processes with biological activity. Our findings suggest that the temporal variability of DOM composition and bioavailability is strongly influenced by the interaction of physical processes with biological activity.
may directly impact observations at nearby AmeriFlux towers. We have collected lake water samples, analyzed above lake CO2 content of the strom, measured CO2 fluxes, and developed a coupled ecosystem carbon-hydrodynamic model of Lake Superior in an attempt to estimate these fluxes and understand their controlling mechanisms. Water samples collected monthly since January 2007 have pCO2 concentrations above the atmospheric equilibrium value; CO2 concentrations measured in June were elevated above what would be expected on land, and direct flux measurement in August confirmed that the lake was emitting CO2. Simplest extrapolations from these observations suggest the lake source may be significant. Initial whole lake flux estimates from the coupled hydrodynamic model will be compared with measured fluxes.

BIO-OPTICAL CHARACTERISTICS OF THE WESTERN ARCTIC OCEAN: IMPLICATIONS FOR OCEAN COLOR ALGORITHMS

Global ocean color algorithms designed to estimate chlorophyll a concentration (chl) are not accurate at high latitudes. While a regional Arctic OC4 algorithm was designed to be applicable to high northern latitudes, its applicability also remains uncertain. To examine these issues, we investigated the light absorption coefficient of phytoplankton, non-algal particles (NAP), colored dissolved organic matter (CDOM), and remote sensing reflectance, Rs(t) above-most part of the Western Arctic Ocean. A higher pigment packaging effect was identified relative to that at lower latitudes. The CDOM absorption dominated and is accounted for over 50% of the total non-water absorption at all wavelengths used for ocean color algorithms, and did not covary with chla. Our evaluation shows that when turbid waters are excluded, the performance of the OC4L is much better than that of SeaWiFS OC4V4 and MODIS OC3M. The reason why the OC4L performs well despite strong CDOM absorption is discussed.

RELIANT PHYSICAL AND BIOLOGICAL CLIMATE CHANGES IN THE GULF OF ALASKA

Recent measurements of zooplankton biomass and biological productivity in the Gulf of Alaska have raised a number of questions regarding possible linkages between climate and availability of renewable resources. In this article we compare 3 abrupt oceanic regime shifts in the Gulf of Alaska, the 1976-1977 warming shift, the 1998 cooling episode, and the 1998 to 1999 El Niño to La Niña transition. We investigated the light absorption coefficient of phytoplankton, non-algal particles (NAP), colored dissolved organic matter (CDOM), and remote sensing reflectance, Rs(t) above the seasonal warming that had on estuarine salt exchange. A geometrically similar estuary to the Chesapeake Bay (200 km long, 20 km wide) and a similar mean freshwater flux (2500 m3s) was used to force the model. Applying a Mellor-Yamada vertical mixing scheme with a backscattering coefficient of 0.001 m3s to a 150-day model run, we first established the initial estuary salinity equilibrium gradient. Then running the model for 10 days, a river induced freshwater plume progressed southward over the shelf and detached from the coast. When upwelling winds were imposed for 3 days, the river plume moved northward in the alongshore direction, increasing the estuary salinity and total salt exchange out of the estuary. We quantified these changes in estuarine salt exchange and volume by also shifting the onshore and duration of upwelling winds in order to compare with past Chesapeake Bay research.

THE INFLUENCE OF UPWELLING WINDS ON ESTUARINE SALT EXCHANGE

Typical shelf-estuary modeling has integrated simplified models for either the estuary or the coastal ocean. In this analysis we included the complexity of each region using the Regional Ocean Modeling System (ROMS) to characterize the impact that upwelling directed winds had on estuarine salt exchange. A geometrically similar estuary to the Chesapeake Bay (200 km long, 20 km wide) and a similar mean freshwater flux (2500 m3s) was used to force the model. Applying a Mellor-Yamada vertical mixing scheme with a backscattering coefficient of 0.001 m3s to a 150-day model run, we first established the initial estuary salinity equilibrium gradient. Then running the model for 10 days, a river induced freshwater plume progressed southward over the shelf and detached from the coast. When upwelling winds were imposed for 3 days, the river plume moved northward in the alongshore direction, increasing the estuary salinity and total salt exchange out of the estuary. We quantified these changes in estuarine salt exchange and volume by also shifting the onshore and duration of upwelling winds in order to compare with past Chesapeake Bay research.

THE COUPLING OF HYDRODYNAMICS AND NUTRIENT EXCHANGE IN NATURAL SEAGRASS CANOPIES, PART TWO: CANOPY CHARACTERISTICS AND NUTRIENT UPTAKE

Rates of nutrient uptake and the partitioning of uptake spatially within a canopy are the result of both biological characteristics of the canopy and the interaction between the canopy and the overlying water. Here we examine these interactions within vegetated canopies in Florida Bay, FL. These canopies are dominated by the seagrass, Thalassia testudinum. However they have a range of blade densities and understory characteristics. We identified species within each canopy and estimated the volume and cross sectional area of the canopy filled by vegetation. These characteristics were then compared with hydrodynamic data from a multi-instrument array to examine how complex canopy form influences hydrodynamics. We also used a field-deployable racetrack flume to measure the uptake of ISNO ammonium by the canopy over a range of hydrodynamic conditions and partitioned uptake among species and among locations within the canopy. Our data indicates that hydrodynamic regime and partitioning of nutrient uptake are influenced by characteristics of natural canopies.
the composition of Ocean samples in terms of end members of the water masses that Schlosser, P. Truong, G. Babbin, A. R. the future carbonate system in deep North Atlantic will be discussed. fluvial input in the water formation regions, calcium carbonate dissolution, remineralization of salinity abruptly increased in LSW and NEADW in 2003, persisting to the present, and showed changes in alkalinity-salinity relationships over the last 15 years. Through the 1990s and up formed every winter in the Labrador Sea, and North East Atlantic Deep Water (NEADW) and The Labrador Sea is one of two sites in the North Atlantic that produce intermediate and spheric forcing fields come from the ERA40 reanalysis and from the CORE product. Estimations of the mixed layer heat content and the study of associated mechanisms often rely on numerical simulations. OGCMs are usually forced with NWP fields such as the ECMWF or NCEP (re)analyses or with observations-derived products. Although it is clear that the nature of atmospheric forcing products and their space-time resolution have a significant impact on model results in terms of surface heat content, little is known about the influence of uncertainties in one given atmospheric product. In this study we propose to explore the sensitivity of a model response in terms of mixed-layer heat content representation to 1/ the use of different atmospheric reanalyses with similar space-time resolution and 2/ small perturbations on a given reanalysis meant to represent a priori uncertainties. The approach is based on stochastic modelling. We address the case of the North Atlantic during a period of mixed-layer deepening (September 1994 - March 1995). We use the NEMO/OPA model in a A/A, horizontal resolution configuration; atmospheric forcing fields come from the ERA40 reanalysis and from the CORE product.

Aseyt Scott-K, Bedford Institute of Oceanography, Dartmouth, Canada, Aseytu Scott-K@mac.léo-mpo.gc.ca; Jones, E. P, Bedford Institute of Oceanography, Dartmouth, Canada, Jonee@mac.léo-mpo.gc.ca; Gershey, R. M., BDR Research Limited, Halifax, Canada, bd-research@ca.inter.net DECADAL VARIATION OF ALKALINITY IN THE LABRADOR SEA The Labrador Sea is one of two sites in the North Atlantic that produce intermediate and deep water by winter convection. The Labrador Sea consists of Labrador Sea Water (LSW), formed every winter in the Labrador Sea, and North East Atlantic Deep Water (NEADW) and Denmark Strait Overflow Water (DSOW) produced in the Nordic Seas. We report significant changes in alkalinity-salinity relationships over the last 15 years. Through the 1990s and up to 2002, alkalinity and salinity showed strong negative correlation in LSW and NEADW. The salinity abruptly increased in LSW and NEADW in 2003, persisting to the present, and showed a positive correlation with alkalinity. Possible causes of these changes include changes in Arctic fluvial input in the water formation regions, calcium carbonate dissolution, remineralization of organic matter, mixture of different source waters. These will be evaluated and implications for the future carbonate system in deep North Atlantic will be discussed.

Babin, A. R., Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA, ar,babin11@eolouab.com; Truong, G., Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA, gst2102@columbia.edu; Newton, R., Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA, benwton@leidos.columbia.edu; Schlosser, P., Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA, schlosser@leidos.columbia.edu OXYGEN ISOTOPE RATIOS IN THE ARCTIC OCEAN: IMPLICATION FOR THE FRESHWATER BALANCE Oxygen isotope ratios (H18O/H16O and H18O/H16O) of water and salinity data are used to identify the composition of Ocean samples in terms of end members of the water masses that determine the freshwater budget of the Arctic Ocean. These include the Atlantic and Pacific inflows, meteoric water, and sea ice melt. Starting from the GIN Global Seawater Oxygen-18 database (Schmeiker et al., 1999), which contains oxygen isotope and corresponding salinity measurements compiled over the last thirty years, we added new data to the database and determined the errors in the 18O fields, using several methods, including rms error about a smooth fit to profiles. We used the 18O data, together with salinity and nutrient measurements, to calculate the contributions of the individual water masses to the Arctic Ocean freshwater balance. The errors in the freshwater calculations were determined from those of the individual variables through a matrix inversion. Sea ice melt and meteoric water fraction errors were found to be strongly anti-correlated.

Babolin, M. CNRS - Laboratoire d'Océanographie de Villefranche, Villefranche-sur-Mer, France, merve@obs-vlfr.fr; Belanger, S., Université E du Québec I Rimouski, Rimouski, Canada, sionel_belanger@ uqtr.ca PAN-ARCTIC PRIMARY PRODUCTION AND ORGANIC MATTER PHOTOSYNTHESIS: SIGNIFICANCE OF THESE TWO LIGHT-DRIVEN PROCESSES Primary production and CDOM photo-oxidation have opposing impacts on carbon fluxes in the ocean. The balance between the two processes may be significantly affected in the near future by climate change. This is especially true for the Arctic Ocean, which is increasingly exposed to light as perennial ice recedes, and which receives increasing amounts of terrigenous organic matter as the permafrost thaws and river discharges increase. In this study, we used remote sensing data to estimate the pan-Arctic distributions of primary production and CDOM photo-oxidation, and how they evolved from 1998 to now. Ocean color, ozone, cloud and ice data are combined to run a radiative transfer, and primary production and photo-oxidation, and sensitivity analysis is conducted to quantify the impact of chosen ocean color algorithms and of various model parameters on results. Our results provide the first pan-Arctic estimates of primary production and CDOM photo-oxidation based on remote sensing, and allow determining how these two processes compare. Also, we show how CDOM affects primary production through shading.

Baio, A. L., AAAS Science and Technology Policy Fellow, Washington, USA, babsona@gmail.com; Kawase, M., University of Washington, Seattle, USA, kawase@ocean.washington.edu MODELLING SILL EFFECTS ON FLOOD STRATIFICATION, INTERNAL TIDES, TRANSPORT AND RESIDENCE TIMES The effects of sill height on stratification, residence time and transport are studied using the Regional Ocean Model System (ROMS) with idealized fjord bathymetry and steady forcing. Six cases of increasing sill height, residence time does not monotonically increase with increasing sill height. This is partially due to the lowest sill height case having anomalous stratification. This case has the highest energy converted to mixing. Internal tides are generated in all cases off the sloping headwall and in some of the cases off of the sill. The three tallest sill cases are jet basins according to Stigebrandt and Aureus (1989) dividing between jet and wave basins. Jet basins have a mean tidal velocity that is greater than the internal wave speed. Within the basin is a cyclonic gyre, in the time mean, at all depths except the thin outflowing surface layer and a thin bottom layer. The strength of this gyres increases with sill height, as internal Rossby radius decreases. Bachratt, B. C., University of Montreal, Montreal, Canada, charlyne.bachratt@umontreal.ca A MODEL FOR DEEP-SEA HYDROTHERMAL VENT FAUNA BIOGEOGRAPHIC DISPERSAL Since their discovery in 1977, deep-sea hydrothermal vent fields have fascinated marine biologists because of their fauna based on chemosynthesis and the high level of symbiosis among trophic types. This fauna was found to harbor new species, genera, and families that were new to science. Its biomass is high despite harsh environmental conditions. This fauna has been studied by scientists from several countries. Few studies have focused on biogeographic relationships among regions of the world ocean. Our objectives are to (1) recognize large areas (biogeographic provinces) with differing faunal composition and (2) determine the dispersal and evolutionary relationships among these areas. Our study benefited from a recent compilation of all hydrothermal species in 63 fields. Architecturally constrained multivariate regression tree pointed to a preliminary division of the world ocean into 6 to 9 provinces; this result will undoubtedly be revised as new oceanic areas are explored. We then analyzed the relationships among these faunas and generated a hypothesis about the center of dispersal of hydrothermal faunas. This result will be tested using phylogenetic analysis of some groups of organisms.
seep habitats occur in abundance along the entire east and south slope of NZ's North Island. Seep communities were characterized by vestimentiferan worms in the genera Lamellibrachia, Siboglinum pogonophorans, vesicomyid clams, a solemyid (Acharax sp.) and a species of bathymodiolin mussel. Core and grab samples revealed numerous additional described species of paracardid crustaceans and polychaete worms. The initial assessment of community composition suggests that the NZ margin hosts a broad diversity of seep fauna, each likely harboring its own characteristic fauna. While the NZ margin appears to represent a new biogeographic province for seep fauna, there may be high species overlap with the nearby Kermadec Arc hydrothermal vents. Unfortunately, even as these cold-seep ecosystems are being discovered, they appear to be threatened by bottom trawling along the entire NZ margin. Fishing and other anthropogenic disturbance may endanger seep communities on a global scale.

THE ROLE OF MECHANICAL VERSUS BUOYANCY FORCING IN DETERMINING THE RESIDUAL CIRCULATION IN THE OCEAN

Eddy residual-mean circulation in the ocean requires the presence of a gradient in the buoyancy input as argued by Walin (1982). The buoyancy forcing can be a function of the flow, such as the air-sea heat loss associated with western boundary currents. However, we argue that the buoyancy forcing is not always the rate limiting process in determining the residual circulation and instead mechanical forcing is important. Here, the residual circulation is examined for two different regimes: an open ocean front, with characteristics similar to fronts observed in the Southern Ocean, and a shelf-sea front, separating stratified to tidally well-mixed waters. The buoyancy forcing is solved for either as a function of the Ekman flow in the mixed layer or as a function of tidal mixing. For both regimes it is the mechanical forcing that controls, and localize the residual circulation. This process is analogous to the stratosphere, where the breaking of gravity waves is responsible for driving the residual-mean flow.

INFLUENCE OF THE RAPID/MOCHA AND FLORIDA CURRENT CABLE DATA ON THE ECCO-GODAE OCEAN STATE ESTIMATE

The incorporation of local temperature/salinity observations from the RAPID/MOCHA mooring array, as well as the cable estimates of volume transport in the Florida Current, is tested in the ECCO-GODAE estimation system for their impact on the meridional overturning circulation and heat transport in the Atlantic. These data are added to the global data sets normally used in the ECCO-GODAE least-squares fits over the one-year period March 2004-March 2005. Preliminary results show that western and eastern boundary mooring array data without the cable observations modify the estimated state only regionally and produce a shift in the meridional overturning of about 1 Sv. We also investigate the extent to which the non-eddy resolving model can represent the observed variations that include eddy signals. Using the cable data as observational constraint increases the time-mean Gulf Stream transport, the amplitude of the seasonal cycle, higher frequency variability, as well as the overturning circulation by about 3 Sv between 25 and 45N.

HYPERSONTAL DATA IN SPECTRAL ANALYSIS OF NEARSHORE WATER QUALITY PARAMETERS

The focus of the research is to characterize the physically based surface spectral reflectance for the NJ nearshore waters and to retrieve the water constituent concentrations from the atmospherically corrected AVIRIS signals. Hyperpectral data were collected using the NASA/AVIRIS in conjunction with simultaneous in-water measurements. AVIRIS records the integrated effects of the solar source, the atmosphere and the targeted surface. To use AVIRIS data, the generation of accurate reflectance from radiance is a required input parameter for retrieval of nearshore water constituent concentrations. Atmospheric correction algorithm - Tafka developed by the NRL will be used to reduce the effects of the atmosphere so as to infer the water-leaving radiance. The algorithm uses lookup tables generated with the vector radiative-transfer code (RTC). AVIRIS data will be used to do the model inversion to describe the entire system from remote sensor to hydroxys for retrieval of the optical water quality parameters. In conjunction with bio- optical models these optical properties can be used to characterize the water in terms of chlorophyll, CDOM and inorganic material. The bio-optical modeling and RTC are the main tools for using remote sensing as an operational monitoring tool to study the ecological communities of phytoplankton important in global change studies.

DEEP OCEAN ENVIRONMENTAL LONG TERM OBSERVATORY SYSTEM (DELOS); INITIATION OF A 25 YEAR STUDY OF DEEP-OCEAN ECOSYSTEMS OEFFS OFFSHORE HYDROCARBON OPERATIONS

The deep-sea environment into which hydrocarbon operations are gradually extending is generally poorly understood with surveys regularly discovering new habitats and communities of animals previously unknown to science. Hitherto only a very small number of deep-sea sites in the world’s oceans have been the subject of long-term studies exceeding 5 years, but these studies have shown important annual cycles with considerable variability from year to year and changes in dominant fauna over decadal time scales. In an oil production area such spontaneous changes need to be distinguished from any anthropogenic influences imposed on the deep-sea environment. The DELOS system comprises two environmental monitoring platforms situated in the Southwest Atlantic Ocean at 1400m depth off Angola. One in the far field will be 5 km from sea floor infrastructure, and one in the near field within 50 metres of a well. Each platform will have a camera, oceanographic, acoustic, and guest module with an additional sediment trap module in the far field. DELOS will be installed in early 2008 and over time will lead to improved understanding of deep ocean ecology.

VOLATILIZATION OF POLONIUM BY TELLURITE RESISTANT MARINE MICROBES

Tellurite resistant (TeR) microorganisms from Indian River Inlet (Delaware, U.S.A) salt marsh sediments were examined for their potential roles in biogeochemical cycling of tellurium (Te) and its group 16 congener polonium (Po). We hypothesized that TeR microbes may produce volatile alkylated species of both Te and Po thereby mediating transfer of Te and Po from the marine environment to the atmosphere. The hypothesis is based on the homology of some tellurite resistant determinants to S-adenosylmethioine (SAM) alkyltransferases. Previously, we demonstrated that our TeR microbes do volatilize Te, primarily as dimethyl telluride. Here, we show that these organisms also volatilize Po, transferring between 2.3 and 5.5% of a 10 Bq Po-209 spike from the media to the headspace over a 10-day period. The addition of tellurite to cultures appears to suppress Po volatilization, with the majority of the radioactivity being found in particulate materials.

LONG-TERM CHANGES IN ATLANTIC DEEP-WATER FISH POPULATIONS: EFFECTS OF FISHING AND CLIMATE

Nothing is known about long-term trends in the majority of deep-water fishes, particularly those which are not fisheries targets. We analyzed scientific bottom trawl data obtained using identical techniques from 1979-1989 and 2000-2002, and extending from the depths exploited by slope fisheries (<1500 m) to the abyssal plain (>4000 m). At abyssal depths there are possible links between surface climate and fish abundance, probably mediated by changes in carrion supply to scavenging fishes. We also demonstrate that significant decreases in abundance are apparent in both target and non-target species at all depths from 800 to 3000 m. As many deep-water fishes have large adult depth ranges, and some migrate down-slope with increasing age, fishery impacts on the upper slope appear to reduce the recruitment of adult fish to lower slope habitats. This effect at least doubles the depth at which fisheries impacts occur and potentially increases the area affected by fishing from 11% to 23% of the seafloor.
We present novel methods, using k-means clustering combined with statistical tech-
niques, for detecting and segmenting upwelling and frontal boundaries. We demonstrate
our methods in the Monterey Bay coastal regions using Advanced Very High Resolution
Radiometer (AVHRR) satellite data. Using the clusters with different numbers of classes,
we introduce a clustering-differencing approach for detection of frontal boundaries.
We also introduce statistical criteria to determine the presence of upwelling and its
segmentation. We demonstrate the representativeness of this method for the period of
August 2003 and validate the results with the Upwelling Index, a metric based on estimated off-
shore Ekman drift driven by alongshore wind stress.

HOW ON EARTH WILL WE MEASURE THE IMPACT OF OCEAN ACIDIFICATION
OVER BASIN SCALES?

Remote sensing is likely to play a key role in assessing the impact of ocean acidification in
the global ocean. Cocolithophorids could be a key functional group to watch; they
should be particularly sensitive to decreases in ocean pH due to their being covered by
coccoliths made of calcium carbonate (otherwise known as particulate inorganic carbon).
We briefly review the method for space-based remote sensing of suspended PIC,
highlighting the advantages and limitations of the technique. The ocean color PIC algo-
rithm specifically targets backscattered light from the smallest calcium carbonate particles
such as plated cocolithophores and detached coccoliths. We will use field results to
show the utility of the PIC algorithm that has been calibrated and validated as well as the
future challenges for relating cocolithophore variability and PIC standing stock to ocean ac-
idification. The global standing stock and annual production rate of PIC will be discussed.
A five-year time series of suspended PIC concentration (derived from NASA's recently-
reprocessed MODIS AQUA mission) will be shown to highlight the spatial and temporal
variability in the global standing stock of particulate inorganic carbon.

HOTSPOTS: DENSITY AND SPECIES RICHNESS FOR CETACEANS IN
THE OCEANIC EASTERN TROPICAL PACIFIC

Biodiversity hotspots have received much attention but relatively little is known about
hotspots in oceanic systems. We describe density and species richness hotspots for cetae-
cans in the eastern tropical Pacific based on data collected using line transect methods
during an 18-year period. Density hotspots were clearly evident in three oceanographically
distinct regions: the Equatorial cold tongue, the Costa Rica Dome, and waters to the west
and east of the Isthmus of Panama. A smaller hotspot centered along the 10N thermocline
ridge. Hotspot species generally mirrored hotspots of density but tended to be located along
the edges of many species-specific density hotspots. This result contrasts sharply with results
from terrestrial systems, where richness hotspots typically represent centers of endemism.
Endemism is rare for cetaceans in the oceanic tropical Pacific, and richness hotspots may
represent areas of marginal habitat for many species. Focusing conservation efforts on richness
hotspots for oceanic cetaceans, and perhaps for other oceanic species, may not facilitate
their conservation.

THE OCEAN OBSERVATORIES INITIATIVE (OOI) NETWORK: INTEGRATING
ADVANCED TECHNOLOGIES.

The National Science Foundation's (NSF) Ocean Observatories Initiative (OOI) supports
the construction and operation of an interactive, integrated ocean observing network.
This research-driven network will provide advanced technology to enable next-gen-
eration studies of fundamental ocean processes. The OOI will afford observations at
coastal, regional, and global scales on timescales of milliseconds to decades in support
of investigations into climate variability and ocean ecosystems, biogeochemistry, coastal
processes, mixing dynamics, plate-scale geodynamics, fluid-rock interactions, and
the sub-seafloor biosphere. The elements of the OOI include arrays of fixed and re-
locatable moorings, autonomous underwater vehicles, and cabled seafloor nodes. These elements
will be integrated through a system-wide cyberinfrastructure allowing for remote control
of instruments, adaptive sampling, and near-real time access to data. Implementation of
the network will stimulate new avenues of research and the development of new infra-
structure, instrumentation, and sensor technologies. The OOI is coordinated for the NSF
by the Consortium for Ocean Leadership/ Joint Oceanographic Institutions which focuses
on the science, technology, education, and outreach for an emerging network of ocean
observing systems.
MODELING PLANKTONIC GROWTH AND GRAZING IN THE COLUMBIA RIVER PLUME REGION

A coupled circulation/biogeochemical model was developed for the Washington-Oregon coast in order to determine the role of the Columbia River plume in along-coast gradients in primary production. The circulation model (ROMS 2.2) has 400 m resolution near the river mouth and is forced by tides, wind from a mesoscale atmospheric model (MM5), and variable riverflow. The biological model is a constant nitrogen budget which tracks nutrients, phytoplankton, zooplankton, and detritus (NPZD) in every grid cell. Crucially, zooplankton ingestion mortality rate, and some zooplankton model parameters were determined empirically rather than by tuning, using an equivalent models of the equations using a rich biological database obtained in the RISE (River Influences on Shelf Ecosystems) program. Observed and modeled rates in the nutrient-depleted field far are an order of magnitude higher than rates commonly assumed a priori in ecosystem models of this type. Results show that the Columbia River plume acts as a semi-permeable barrier to southward, along-shelf transport, and thus is at least partly responsible for the high productivity of the Washington shelf.

USE OF MODIS IMAGERY TO DETECT LANDSCAPE-SCALE CHANGES IN VEGETATIVE AND HYDROLOGIC PROPERTIES OF THE FLORIDA EVERGLADES

The Comprehensive Everglades Restoration Plan (CERP) will impact the Everglades from its northern headwaters in the Kissimmee basin to Florida Bay in the south. The Moderate Resolution Imaging Spectroradiometer (MODIS) offers an inexpensive tool to detect and monitor inter-seasonal changes in vegetation and inundation in the CERP-impacted areas at a 250-1000 m spatial resolution. A monthly dataset extending from 2000 to 2007 was analyzed to establish a pre-CERP baseline for detectable changes in the Everglades system. The temporal progression of parameters such as the Normalized Difference Vegetation Index (NDVI) and Land Surface Water index (LSWI) was examined in the Everglades National Park as well as adjacent water conservation areas. The seasonal pattern of satellite-derived areal water cover generally agreed with groundtruth water level data. The total freshwater volume was also estimated to assess the potential impact of discharge on coastal salinity distributions, and consequently ecological communities. These results provide a baseline against which the detection of future changes, both natural and CERP-related, may be evaluated.

NUMERICAL SIMULATION OF HURRICANE INTERACTION IN COASTAL OCEANS USING A HIGH RESOLUTION WRF/ROMS COUPLED MODEL

With the increase of population and economic development, hurricanes are becoming a more severe threat to the lives and properties in US coastal regions. It is critically important to have accurate and timely forecasts of hurricane-caused storm surge and inundation, so that evacuation decisions can be made accurately. The accuracy of storm surge and inundation forecasts depends on the quality of atmospheric wind forcing, which in turn, is affected by the ocean’s response to the storms. An interactively coupled model is developed, by coupling the Weather Research and Forecast (WRF) and Regional Ocean Modeling System (ROMS) models within the Earth Science Modeling Framework (ESMF). The effects of the hurricane and coastal ocean interaction in both the atmosphere and ocean are investigated. Results show that by incorporating the Sea Surface Temperature (SST) change into hurricane model, the hurricane intensity simulation is significantly improved. The improved hurricane intensity led to a more realistic storm surge and inundation simulation.

CIRCULATION DYNAMICS IN THE COLUMBIA RIVER ESTUARY: AN OBSERVATORY-ENABLED PERSPECTIVE

Long-term simulation (~8 years) and observational (~11 years) databases have been generated as a part the CORIE end-to-end observatory for the Columbia River estuary and plume. This exceptionally comprehensive dataset provides unique insights into perhaps one of the most complex river-to-ocean systems in the USA. Here, we will attempt to summarize key aspects of the circulation dynamics of the estuary, with an emphasis on salinity intrusion and stratification, as they respond to climate variability, climate change, and hydropower regulation.

SURFACE SIGNATURES GENERATED BY ONE- AND TWO-DIMENSIONAL SINUSOIDAL BATHYMETRY

The objective of this numerical study is to examine the impact of well-defined bedforms on free-surface signatures that may be observed in estuaries and nearshore environments. Rather than examine the surface pattern generation mechanisms or the interior flow patterns, we focus on surface observable coherent flow structures. Simulations are performed in a horizontally-periodic domain with idealized sinusoidal bathymetry and a rigid lid. The fluid is homogeneous, incompressible, and forced by a constant horizontal pressure gradient. Analysis of water surface results will be presented, and may include instantaneous streamlines, vorticity patterns, horizontal convergence, and perturbation velocity vectors (instantaneous minus time-average). These simulations will be used to develop techniques to infer bedform morphology based on the behavior of the free-surface signatures. This work was supported by ONR Award N00014-05-1-0485.
LESSONS FROM THE FIELD: BUILDING AND SUSTAINING PARTNERSHIPS AMONG ORGANIZATIONS WITH DIVERSE BACKGROUNDS

Building networks and partnerships among individuals and communities from different backgrounds and cultures work place, socio-economic and societal have many common aspects that are relevant to network and partnership building for ocean education. Some of these such as shared objectives and a common vision are key to the success of any partnership. In addition, the process used to create these common objectives and vision is an important element of a successful partnership. Building education and educational partnerships among international parties and within the National Estuarine Research Reserve System’s Coastal Training Program will be used as case studies to highlight attributes of successful partnerships. Identifying and understanding the challenges to build successful partnerships are often more important than understanding the elements that enable a partnership to be successful. These challenges provide valuable insights that aid in extension of existing partnerships and in expanding partnerships to include new members.

IRON CYCLING IN MARINE SYSTEMS: THE ROLE OF PARTICLE-ASSOCIATED BACTERIA

Iron is a limiting micronutrient for phytoplankton growth in large areas of the world’s oceans, but little is known about mechanisms of iron recycling in the oceanic water column. Microbes, especially particle-associated bacteria, are likely to mediate these processes since particles are sites of enhanced microbial activity and nutrient remineralization. We have employed Microscilla marina (phylum Bacteroidetes; family Flexibacteriaceae) as a model organism to examine iron cycling by particle-associated marine bacteria. Searches of the M. marina genome revealed analogs to known iron chelate transport proteins, including siderophore and heme transporters. A putative siderophore biosynthesis gene cluster was also identified. RT-Q-PCR analysis of heme transport and siderophore biosynthesis genes confirmed that they were expressed and upregulated under iron stress. We have also identified putative heme and siderophore transport components in the available genomes of diverse particle-associated marine bacteria, but found them to be notably lacking in the genomes of known free-living organisms (e.g. Pelagibacter ubique, marine cyanobacteria). These findings are consistent with the suggested importance of particle-associated bacteria in the recycling and chemical transformation of iron in marine systems.

GEOHYDRODYNAMIC MODELING OF ESTUARINE CIRCULATION IN HUDSON STRAIT: 8,000 YR BP AND PRESENT

As the last ice age ended and its ice dam collapsed, Glacial Lake Agassiz drained to the North Atlantic via Hudson Strait. The freshwater pulse generated by the Agassiz outburst is hypothesized to have perturbed the thermohaline circulation, leading to regional cooling 8,200 yr BP. Questions persist however, because sediment core data do not delimit the outburst’s duration or discharge, and the paleo-record is ambiguous. On the other hand, paleo-lakeshore maps constrain the maximum outflow volume, and glacioclynnematic models provide a suite of outburst discharge scenarios. In order to discriminate among the outburst scenarios, we used a geohydrodynamic model to simulate estuarine circulation in Hudson Strait under a range of discharge and bathymetry conditions. This model adequately reproduces modern Hudson Strait salinity distributions using inputs of recent river discharge data and appropriate seaward boundary conditions. Sediment distributions predicted by the geohydrodynamic model are compatible with plume layer thicknesses (15-180 cm) in Hudson Strait cores. However, the short-duration, high-discharge outburst scenarios produce very high water surface elevations (50+ m) in the strait, for which no geomorphological evidence has been reported.

RUMORS OF PROGRESS IN THE USE OF OPERATIONAL ECOLOGICAL FORECASTING FOR LIVING OCEAN RESOURCE MANAGEMENT

Ideally, society’s need for timely and accurate forecasting of the living resources of the ocean will converge with the analytical power provided by the recent advances in ocean observing, modeling and assimilation made possible by advances in computing power, remote sensing and data manipulation theory. Since the early 1970s the raison d’etre of ocean ecosystem modeling has been useful forecasts of ocean living resources to improve management, optimize investment, and achieve sustainability. Progress towards timely and accurate ocean ecosystem forecasting has been surprisingly slow. We believe that initially this slow progress was not due to inadequate ecosystem theory, but due to the crude time/space resolution, initialization and ecosystem representation that followed from the primitive state of both computing (that limited both resolution and ecosystem complexity) and of observing systems (that limited both). Initialization and model complexity suggests that two issues, i.e., forcing and response resolution and ecosystem or food web complexity, are no longer limiting operational ecological forecasting. But removal of these limits may enable models to recognize other potentially problematic issues in operational ocean ecosystem forecasting.

TIME-SERIES STUDY OF THE AIR-SEA CO2 FLUX IN FRONTAL REGIONS OF THE SOUTHERN OCEAN FROM IN SITU DATA

A time-series of CO2 fugacity, CO2 has been obtained from twelve CARIOCA drifters deployed in the Southern Ocean between 2001 and 2007, and which record more than 70 months of measurements. Hydrological fronts detected from altimetry data between 1993 and 2005 allow us to situate the buoy in relation to the polar, subantarctic and subtropical fronts (PE, SAF and STF). In most regions, CO2 is undersaturated with respect to the atmospheric value. The air-sea CO2 fluxes along the trajectories are primarily driven by ICGO spatial variability with the largest sinks occurring close to the STF. When extrapolo low, over the whole regions, the yearly fluxes computed from the CARIOCA drifters amount to ~0.8 PgC/yr in the Subantarctic Zone, SAL, and to ~0.1 PgC/yr in the Polar Zone with very small seasonal variates. Additional data are used in order to refine air-sea CO2 flux estimates in the SAZ and increase data coverage, particularly in the eastern Pacific Ocean. The observed variability is analyzed in relation with the mixed layer depth detected from ARGO profiles.

GEOCHEMISTRY OF TRACE METALS IN SEDIMENT CORES FROM THE BASQUE CONTINENTAL SHELF

Metal pollution history in densely populated coastal areas is usually studied using sediments. However, it is related to the large and rapid sediment fluxes of fine-grained fraction of sediments through adsorption processes. The fate of trace metals can be also greatly influenced by redox cycles driven by the degradation of reactive organic matter. This study is based on bed and down-core sediments taken from the Basque continental shelf. Trace metals were determined in the solid phase on spatial and temporal scales to identify metal pollution history and the main geochemical processes affecting the distribution of metals. The age of the sediment sections was assessed by using 210Pb in excess and 14C AMS dates. Grain-size effect was corrected by normalizing all elements to Li. Results indicated higher trace metals levels, mainly for Cu, Zn, Cd and Pb, in recent sediments deposited during the industrialized period compared to the geochemical background of the region. These excess in metals are furthermore strongly related to Mn suggesting that redox reactions at the oxic/suboxic zones are driving the observed profiles.

Baringer, M. O., NOAA - AOML, Miami, USA, molly.baringer@noaa.gov

HEAT AND TEMPERATURE CHANGES FROM HIGH DENSITY XBT LINES IN THE NORTH ATLANTIC

High-density XBT sections along tracklines from the Gibraltar Straits to the Straits of Florida (AX7) since 1995 with average spatial sampling of 30-40 km can be used to infer the recent temperature changes in the upper ocean and associated heat transport changes. A mean heat transport of 0.98 PW was observed in this time period with a small trend towards decreasing heat transport through time, barely distinguishable amidst the large interannual and shorter time-scale variability. No annual cycle is evident. The heat transport does not appear to be correlated with climate signals such as the North Atlantic Oscillation, however the heat transport bears some similarity to the integrated surface heat transport. The drifters amount to -0.8 PgC/yr in the Subantarctic Zone, SAZ, and to -0.1 PgC/yr in the Polar Zone with very small seasonal variates. Additional data are used in order to refine air-sea CO2 flux estimates in the SAZ and increase data coverage, particularly in the eastern Pacific Ocean. The observed variability is analyzed in relation with the mixed layer depth detected from ARGO profiles.
GLOBAL EVALUATION OF SINGLE SOURCE AND MULTI-SENSOR SST ANALYSES

Global gridded estimates of sea surface temperature (SST) are produced using satellite observations from infrared and microwave sensors in both single-sensor and multi-sensor products. Blended analyses attempt to emphasize advantages and mitigate the limitations of individual sensors. Product accuracy is evaluated relative to in situ observations, while individual snapshots are compared to identify differing qualitative characteristics. Root mean squared differences from the in situ observations are generally below 0.7 with differences in mean bias and regional trends. Global patterns of SST time correlation scales are similar over most of the globe for the different products. Differences are evident in persistently overcast regions such as the Pacific warm pool where the advantages of cloud-penetrating microwave sensors are maximized. The various SST products are incorporated in operational ocean models to assess the impact of differing performance or other characteristics.

AN ADAPTIVE MULTI-GRAIN SEDIMENT TRANSPORT MODEL

This presentation discusses the capabilities of an adaptive, mixed, multi-grain sediment transport model developed for the Adaptive Hydraulics Modeling system (AdHi) for two-dimensional shallow water problems. This sediment transport module takes advantage of the mesh adaptation capability in AdHi allowing it to automatically and dynamically split elements to produce a more accurate representation of sediment transport. This modeling system consists of two coupled modules designed for the analysis of two-dimensional, depth-averaged flow, and sediment transport, in both riverine and estuarine surface waters. The coupled models are a finite element hydrodynamic module (AdHi) and a finite element sediment transport module. The sediment transport module is capable of handling multiple single grain sizes and mixtures of both cohesiveless and cohesive sediment. It simulates the processes of bedload, dispersion, erosion, settling, deposition, armoring, and consolidation. It solves the two-dimensional, depth-averaged advection-dispersion equation with source and sink terms by the finite element method. It also includes a three-dimensional multi-grain sediment bed model capable of handling different material types and incorporating 3DFlume data. The output from the module consists of nodal values of the bed elevation, the bed composition, the bed properties, and the depth-averaged suspended sediment concentration.

SUMMERTIME HYPOXIA OFF CENTRAL OREGON AS OBSERVED USING AUTONOMOUS UNDERWATER GLIDERS

Beginning in April 2006, we have used an autonomous underwater vehicle glider to sample a cross-shelf transect along the Newport Hydrographic Line off central Oregon (64 39.1N). The section runs from the 20-m isobath out about 90 km, and takes 3-7 days to complete. The glider undulates from the surface to 2-3 m above the bottom (200 m maximum) with an along-track resolution ranging from 100 m in shallow water to 400 m in deep water. Position and oceanographic data are relayed to shore every 6 hours via Iridium cell phone. The glider is equipped with a conductivity-temperature-depth instrument and seafloor fluorometers (chlorophyll fluorescence, dissolved oxygen, light backscatter for a measure of particles, dissolved oxygen). The glider observations are supplemented, calibrated and extended using measurements from an 80-m mid-shelf mooring, 10 miles offshore of Newport, and ship-based data. The near-real-time glider observations are used to track and understand the evolution of the extreme hypoxic event off central Oregon during summer 2006. The time-varying, subsurface dissolved oxygen fields are related to wind-forced upwelling and downwelling.

PHYSICAL IMPACT ON THE SIZE-SPECIFIC DISTRIBUTION OF ZOOPLANKTON ACROSS AND ALONG THE POLAR FRONT

The Polar Front forms the border of warm Atlantic Water penetrating into the Arctic Ocean. As such, it can give valuable insight into processes that will become important during a future warming of the Arctic. Along and across the Polar Front in the northern Barents Sea, we collected simultaneous high-resolution (spatial and temporal) data on hydrographic parameters using high-resolution trawl tows and ship-based data. The near real-time glider observations are used to track and understand the evolution of the extreme hypoxic event off central Oregon during summer 2006. The time-varying, subsurface dissolved oxygen fields are related to wind-forced upwelling and downwelling.

The Atlantic meridional overturning circulation (AMOC) in several modern day global climate simulations contains a prominent 20–25 year oscillation. We find the timescale for an AMOC-like oscillation in a last glacial maximum (LGM) simulation of the CCSM3 is approximately half that found in the modern day simulation. Previous studies suggest that the oscillation timescale is set by the ocean while the forcing is atmospheric, with an association to North Atlantic Oscillation (NAO). The NAO in the CCSM3 modern simulation also contains an approximate 20-year oscillation. Previous research shows that the NAO forces a delayed flux of subpolar gyre water into the Nordic Seas, where deep water forms, due to subpolar gyre (SPG) adjustments. We suggest that the resulting SST and sea ice anomalies in the Nordic Seas provide a feedback to the atmosphere, which, being delayed from the initial NAO forcing, may set the longer timescale for the NAO. Preliminary results indicate a strong correlation between the NAO and the baroclinic streamfunction in the SPG as well as an SST pattern consistent with the SPG adjustment. Differences in feedbacks in the LGM climate give rise to key differences in the AMOC-like mechanism in the LGM simulation. Using linear inverse modeling, we are able to decipher which variables are important to the longer timescale fluctuations, the optimal patterns for growth, and the differences in predictability of the NAO and AMOC within the LGM and modern scenarios.

TRANSFORMATIONS OF ORGANIC MATTER IN A MAJOR U.S. EAST COAST ESTUARY: IMPLICATIONS FOR IDENTIFYING DOM AND POM SOURCE AND AGE SIGNATURES IN OCEAN MARGINS

Estuaries are dynamic regions of both allochthonous and autochthonous organic matter (OM) input and degradation and may have profound effects on the character and amounts of OM exported to ocean margins. To assess these impacts, we undertook detailed isotopic (natural abundance 14C and 13C) transects and experimental incubation studies of DOM and POM throughout Delaware Bay estuary in 2004–2006 from river to continental shelf and slope. DOM end-members consisted of modern river/terrestrial and aged marine sources and showed a strong mesohaline estuarine input, while POM end-members and distributions were essentially the opposite of those for DOM. In spring, dissolved inorganic carbon (DIC) exhibited near-conservative distributions and isotopic distributions throughout the estuary, suggesting that much of the DOM and POM was non-reactive over the timescales of estuarine residence time. However, excess DIC in full suggested that greater amounts of variably aged DOM and/or POM were respired in the system at that time. Experimental DOM and POM degradation studies further highlight the significant roles of photochemical and microbial modification on the amounts and isotopic character of this material prior to shelf/slope export.

20TH CENTURY DEPOSITION IN THE TAPPAN ZEE SECTION OF THE HUDSON RIVER ESTUARY: COMBINING GEOPHYSICAL AND GEOCHEMICAL TECHNIQUES

The details of sediment deposition in estuaries are still not completely understood. Mapping the location of 20th century deposition in the Hudson River Estuary will contribute to understanding the complex estuarine processes. In addition, adequate mapping of 20th century deposition will reveal the likely locations of contaminants, including heavy metals and polychlorinated biphenyls (PCBs), which entered the river and bound to fine sediment in the early to mid 20th century. This comprehensive study of the Tappan Zee section of the Hudson River Estuary uses a combination of acoustic sub-bottom profiling and X-ray fluorescence spectrometry to find and quantify areas of 20th century deposition. Using sediment cores to time the deposition of acoustically identifiable layers allows this study to have high resolution. The data collected in the Tappan Zee will be compared to the Haverstraw Bay section of the Hudson, where there is a large amount of deposition, in order to further understand the processes of sediment movement in the Hudson River Estuary.

SPRINGTIME FORAGING ECOLOGY OF NORTH ATLANTIC RIGHT WHALES

The North Atlantic right whale is a zooplanktivorous whale that feeds on the calanoid copepod Calanus finmarchicus in the northwestern Atlantic Ocean. The foraging ecology of this species has been studied extensively in summertime habitats where it feeds on deep layers of diapling C. finmarchicus. We conducted a study of right whale foraging ecol-
ogy in a springtime habitat where right whales feed primarily on active non-diapausing (often vertically migrating) populations of C. finmarchicus that aggregate at the surface near the sea floor, and at the gyccline. These conditions are different from the right whale summertime habitats, and consequently, right whales employ different foraging strategies. We attached tags consisting of time-depth recorders and pitch and roll sensors to right whales, tracked their movements, and sampled both oceanographic conditions and prey distribution in proximity to the tagged whales using a CTD, optical plankton counter, and a video plankton recorder. The results of our study demonstrate the importance of predation behavior and prey life history in the development of oceanic hotspots.

A GENETIC APPROACH TO DETECT ENSO-RELATED CHANGES IN CONNECTIVITY BETWEEN EASTERN AND CENTRAL PACIFIC CORAL POPULATIONS

Coral populations in the eastern Pacific Ocean are isolated from other corals by 5000-8000 km of unhabitable deep water (the Eastern Pacific Barrier, EPB). Recent increases in intensity of El-Nino-Southern Oscillation (ENSO) events may have altered patterns of inter-population dispersal over the last few generations. Such ENSO events have the potential to transport propagules traveling from luxuriant central Pacific coral reefs to the depauperate eastern Pacific. A combination of genetic techniques is employed to determine 1) when populations of corals in the eastern Pacific diverged from those in the central Pacific, 2) how present-day coral populations are linked by dispersal, and 3) whether recent changes in currents caused by ENSO events have altered patterns of exchange. The work focuses on Porites lobata. Samples from localities spanning the EPB are analyzed for microsatellite loci and nuclear markers. These genetic analyses describe how migration presently connects central and eastern Pacific corals and whether and how changes in ENSO events have altered these patterns.

THE EFFECT OF LIGHT ON HYPOXIC BOTTOM WATER OXYGEN CONCENTRATIONS IN THE NORTHERN GULF OF MEXICO

We predict that when low levels of photosynthetically active radiation (PAR) reach the seafloor on the seasonally hypoxic northern Gulf of Mexico continental shelf benthic photosynthesis may be greatly reduced or prevented below bottom water oxygen concentrations. To test this we exposed incubated light and dark sediment cores from two stations (15 and 20 m water depth) that are frequently hypoxic (including summer 2007) for 48 hours. Bottom water oxygen concentrations decreased from 5.40 mg/L in June to 0.4 mg/L in September prior to our incubations. We treated the cores with in-situ PAR conditions for the first 24 hours. We found the cores to be highly heterogeneous with small sediment oxygen consumption rates decreasing throughout the summer (June to September). The cores were exposed to ~50% more PAR than in-situ conditions for the second 24 hours. We found little change in the oxygen concentrations over time. The second day however, started at low oxygen concentrations (~ 0.5 mg/L), from which an effect of the increased PAR may not be detectable. These incubations will be repeated with variable PAR treatments in subsequent experiments.

THE EXPLORER OF THE SEAS OBSERVATORY: ANNUAL AND INTERANNUAL VARIABILITY OF THE FLORIDA CURRENT

Variability of the velocity structure and transport of the Florida Current at latitude 26 N is presented for a five-year period from May 2001 to May 2006. Data were collected continuously from two ADCPs mounted on the Royal Caribbean Cruise Ship Explorer. We attached tags consisting of time-depth recorders and pitch and roll sensors to right whales, tracked their movements, and sampled both oceanographic conditions and prey distribution in proximity to the tagged whales using a CTD, optical plankton counter, and a video plankton recorder. The results of our study demonstrate the importance of predation behavior and prey life history in the development of oceanic hotspots.

NUTRIENT SUPPLY AFFECTS THE COMMUNITY STRUCTURE AND SPATIAL DISTRIBUTION OF SMALL PHYTOPLANKTON AND BACTERIOPLANKTON IN THE COASTAL SUBARCTIC PACIFIC OCEAN

Flow cytometry was used to characterize the small phytoplankton and bacterioplankton community in the coastal waters of British Columbia, Canada, and Washington State, U.S.A. in the fall of 2004 and 2005 as part of the ECOCAB PNW project. Populations were classified by size, chlorophyll and phycocyanin fluorescence, and nucleic acid content (for the heterotrophic prokaryotes). The abundance and growth rate of the picocyanobacterium, nanoplankton, cyanobacterial, and heterotrophic prokaryotic groups varied significantly in space and time. The structure of the community was associated with the major oceanographic features of the area, particularly the Juan de Fuca eddy. Furthermore, the phytoplankton community groups had differential growth responses to macronutrients (NPSi), iron, and copper amendments in short-term growth experiments. All growth of all phytoplankton groups were enhanced by the addition of macronutrients, while the iron and copper amendments enhanced the growth of the larger nanoplankton cells. The connections between nutrient supply, growth response, and physical oceanography of the region supports a model where nutrient supply effects the structure of the plankton community in coastal marine ecosystems.

FACTORS CONTROLLING TIDAL FLAT MORPHODYNAMICS IN SOUTH SAN FRANCISCO BAY

Since the 1850s, saltmarshes and mudflats of San Francisco Bay (SSFB) have decreased in area 80% and 40%, due to both natural and human-induced factors. Mudflat morphologic change is examined, using bathymetric data collected by the USGS (NOS) and USGS. The mudflats of SSFB are grouped by geographically similar regions and multiple cross-sections are drawn across the extent of the mudflats at close ~50m intervals, allowing for a determination of mean mudflat bathymetric profile at each segment during five time periods - 1899, 1931, 1956, 1983, 2005. Eigenfunction analysis is used to separate profile shapes into the dominant components of morphologic variability, which are compared to theoretical models for profile shape as a function of waves, tide and sediment supply. Theory predicts that wave-dominated or sediment-starved flats tend to have concave-upward bathymetric profiles; tide-dominated or accretionary flats tend to have convex-upward bathymetric profiles. SSFB mudflats morphology is classified spatially and temporally and compared to trends in winds, waves, deposition/erosion, flat width, and tidal range in order to determine which forcings factor heaviest in controlling shape.

OCÉANIC TIME-SERIES OF DISSOLVED ORGANIC CARBON (DOC) CONCENTRATIONS AND δ14C VALUES

A time-series of marine dissolved organic carbon (DOC) concentrations and δ14C values in the NE Pacific (Station M, 34°4'52" N, 123°08'30" W) has been extended with new measurements of archived samples from April 1998 to October 2004. The magnitudes and variability of major δ14C signals throughout the time-series imply transport of DOC from the surface ocean to depths of at least 450 m on the timescale of months. Keeling-plots of all measurements predict a continuum of possible background DOC compositions containing at least 21 μmol of 14C - DOC, but are more consistent with the composition of mean deep DOC (38 μmol 14C - DOC). A pre-bomb DOC δ14C depth profile and longer-term time-series (1985-present) has been calculated based on these regression models, a strong relationship between δ14C values of DOC and DIC at all depths, and coral records of surface DIC δ14C. The model results indicate that bomb-14C has penetrated the DOC pool to depths of 450 m at Station M, though the signal at that depth may be obscured by short-term variability.

BIOGEOCHEMICAL CYCLING OF CARBON AND NITROGEN BY THE CORAL DIPLORIA STRIGOSA IN BERMUDA

We have used a new approach to quantify the net carbon utilization by Diploria strigosa; measurement of drawdown of dissolved inorganic carbon (DIC). Using the DIC drawdown as the total carbon use, we have also measured dissolved organic carbon and nitrogen loss from the coral and have tagged the DIC and dissolved inorganic nitrogen pools with 13C and 15N to evaluate incorporation into zooxanthellae and coral tissue. The central focus of this research is that the coral-zooxanthellae symbiotic association is a source of large amounts of dissolved organic matter as a direct short-term byproduct of photosynthesis. Our efforts attempt to investigate simultaneously both the biogeochemical details of this process at the organism level and in relation to trophic transfer to the reef ecosystem.
To investigate the importance of sea primary production to the nutrition of L. pertusa and associated communities and examine local trophic interactions, we analyzed stable carbon, nitrogen, and sulfur isotope ratios in 7 L. pertusa community collections. A significant seaweed signature was only detected in one of the 35 species tested Provonna sculptula, a gastropod despite the presence of sea fauna at all sample sites. A potential predator of L. pertusa was identified (Coralliphila sp.), and a variety of other trophic interactions among the fauna occupying the coral framework were suggested by the data. Stable carbon ratios were also determined for different sections of the skeleton representing different stages in the growth and life of the aggregation. There was no temporal trend detected in the skeleton isotope values, suggesting that L. pertusa settles in these areas only after seepage has largely subsided. Together our data suggest that it is the presence of carbonate substrate for settlement and growth that drives L. pertusa occurrence at seep sites in the Gulf of Mexico, not local primary production.

SOUTHWEST PROPAGATION OF ARCTIC/SUBARCTIC TEMPERATURE ANOMALIES ALONG NORTH AMERICA’S EASTERN SEABOARD

Satellite sea surface temperature (SST) data from 1986-2007 are used to study thermal anomalies and their propagation along North America’s eastern seaboard. The Shelf-Slope Front appears as a main conduit for these anomalies which originate in the Arctic/Subarctic and propagate southward along the shelf break. These anomalies are traced as far south as Cape Hatteras. Decadal cold anomalies are observed off the U.S. Northeast in 1987-1988, 1996-1997 and 2005. The intervening warm anomalies are less noticeable, except for a distinct warm anomaly in 2000. Thus, the Arctic/Subarctic forcing appears as a dominant factor that causes decadal regime shifts in the Northwest Atlantic Ocean.

DIAPYCNAL MIXING IN A NEXT GENERATION OCEAN MODEL

The accurate representation of ocean tracer transports continues to challenge models. Trying to replicate the quasi 2D flow of the large scale ocean is made difficult by spurious implicit mixing from the advection numerics and spurious explicit mixing from inaccurate parameterization, reducing eddy eddy transports and disrupting the large scale circulation. The Imperial College Ocean Model is one of the next generation of ocean models, employing an unstructured finite element mesh, able to conform more accurately to boundaries than traditional finite difference models. The mesh is adaptive, able to capture important dynamical features and follow their evolution, however this adaptive procedure introduces a third source of spurious mixing through the process of remeshing. Simulations have been run of the evolution of eddies in a 200 km square portion of the North Atlantic. Results show that for this system, the adaptive process contributes a significant amount of mixing itself. For adaptivity to be feasible for climate simulations, it’s effect on tracer fields must be explored for a range of parameters and subsequently reduced.

PROGRESS AND CHALLENGES IN OPERATIONAL OCEAN FORECASTING

Daily dynamical analyses and forecasts of surface waves, sea-ice and the global three-di- mensional temperature and current structure of the ocean have now been available for 10 years. Most operational ocean forecast centres use nesting to provide high-resolution information for specific areas including coastal waters. Spurred on by the Global Ocean Data Assimilation Experiment (GODE) and other initiatives, excellent progress has been made in the development of the forecasting systems, in international coordination, in strengthening the links between operational and research teams and in the modelling of the ocean ecosystem. As GODE draws to a close it is timely to discuss the outstanding opportunities and challenges for operational oceanography. These include scientific and technical opportunities, the need to focus the exploitation and justification of the observing and assimilation systems on the right applications and the challenges involved in co-ordination of the wide-range of expertise operational oceanography requires.

MAPPING THE BATHYMETRY OF THE DEE ESTUARY USING WAVE INVERNSIONS OF MARINE RADAR IMAGE SEQUENCES

The bathymetry of a 4km radius area of the Dee Estuary in Liverpool Bay has been mapped using a wave inversion of marine radar data. The radar is mounted 30m above sea level on an island in the estuary and 10 minute sequences of radar images of the sea surface are recorded automatically each hour giving 360 degree coverage of the area. Several such records taken around high tide during moderate wave events have been processed to produce the map using a wave inversion that accounts for both frequency and amplitude dispersion. The results are compared to those of a LIDAR survey of the intertidal areas carried out in 2006, and also to a combined LIDAR and Multibeam echosounder survey carried out in 2003, clearly identifying migrating sand banks within the estuary.

INTERDEcadal NUTRIENT VARIABILITY THROUGHOUT THE WATER COLUMN IN THE WESTERN NORTH ATLANTIC SUBTROPICAL GYRE

Macronutrient (N,P,SI) concentrations have been a core measurement at the Bermuda Atlantic Time-Series Station (BATS) since the beginning in October 1988. Here we present a synthesis of this 19 year time-series with emphasis on relative changes in nutrient ratios through the water column. In particular, we investigate the temporal variability of the N:P ratios and variations with respect to the canonical Redfield values. A principle characteristic of the vertical nutrient profile is the shift from excess N in the surface and subtropical mode water to Redfield ratios at 800m (coincident with the deep oxygen minimum and maximum in remineralization) and then to excess P in the deeper depths (e.g., mean N:P ratio in the mode water is ~23.8 while for North Atlantic Deep Water is ~15). We also look at nutrient concentrations. For the deeper waters (>1000m), multi-year to decadal trends are evident in the individual nutrients which are not necessarily coherent with other nutrient species or density changes. In contrast, the shallower depths (160-800m) exhibit substantial monthly variability which appears conservative and predominately consistent with mesoscale eddy dynamics.

THE IMPORTANCE OF ATMOSPHERIC NITROGEN IN THE Oligotrophic ATLANTIC

Measurements of major ion concentrations in atmospheric aerosol and rain in the marine boundary layer have been made on a total of 10 recent research cruises that transect the North and South Atlantic oligotrophic gyres (latitudinal and longitudinal crossings). From these, we have begun to construct a climatology of dry and wet deposition to the oligotrophic Atlantic gyres (particularly nitrate and ammonium). In addition, air-sea gas exchange measurements were made on some Atlantic Meridional Transit (AMT) cruises (http://web.pml.ac.uk/amt/), suggesting that warm, low latitude waters may be a source of ammonia to the remote marine atmosphere (Johnson, M., Bell, T.G. et al., GBC, In Press.).

In the context of other nitrogen fluxes to/from the oligotrophic gyres, our results suggest that ocean-atmosphere exchange of nitrogen is significant for these waters. Finally, we will discuss a new project (SOLAS Project Integration; http://www.bodc.ac.uk/solas_integration/), which aims to develop global flux climatologies of SOLAS-relevant compounds and particles. In the context of this presentation, the focus will be on producing atmospheric aerosol and rain deposition fields for the global ocean.

IMPROVING AUV-BASED COASTAL OBSERVING SYSTEMS

A series of large field programs in Monterey Bay, using fleets of Autonomous Underwater Vehicles (AUVs), have generated a body of experience in the synoptic observation of oceanographic processes. Here we draw on performance analysis of the AUSN II field program, which was carried out in 2003, to draw lessons regarding the use and configuration of distributed arrays of mobile platforms. In previous papers and presentations, the statistics of variability of Monterey Bay has been determined from the intensive observations resulting from sustained observations by an average of 11 platforms over a month of active upwelling. Here we draw on those results, and advances in AUV and sensor technology, to explore observation system design. Observation performance can be improved, and operational overhead reduced, by optimizing the AUV and modifying the survey strategy. In particular, we show that improved survey performance, as measured by root mean square error of the reconstructed ocean field, can be obtained with fewer platforms. This is achieved by carefully selecting vehicle speed, and focusing observations in regions which contribute most greatly to reconstruction error.

HISTORIC ALTERATIONS AND CURRENT RESTORATION FOR BISCAYNE BAY

Biscayne Bay has experienced extreme adverse conditions since the city of Miami was established in the late 1800’s. With the opening of government cut in Miami Beach, the Bay experienced an important increase in salinity in the north. Until the late 1950s raw sewage was discharged directly into Biscayne Bay causing effects to fish and other organisms. The U.S. Army Corps of Engineers construction of the Central and Southern Florida Project over-dranked the Everglades. Salinity control structures were added to hold water higher in the Everglades and to prevent saltwater intrusion from adversely affecting freshwater wells, drinking water well fields, and coastal farming. The Comprehensive Everglades Restoration Plan proposes to significantly alter freshwater flow to Biscayne Bay. Currently three of the most significant impacts to the bay are 1) alteration of the watershed hydrology; 2) degradation of water and sediment quality, and 3) loss of freshwater flow.
The Quantitative Filter Technique (QFT) for measuring the spectral absorption of particles is now a routine method in aquatic research. Typically, particles are concentrated on glass filters in the field by filtration, stored frozen, and returned to a laboratory for absorption measurements using a bench top spectrophotometer. While this approach is reasonably simple, errors may be introduced during transport and storage. We describe a new portable fiber optic system to acquire particle absorption measurements at sea. The system (QFT), consists of an especially designed 25 mm Glass Fiber Filter holder coupled via fiber optic cables to a light source (215-1800 nm or 380-1800 nm) and photo diode array based spectrometer (200-730nm, 5nm FWHM). We demonstrate the performance of the QFT1 by comparing particle absorption measurements taken on the QFT1 and several dual beam spectrophotometers using a diverse range of water sample types.

SEASONAL VARIATION OF THE SUBPOLAR FRONT IN THE JAPANESE/EASt SEA DURING 2002-2007
Remote sensing data is used to analyze the seasonal variability in strength and location of the subpolar front in the Japan / East Sea. Monthly averaged seas of surface temperature data for July 2002 through August 2007 reveal warmest surface temperatures in August and coolest temperatures in February and March. Strengthening of the zonally-oriented front near 40N during November and December is consistent with the onset of cold air outbreaks from the northwest, and the front persists through March. This study is facilitated by the MODIS-Aqua monthly global 9 km sea surface temperature data produced by NASA's Ocean Biology Processing Group and made available through the Goddard Earth Sciences Data and Information Services Center (GES-DISC) Interactive Online Visualization and Analysis Infrastructure (GIOVANI).

UNDERSTANDING THE CONNECTION BETWEEN DIFFERING NITROGEN SOURCES AND THE UREA CYCLE IN THE DIATOM, THALASSOSSIRA PSEUDONANA
The urea cycle is used in heterotrophic organisms, and provides a way for cells to detoxify ammonium. Recently, a complete urea cycle was identified in the photosynthetic marine diatom Thalassiosira pseudonana, and although it is hypothesized that this cycle contributes to several vital cellular pathways to one another within the diatom, the specific function of this pathway has yet to be elucidated. Here, we examined the physiological and molecular responses of T. pseudonana to growth on ammonium (NH4+), nitrate (NO3-), and urea as sole nitrogen sources to determine whether varying N sources affect the urea cycle. Specifically, we monitored the growth rates under each condition, as well as quantified the differential gene expression of seven key genes associated with U-takes and the urea cycle. Similar growth rates were found for NH4+ and NO3; however, growth on urea was reduced. We are currently examining the differences in urea cycle gene expression in cells grown on urea versus NH4+ and NO3. Our results will help to clarify the role of the urea cycle in T. pseudonana, and its relationship to different metabolic pathways within diatoms.

DIEL FEEDING CHRONOLOGY, GASTRIC EVACUATION AND DAILY FOOD CONSUMPTION OF JUVENILE CHINOOK SALMON IN COASTAL WATERS
The dief feeding periodicity of juvenile Chinook salmon (Oncorhyncus tschawytscha) was determined from stomach collections in coastal waters off Oregon in 2003. Juvenile Chinook salmon exhibited two crepuscular feeding periods, around dawn and dusk, with the highest percent body weights of stomach contents at dusk between 19:00 and 23:00 hours. Gastric evacuation rates of euphausiid meals were estimated from laboratory experiments at 9.3, 10.7, and 11.9 C. Based on an exponential model, the instantaneous evacuation rates at these three temperatures were 0.0407, 0.0589, and 0.0807 h⁻¹, respectively. The Elliott and Persson model was used to estimate a daily ration for juvenile Chinook salmon in Oregon coastal waters of 2.57% BW d⁻¹ from previous diei studies in 2000 and 2.46% BW d⁻¹ in 2003. The Eggers model provided similar daily ration estimates (2.04% and 2.93%, respectively). The MAXIMS model, which does not rely on laboratory-derived evacuation rates, produced higher estimates of daily ration (3.84% and 4.28% BW d⁻¹). Our dief feeding chronology, gastric evacuation rate, and daily ration estimates for juvenile Chinook salmon were comparable to those found for other juvenile salmonid species.

OBSERVATIONS OF TIDAL AND RESIDUAL CIRCULATION IN LONG ISLAND SOUND
To quantify the transport of materials in estuaries it is critical to establish the horizontal and vertical variation of the energetic tidal constituents. The LISICOS (Long Island Sound Integrated Coastal Observation System) program seeks to understand the variability of dissolved oxygen in western Long Island Sound. In order to accomplish this, the program has maintained an array of five current profilers in the area for three years, complemented by ship surveys. Using these data we present a summary of the spatial structure of the tidal constituents, their relative strengths, and seasonal variations. The overlaps are diagnostically of the nonlinearity in the estuarine dynamics and the long term records allow the detection of the structure of these constituents. We use the tidal current estimates to de-tide ship surveys in order to reveal the structure of the residual circulation and its low frequency variability.

The role of predation by fish in the formation and persistence of thin layers was assessed by Ueyama and Monger (2005) and are verified using SeaWiFS data. Model results show that yearly export is not well understood. Using a general ocean circulation model coupled to a medium-complexity ecosystem, the relationships between bloom strength, longevity, timing of export, and nutrient consumption are investigated in the North Atlantic between 1982 and 2006. Model bloom dates are identified using a technique developed by Ueyama and Monger (2005) and are verified using SeaWiFS data. Model results show a strong correlation between bloom period biomass and annual export for much of the ocean. The results show that bloom timing and peak values are indicative of annual export only in distinct regions, suggesting satellite observations may be able to capture export variability for specific parts of the ocean.

Eddy correlation measurements of benthic oxygen exchange: An update on the technique and results from new deployments

With the eddy correlation technique, in situ oxygen exchange rates across the sediment-water interface are derived from measurements in the bottom water of the fluctuating vertical velocity and the fluctuating oxygen concentration. After an update on our latest development of the technique and its availability to users, we present results from our new deployments in dynamic systems where measuring oxygen exchange with other methods is challenging. These include shallow seagrass-vegetated sediments, permeable sandy sediments in the surf zone, estuarine sediments with dense microalgal populations, permeable shelf sediments, and freshwater sediments inhabited with quagga mussels. In addition to quantifying the oxygen fluxes through time for these sites, we relate the exchange to dynamic variables such as light, current velocity, and wave action.

HIGH FREQUENCY VARIABILITY IN DISSOLVED ORGANIC MATTER COMPOSITION AND ACTIVITY AS DETERMINED USING IN SITU OPTICAL MEASUREMENTS

Most of our understanding of sources and controls over dissolved organic (DOM) concentration and composition is focused on variability over seasonal or interannual timescales. Spectral properties of absorbance and fluorescence of colored dissolved organic (cDOM) contain intrinsic information about the chemical composition of the DOM as a whole, as well as extrinsic information about the sources and environmental processes. These properties can be measured rapidly in situ, and thus provide new and unique information about high frequency variability - on the order of minutes to hours - in the concentration, composition, and source of DOM. We use continuous in situ measurements of cDOM spectral absorbance and fluorescence to examine changes in DOM at unprecedented time scales. We observe changes that result from diurnal processes in river systems, tidal processes in wetland systems, and hydrologic processes in watersheds. We will present results from these studies in which we observe rapid changes in inferred intrinsic properties such as humic content and reactivity, as well as rapidly changing extrinsic properties such as source and association with metals. These observations provide new insights into biogeochemical processes.
The extended draft platform: The OOI Global-scale node for the mid-Atlantic site

The network design for the OOI Global-scale nodes will initially use two platforms: a discrete buoy moored with an inverse-catenary mooring employing acoustic telemetry to sub-surface instruments and a semi-attached, multi-level, multidisciplinary mooring which will provide substantial power and bandwidth to the seafloor. This paper describes the EDP, which has been designed using industry and NSF support and will be funded and built by industry for the OOI. The EDP is a very capable platform, planned for deployment early in the program at the mid-Atlantic site near the DSDP Hole 996B. Thus, it will generate early time-series results at a test site for power generation, communication and sensor technologies. The EDP comprises three vertical columns between a deck structure and a submerged pontoon. The columns and pontoon are raised when at quayside and during tow ing. When lowered, the structure behaves like a deep draft semi-submersible and motions are comparable to those of a spar buoy. The EDP will have a draft of about 25 m and the deck will be over 10 m above the sea surface. It will weigh 800 t and be able to support payloads of over 50 t. An offshore supply vessel assisted by a small offshore tug can install the EDP while an ROV equipped vessel would install the EO cable and the seafloor instrumentation.

Ocean scientist - rock star

An esteemed marine ecologist swims through a sea of eager fans, hovering close by and patiently queuing for both autographs. A semi-retired mollusk biologist poses for photos as shy students linger and others clamor to say hello. A deep sea explorer discovers an elusive giant from our past, inspiring a Hollywood blockbuster, launching acting careers for a few and creating a fascination of the ocean for many. But, you don't have to swim with whale sharks, wrestle a giant squid or uncover the mighty Titanic to make a huge splash of your own. As an ocean scientist, YOU have an intriguing and captivating story to tell. Don't believe it? Think again. Join Rachel Bergen, from Shedd Aquarium, and discover how you and your colleagues can engage and inform the public, inspire environmental stewardship and prepare young scientists to create a better future for our oceans. You'll hear about general ideas for outreach and information sharing, as well as specific opportunities to work with existing programs in your region or within your area of expertise.

Exploring the mid-Atlantic ridge macro- and megafaunal communities

Despite the wide distribution and extensive area of mid-ocean ridges, relatively few previous investigations have provided comprehensive information on animal communities inhabiting these vast areas of the world ocean. The more technologically advanced ridge studies have either been purely geological or geophysical or focused very strongly on chemosynthetic ecosystems. The MAR-ECO project, an international biodiversity study under the Census of Marine Life programme, investigates the animal communities associated with the mid-Atlantic Ridge between Iceland and the Azores. The study focuses on pelagic and benthic macro- and megafauna associated with photosynthetic systems, and utilise innovative methods and up-to-date technology to map distributions, analyse community structure, study life histories and trophic relationships. Experiences from the 2003-2005 field phase of the project are summarised, with emphasis on scientific and methodological challenges and results of preliminary analyses. The strategies and technologies adopted to achieve comprehensive data on organisms of size ranges from mesozooplankton to whales are described. The project continues with cruises in 2009-2010 and comprehensive synthesis towards 2010. Plans are developing for new efforts in the South Atlantic.

Dissecting the life-dinner principle: Analyzing effects of odor signal separation on blue crab foraging

Chemical cues convey critical information for aquatic animals on the presence of mates, food, shelter. Blue crabs utilize alarm cues from injured conspecifics to detect predators. The Life-Dinner Principle suggests the presence of alarm cues should deter blue crab foraging to increase survivability. However, blue crabs naturally are exposed to complex predator and conspecific alarm cues as they travel through their environment. The underlying dynamical mechanism of the jet formation is illuminated with the linear stability analysis. The mechanism is non-local in space, and it involves interactions between the unstable and weakly stable linear modes.
Ecosystem Impacts of a Cochlodinium Polykrikoides Bloom in a Mid-Atlantic Estuary

The Chesapeake Bay has seen a general increase in the abundance of Cochlodinium sp. over the past two decades. Cochlodinium sp. have been found to be associated with fish kills around the globe. In August 2007, a bloom of Cochlodinium polykrikoides, was reported in the James River, a tributary of the Chesapeake Bay. Cell densities of over 15,000 cells mL−1 were reported along with chlorophyll a levels of up to 367 µg L−1. As the bloom progressed and spread into the Chesapeake Bay and the Atlantic Ocean, beach closures were reported. The bloom persisted for over a month. We sampled this event at numerous sites on 5 dates between August and September 2007. We measured cell abundance, nutrient concentrations, nitrogen and carbon uptake rates, and conducted bioassay toxicity tests. These organisms took up a variety of nitrogen compounds, as had been observed during blooms in previous years. Larval fish experienced 100% mortality within 3.5 hours of exposure to Cochlodinium polykrikoides and 20% of the juvenile oysters exposed to this organism died within 48 hours. No mortality was observed in the control populations.

Mesoscale Vortices as Revealed by Lagrangian Coherent Structures

We use Lagrangian coherent structures (LCSs) to identify and track mesoscale vortices. LCSs are material lines which delineate boundaries of fluid domains with different advection characteristics that do not mix, and thereby provide an objective (i.e., frame independent) vortex identification method. Being of a fundamentally Lagrangian nature, LCSs cannot be resolved directly from synoptic surface observations. Rather, they can be identified by maximizing curves or “ridges” in direct finite-time Lyapunov exponents (DFTLEs). We compute DFTLE fields, and identify LCSs on these fields, based on altitude–derived surface geostrophic currents in two regions of the Atlantic. These regions are the North Brazil and Agulhas retroreflection regions, where application of nonobjective vortex identification methods, such as the Okubo–Weiss criterion, has shown limited success. Identification and monitoring of rings in particular using this methodology will improve estimates of critical oceanic parameters, such as the interbasin exchange of mass, salt, and heat between the Indian and Atlantic basins and between the South and North Atlantic oceans, which are key in the study of the Meridional Overturning Circulation.

Linked Nitrogen Fixation and Sulfate Reduction in a Benthic System Heavily Influenced by Bioturbation

Nitrogen fixation rates are sometimes low in marine sediments, and this lack of activity is at times attributed to high levels of pore-water ammonium, an inhibitor of nitrogen fixation. Bioturbation, however, can lead to the transport of ammonium out of the sediment, forming a zone of ammonium depletion around a burrow. Burrow compartments can also become storage areas for suspended organic matter, leading to an increase in decomposition with an associated increase in sulfate reduction rates (SSR). This study focused on the impact of the ghost shrimp, Callianassa californiensis, on sediment nitrogen fixation and SSR in Catalina Harbor, California. We determined how different levels of bioturbation influence these rates independently and estimated the amount of nitrogen fixation that can be attributed to sulfate reducers. Highest reaction rates were found concurrent with moderate levels of bioturbation. When the sulfate reduction inhibitor sodium molybdate was added to incubation experiments, the majority of nitrogen fixation was also inhibited, suggesting a link between both reactions. Current work is looking to determine those nitrogen-fixing phylootypes present through the amplification of nifH sequences.

Changes in Subtropical North Atlantic Air-Sea Carbon Dioxide Fluxes and Carbon Storage in Eighteen Degree Mode Water Over the Last Two Decades

We examine interannual variability of air-sea carbon dioxide fluxes in the North Atlantic Ocean near Bermuda from 1983 on. On an annual basis, the ocean was a net sink for carbon dioxide, with a mean net annual air-sea carbon dioxide flux rate of −815 +/- 251 and −1295 +/- 294 mol carbon dioxide m2 yr−1, respectively, estimated using different synoptic and data assimilation model windspeed datasets. Wintertime air-to-sea carbon dioxide flux was greater than the summertime sea-to-air carbon dioxide efflux. The year-to-year variability was ~850–1950 mmol carbon dioxide m−2 yr−1, which, if scaled to the subtropical gyre, represented an interannual variability of ~0.2–0.3 Pg C yr−1 for the mid-latitude North Atlantic oceanic carbon dioxide sink. The long-term trend over the 1983–2005 period was a slight increase in the oceanic carbon dioxide sink, associated primarily with a gradual increase in windspeed over the same period. In addition to surface trends, we examine changes in the storage of carbon dioxide in Eighteen Degree Water (EDW), a mode water that ventilates the depths between the seasonal and permanent thermocline in the subtropical gyre.

Shallow Water Hydrodynamics and Sediment Dispersal Offshore of a Small Mountainous River: The Waipaoa River, New Zealand

Small mountainous rivers deliver tremendous amounts of sediment to the coastal ocean, but our understanding of the processes important for dispersal of this material has been hampered by the difficulty in observing sediment transport near river mouths during floods and storms. The Waipaoa River, within a Margins 525 system on the North Island, NZ, is a small mountainous river delivering about 15 million metric tons of sediment per year to Poverty Bay, a small embayment of the Pacific Ocean. Sediment dispersal processes there were observed by instruments measuring current velocity and turbidity within 5km of the river mouth, about 15m water depth, during the winter of 2006. Elevated river discharge and strong offshore winds drove bay wide counterclockwise circulation on the order of 0.3 m/s. Peaks in suspended sediment concentrations coincided with increased river discharge or energetic waves following flooding. Within weeks of flooding sediment concentrations were reduced, indicating either consolidation or winnowing of the fine sediments. Waves capable of resuspending fine sediments more than 75% of the time and ADP derived erosion depths suggest winnowing of the fine sediment.

Aerobic Production of Methane in the Sea

Methane is a potent greenhouse gas that has contributed approximately 20% of the enhanced radiative forcing since pre-industrial times. Despite its importance to Earth’s climate, the global methane budget source terms are poorly constrained. Methane concentrations in the surface waters of most of the world’s oceans are 5–75% supersaturated with respect to atmospheric methane concentrations, implying both a local in situ methane source and a net flux from the ocean to the atmosphere. However, marine methane production is thought to occur only in strictly anaerobic environments. Because the surface ocean is also saturated with respect to atmospheric oxygen, the as yet unexplained methane supersaturation has been termed the oceanic methane paradox. We provide evidence for a previously unrecognized pathway for methane production in the sea. This pathway involves production of methane via the decomposition of methylphosphonate as a phosphorus source for growth. The diazotroph, Trichodesmium, is one organism capable of growth and methane production via methylphosphonate metabolism. As such, this aerobic methane pathway is predicted to be climate sensitive and responsive to changes in water column stratification and nutrient limitation.

Optimizing Power Generation by Microbial Fuel Cells

To test various strategies used in operating Microbial Fuel Cells (MFCs), we have designed and constructed and electronic device – an MFC tester - which can be used in the laboratory and in the field. Our goal is to maximize the power generated by MFCs and the MFC tester is used to compare the effect that various operational parameters may have effect on power generation using MFCs. Because typically MFCs generate low power density, it is difficult to use this energy to power external devices directly. Instead, the energy from MFCs is stored in capacitors and later used to power electronic devices. The paper discusses the methods of optimizing power generation by MFCs and the electronic tester we have developed and used to evaluate how efficiently the power was generated. We have used the MFC tester to evaluate the performance of MFCs in the laboratory, marine environment and in the freshwater environment.
There is substantial disagreement about the location of the upwelling branch of the meridional overturning circulation with helium-3 numerical simulations. There is substantial disagreement about the location of the upwelling branch of the meridional overturning circulation. Observational syntheses suggest that most of the upwelling occurs in the interior ocean, either spread broadly throughout the thermocline or focused in regions of exceptionally intense mixing. However, a number of numerical models suggest that the upwelling occurs in the Southern Ocean. Primordial helium-3 from mid-ocean ridges is an ideal tracer for determining where the upwelling occurs. We include this tracer in a suite of models with different mixing parameterizations, representing the spectrum of behaviors between upwelling occurring primarily in the Southern Ocean and outside of it. Results from these simulations are compared to a new helium-3 dataset compiled from the measurements of the World Ocean Circulation Experiment.

The Greenland Ice Sheet (GIS) represents the largest expanse of glacial ice in the Northern hemisphere and contains significant melt water, along with unknown quantities of associated carbon material, to the North Atlantic and Arctic Oceans. Our goal is to understand the interaction between microbial metabolism and carbon turnover on the surface of the GIS, with a view to ultimately quantifying the contribution of this surface carbon reservoir to total carbon export from the ice sheet to the ocean. In July 2007 we collected samples from glacial ice, snow, supraglacial lake water, and cryoconite-water at two sites on the western margin of the GIS. Here we present results from a suite of analyses that describe the magnitude and biological reactivity of the surface carbon reservoir. We use bulk biochemical analyses to establish baseline values of the magnitude of carbon and nutrients present. We use ultrahigh resolution mass spectrometry to characterize the polaron fraction of dissolved organic matter. We use community phylogenetic analyses to characterize metabolically-active microbes that facilitate transformations of the bulk organic carbon pool prior to export.
ecosystems are useful indicators of global change because they integrate processes related and export flux occur seasonally and interannually in overlying waters. Deep-sea benthic (OM) to the seafloor and/or the quality of the OM. Large changes in primary productivity dominance with time have been recorded in all size fractions. The changes in faunal exceed 2.5 years to one of less than 6 weeks. Meiofauna and macrofauna also increased reduced the time for the complete reworking of the sediment surface from a period ex 1997 and 2002. There was no significant increase in biomass. The increase in abundance of abyssal megafauna increased in abundance by over three orders of magnitude between Large-scale changes have occurred over the last 18 years (1989 to 2007) in the structure of SUSTAINED OBSERVATORY - THE €˜AMPERIMA ‘EVENT.

SECULAR CYCLES OF MIXED LAYER SALINITY IN THE NORTH PACIFIC FROM ARGO DATA

The seasonal variability of mixed-layer salinity (MLS) is examined in the North Pacific Ocean using Argo data. Significant seasonal cycles were found in four regions: 1) The western North Pacific just south of Japan, 2) The northeastern North Pacific and Alaska gry, 3) the intertropical convergence zone (ITCZ) and 4) an area of the central North Pacific north of the Hawaiian Islands. The phase and amplitude of the seasonal cycle were determined. Amplitudes range from 0.1 to ±0.5, with 0.1–0.2 being most common. The largest amplitudes are in the tropical band. Maximum salinity is obtained in late winter in area 1, late winter and early spring in area 2, early summer in area 3 and late summer and early fall in area 4. Large portions of the North and Tropical Pacific have no significant seasonal variation in MLS. Seasonal cycles of evaporation and precipitation were also calculated using the NCEP Reanalysis 2 data. In general, the phase of E-P agrees well with the MLS in the ITCZ and in the western North Pacific. However, the area of seasonal variability in MLS in the Alaskan gyre does not correspond to any significant seasonal variations in E-P.

THIN LAYERS OF PLANKTON: FORMATION AND DESTRUCTION BY SHEAR, STRAIN, AND DIFFUSION

We use explicit solutions of the advection-diffusion equation to show that thin layers of plankton can be formed by vertically sheared currents differentially advecting generic initial distributions of plankton. The most realistic current model includes both horizontal and vertical shear, which together cause an exponential-in-time decrease of the layer thickness until diffusion prevents further scale reduction. We give simple estimates of the minimum layer thickness and show that the initial scale of the patch has no effect on the ultimate scale. A signature of the shear-thinning mechanism is that the resulting thin layer is systematically tilted across isopycnals; this property can be used to distinguish shear-driven thinning from one-dimensional mechanisms, such as depth-seeking behavior or settling onto pycnoclines. Horizontal shear alone is also sufficient for exponential-in-time destruction in the intensity of thin layers. Therefore, to maintain the layer intensity, exponential production which is faster than the strain time-scale is required. Rough numerical estimate using oceanic parameter values indicate that this condition, and therefore biologically sustained thin layers, may be satisfied.

EXPLORING THE COMBINED POTENTIAL OF RADAR AND LIDAR ALTIMETRIC DATASETS FOR INLAND WATER ALTIMETRY

Satellite radar and lidar altimetry are valuable tools in providing surface height (stage) measurements of inland water targets and hydrological-based altimetric studies have been ongoing for well over a decade. The technique has been utilized in many interdisciplinary projects seeking surface elevation for lakes, rivers and wetlands, in many cases providing new insight into time or space. Moreover, very rapid changes in in-situ SSS show the challenge faced by remote sensing in frontal ocean regions. Other variables are compared with existing products when available.

LONG-TERM CHANGE IN ORGANIC MATTER FLUX AND DEEP-SEA COMMUNITIES AT THE PORCUPINE ABYSSAL PLAIN (NE ATLANTIC) SUSTAINED OBSERVATORY: THE ‘Æ AMPERIMA€EVENT.

Large-scale changes have occurred over the last 18 years (1989 to 2007) in the structure of the benthic community on the Porcupine Abyssal Plain in the NE Atlantic (48°50'). The abyssal meiofauna increased in abundance by over three orders of magnitude between 1997 and 2002. There was no significant increase in biomass. The increase in abundance reduced the time for the complete reworking of the sediment surface from a period exceeding 2.5 years to one of less than 6 weeks. Mesoofauna and macrofauna also increased in abundance at the same time, but only by a factor of about two. Changes in species dominance with time have been recorded in all size fractions. The changes in faunal abundance and composition may be related to large-scale episodic fluxes of organic matter (OM) to the seafloor and/or the quality of the OM. Large changes in primary productivity and export flux occur seasonally and interannually in overlying waters. Deep-sea benthic ecosystems are useful indicators of global change because they integrate processes related to the biological carbon pump over space and time.
SHELF WATER SALINITY VARIABILITY, EASTERN NEWFOUNDLAND TO CAPE HATTERAS, 1950-2003

Given large Middle Atlantic Bight shelf water salinity and volume variability from the 1970s to 1990s, an analysis from 1950 to 2003 was conducted using data from eastern Newfoundland to Cape Hatteras to examine possible sources. Analysis uses data containing all temperature and salinity pairs from Bedford Institute of Oceanography’s Climate database, along with Russian data from a NOAA-funded data rescue effort, providing over 500,000 data points. Partitioning data into ten sub-regions allows examination of regional seasonal and inter-annual variability (IAV). Results show a seasonal pulse of near-surface, low-salinity water entering off eastern Newfoundland during September that propagates southwest to the Scotian shelf by November. Timing of this freshwater signal occurs 2-3 months earlier than seaward movement of the shelf-slope front. From the Gulf of Maine to Hatteras shelf, lowest salinities occur nearly simultaneously due to the annual spring freshet. Salinity IAV increases westward, with largest anomalies located from the eastern Scotian to Hatteras shelves. IAV of salinity in this western-most region may be due to upstream freshwater sources from the eastern Newfoundland shelf and Gulf of St. Lawrence.

SHELF METAL AND SULPHUR ISOTOPES IN SMALL BOREAL STREAMS: THE INFLUENCE OF LANDSCAPE TYPE

The transport of trace metals (TM) and dissolved organic carbon (DOC) from headwater streams to the sea is influenced by various landscape elements. Our focus was to investigate the influence of major landscape elements on observed concentrations of dissolved metals (e.g., As, Cd, Co, Pb), DOC, sulphate, and sulphur isotope composition in streams, north-eastern Sweden, a coastal region characterized by peat wetlands and coniferous forests. Stream water samples collected from 10 streams (0.13 to 67 km²) in a boreal stream network reveal that landscape type (i.e. coverage of wetland and forest) is significant for river chemistry. Streams with different catchment characteristics responded differently to hydrological episodes. In forested streams, concentrations of TM, Fe and DOC increased, while they decreased in wetland influenced streams. Furthermore, Fe and Pb correlated positively with wetland coverage. Moreover, significantly lower average sulphate concentrations, but higher isotope values, were observed in wetland streams. This study emphasizes the importance of understanding stream water chemistry from a landscape perspective in order to identify potential environmental where climate change may induce enhanced metal mobilization in the future.

APPLICATION OF THE TRACER Fe²⁺ TO A FIELD DATA SET FROM THE SOUTH EAST PACIFIC: INTEREST AND LIMIT OF THE CONCEPT

The geochemical tracers N² and C¹ have been successfully used to estimate the importance of key biogeochemical processes. Based on the same approach, the Fe²⁺ (Fe³⁺) was recently used in monitoring settings (Panuck et al., 2005). We have applied the Fe²⁺ concept to a large data set (137 values of Fe²⁺ and P) gathered between 0 and 400 m along a 8000 km transect extending and across the South Pacific gyre from the Marquesas Islands to the Chilean coast. By contrast with the definition of N² or C¹, which relies on quite robust elemental ratio, Fe²⁺ depends on rFe:P which is highly variable. Appropriate rFe:P for our study was derived from the data set. The analysis of the distribution of Fe²⁺ leads to the unexpected conclusion that the Fe enrichment in the vicinity of Marquesas Islands is very likely not related to a local source of Fe but rather to the extension of the oxygen minimum zone. The limits of the method are also discussed. GEOTRACES should generate large data sets which will help to fully explore the potential of Fe²⁺.

INTRA- AND INTER-SPECIES VARIATION OF D-MG AND D-SR IN LIVE BENTHIC FORAMINIFERAL CALCITE AND ARAGONITE FROM THE CHARLESTON BUMP SPANNING FIVE YEARS OF STUDY

Mg/Ca and Sr/Ca from live (CellTracker Green labeled) individual tests of Bulimina aculeata, Bulimina marginita, Cassidulina laevigata, Lenticulina spp., and Hoeglundina elegans were compared across bottom-water properties and ontogenetic variability from cores collected in 2001, 2005, and 2006 from the Charleston Bump (~22m water depth; 8.9-11.6°C). No significant correlations existed between Mg/Ca and Sr/Ca and benthic foraminiferal population densities or bottom-water temperature. This suggests that annual patterns affecting population dynamics may not induce vital effects on element/calcium shell chemistry. Lenticulina spp. and H. elegans exhibited an ontogenetic effect where higher Mg/Ca and lower Sr/Ca values were observed in smaller individuals. Mg/Ca values varied across different sized individual Bulimina spp. and C. laevigata, but no significant trend was observed for these species. Sr/Ca values were consistent across varied shell size of an individual foraminiferal, but were species dependent. The values for Sr/Ca were significantly different among species and co-varied with Mg/Ca signatures, suggesting that a multi-species paleo-temperature proxy may be useful where gaps exist in single or non-concurrent species records. Funded by NSF OCE0911654, OCE03351029, OCE 0437366, and OCE 0350794.

ABUNDANCE AND BIOMASS OF CYANOBACTERIA IN THE SOUTHERN MID-ATLANTIC BIGHT

Cyanobacteria are important primary producers and agents of nitrogen fixation in marine ecosystems. In this study, epifluorescence microscopy combined with computer-mediated image analysis software was employed to assess cyanobacteria abundance and biomass off the coast of Chincoteague, VA and on oceanographic cruises in the southern Mid-Atlantic Bight (between Lewes, Delaware and the tip of North Carolina). As a secondary objective, this study sought to characterize the cyanobacteria based on cell size, shape and fluorescence. Cell size ranged from 0.7-2.4 μm and averaged 1.3 μm, which lead to the conclusion that the community is dominated by Synechococcus sp. In addition to characterization, correlations between cyanobacteria abundance and nutrient, temperature, and salinity data were explored. Cyanobacteria abundance and biomass exhibited seasonal variability often correlating with changes in water temperature, which ranged from 5°C to 25°C. Cell concentrations ranged as low as 4x10^2 cells mL^-1 during the winter months to as high as 16x10^4 cells mL^-1 during the summer months. As a whole, our efforts are contributing to the Wallops Coastal Ocean Observing Laboratory (WA-COOL) on the Delmarva Peninsula.

NUMERICAL SIMULATIONS OF SHOALING INTERNAL SOLITARY WAVES OF ELEVATION

The interaction of internal solitary waves (ISW) of depression with shoaling bottoms is examined with nonhydrostatic numerical simulations. As ISW shoal, wave breaking occurs and a number of bubbly-fall layers form. In the case of semi-stationary ISWs, these layers can produce boluses transport dense fluid upslope, above where the pycnocline meets the bottom. The number of boluses produced during a shoaling event, their energetics and transport properties are examined. The impact on the slope of a wavetrain consisting of more than one ISW is also examined. It is found that a wavetrain composed of two ISWs that are separated by roughly one wavelength, does not significantly increase the volume of dense water being brought upslope when compared to the case of only one impinging ISW, except for situations characterized with an Irribarren number greater than 0.2.

OPTICAL PROPERTIES OF CHROMOPHORIC DISSOLVED ORGANIC MATTER AND MODEL COMPOUNDS: RELATION TO STRUCTURE

Extracted lignins exhibit optical absorption and emission properties that are highly similar to hemic substances and CDOM, including long-wavelength absorption and emission that would not be predicted on the basis of lignin structure. Instead, these optical properties are proposed to arise from intramolecular charge transfer interactions between hydroxy-(methoxy)-aromatic donors and quinoid acceptors formed by partial oxidation of lignin precursors (Del Vecchio and Blough, 2004 ES&T). Emission quantum yields for a series of quinone model compounds were negligible, suggesting that the long-wavelength emission does not originate from quinoid moieties, and is instead attributed to recombination luminescence from the charge transfer states. Further, concentrated solutions of CDOM (and lignins) exhibit absorption well into the infrared, outside of the range that would be expected for most quinones. However, reaction with borohydride, a good quinone reductant, produces preferential loss of long-wavelength absorption and enhanced blue-shifted emission consistent with the charge transfer model. Preliminary time-resolved fluorescence measurements are also compatible with this model. These results thus suggest the idea that degraded (partially-oxidized) forms of lignin are the predominant source of terrestrial CDOM.

IN- AND EPIFAUNAL BENTHIC COMMUNITY STRUCTURE IN THE ARCTIC CANADA BASIN IN JULY 2005

Benthic in- and epifauna of the Arctic Canada Basin were sampled in July 2005 at depths ranging from 817–3880 m. Mega-epifauna was quantified at 8 stations from 5732 digital images taken with a down-looking digital camera from 2 to 3 m above the seabed. Infauna was sampled by 33 box cores (0.062m² area) at 11 stations. Epifauna densities were highest at a sub-circular feature on the Chukchi Plateau located in 900 m water depth, 1200 m in diameter with a depth of approximately 60m below the surrounding seabed. Holothurians, mostly Holothuria, were the single-most abundant taxon at this station with over 50 individuals/m² on some images. Mean infaunal abundance per station ranged from 89-5149 individuals/m² with the highest concentrations on the upper Chukchi Sea slope and the lowest in the deep Canada Basin. Mean infaunal biomass per station ranged from less than 0.1-27 g wet weight/m² with the same geographical trend. Polychaetes were most abundant and dominated the biomass. Three new species of polychaetes and one new species of Komokiacea (Foraminifera) were found.

INCORPORATION OF HIGH-RESOLUTION TOPOGRAPHIC INFORMATION, HIGH RESOLUTION WATER QUALITY FORECASTS AND ADVANCED DATA ASSIMILATION INTO A COASTAL INUNDATION MODEL

Coastal inundation is the most dangerous and damaging aspect of extratropical and tropi-
cal weather systems that impact the coastal zone of the eastern United States. Several
factors contribute to the water elevation reached in a given storm each of which is com-
plicated and difficult to address. To ameliorate public concern a high-resolution coastal
inundation forecasting and assessment program has been developed and integrated into
the existing New York Harbor Observing and Prediction System (NYHOPS).

The NYHOPS region not only includes the open waters of New York and New Jersey but now includes
many of the low-lying back bay areas. And, based on end user input, the inclusion of high-
resolution (lat & block) coastal topography grids for overland inundation determination at
select priority areas for application is underway. The model physics has been improved
through the coupling of experimental high-resolution Weather Research and Forecasting
(WRF) meteorological model and a data assimilating scheme for water level data from
existing high-density federal and non-federal coastal and back bay observation systems.

For the purpose of assessing the system performance, the coastal inundation forecasting and
analysis program is applied to determine the coastal and back bay water levels measured
during two major storm events.

ABUNDANCE AND MOLECULAR DIVERSITY OF PROCHLOROCoccus
WITHIN PACIFIC COASTAL ISLAND SYSTEMS

Prochlorococcus dominates oligotrophic, open-oceans ecosystems accounting for as
much as 43% of the biomass and is composed of genetically and physiologically distinct
clades, or ecotypes, each differentially adapted to environmental variables. Preliminary
studies have shown that Prochlorococcus is also present in high concentrations in some
coastal waters such as Kaneohe Bay, Oahu, Hawaii. Here we investigate the abundance and
molecular diversity of Prochlorococcus of several distinct Pacific Ocean coastal island
ecosystems to determine their contribution to local ecosystems and if these local popula-
tions are regulated by local or external processes. Using a combination of flow cytometry,
apPCR, DGGE and clone libraries, we show that in these tropical and sub-tropical coastal
environments that Prochlorococcus is abundant and diverse and composed of some
subpopulations not found in the surrounding open ocean. Some Prochlorococcus groups
appear to be endemic to certain islands, whereas others are widespread. These patterns of
abundance and diversity are mapped onto strong environmental gradients to explore
what factors may be regulating populations.

A NEW FISH PROBE FOR KINETOLASTIDS, AN IMPORTANT GROUP OF
HETEROTROPHIC FLAGELLATES, AND THE EVALUATION OF A DOMAIN-
SPECIFIC PROBE FOR EUKARYOTES

Detection and accurate enumeration of the smallest heterotrophic eukaryotes in the pres-
ence of the vastly more abundant prokaryotes represents a unique challenge. Using stan-
dard counting protocols with epifluorescence microscopy and nucleic acid dyes (DAPI, 
SYBR green), larger nucleomorphs of prokaryotes can be mistaken as eukaryotic nuclei.
On the other hand, eukaryote nuclei can be so small that they are lost among the more
abundant but similar-sized prokaryotic DNA. Fluorescence in situ hybridization (FISH)
provides a more reliable detection of heterotrophic eukaryotes but only when combined
with pyramidal signal amplification (also known as catalyzed reporter deposition FISH), a
step that amplifies the fluorescence signal. Few FISH probes are available and fewer have
been extensively tested for eukaryotes to date. Here we demonstrate the use of a new
probe targeting the 18SSU rRNA which was specifically designed for kinetoplastids, an
important group of free-living and parasitic flagellates. We will contrast this new probe to
a popular domain-specific eukaryote probe, discuss optimal stringencies and the use of
competitor probes in order to obtain an unambiguous signal.

NUTRIENT-RICH, FRESH SUBMARINE GROUNDWATER DISCHARGE IS ENHANCED DURING NEAP TIDES AT AN OPEN OCEAN BEACH

The influence of spring-neap tidal variability on submarine discharge of fresh and saline
groundwaters was examined at Stinson Beach, California - a residential community that
utilizes on-site systems for wastewater disposal. Fresh, shallow groundwater at the site
contains high concentrations of nutrients and human fecal bacteria. A groundwater-de-

resistant bacteria indicates that even open ocean marine animals are exposed to and potentially harbor these organisms.

LONG-TERM TRENDS IN SPICINESS, DISSOLVED OXYGEN, AND INORGANIC NUTRIENTS IN THE SOUTHERN CALIFORNIA CURRENT SYSTEM.

We use historical hydrographic data from the California Cooperative Oceanic Fisheries Investigations (CalCOFI) program to explore the temporal variability of physical and chemical properties of slope waters impacted by the California Undercurrent (CUC) over the period 1984-2006. The upper water column has experienced a strong warming trend, and is greatly impacted by El Nino events. At the depth of the CUC, waters have become progressively warmer, saltier, and lower in oxygen content. There have also been increasing trends in nitrate and phosphate in CUC waters, although at different rates, leading to highly significant declines in the NO3:PO4 and SiO4:NO3 ratios. Variability in CUC net transport and source water properties are the most likely causes of the observed trends. Significant changes in the oxygen content and nutrient composition of CUC waters, which are upwelled upstream, could have important implications for the California Current ecosystem. We also examine the CUC trends in the context of decadal variability in water properties throughout the southern California Current System, based on the CalCOFI 1949-2006 series of temperature, salinity, and dissolved oxygen measurements.

VERTICAL MIGRATION OF CETHIN LAYERS OF THE DINOFLAGELLATE AKASHIW SANGUINEA IN RELATION TO VARYING LIGHT AND NUTRIENT CONDITIONS.

Vertical heterogeneity of physical, chemical and biological properties is nearly ubiquitous in the ocean, and sometimes manifests itself as thin layers or strata of a few meters or less in thickness. One example of this is the dinoflagellate Akashiwo sanguinea, which can form layers near the surface during the day and then migrate downward to form sub-surface layers near the nutricleane at night. We examined this phenomenon in the laboratory using well-controlled and replicated experiments employing 2-m high columnar tanks, in which we manipulated both light intensity (0.06 - 140 μEinstein) and nutrients (0 - 20 μM PO4), both vertically and between treatments. We observed A. sanguinea to exhibit highly variable vertical distribution, and to sometimes not vertically migrate, depending on the exact combination of light and nutrients (i.e., possibly those needed to generate positive net photosynthesis over a daylight cycle). We discuss these results in relation to recent field observations (e.g., ONR LOCO) and experimental studies (e.g., our radiotrace experiments) examining the vertical partitioning and flux of materials within and around thin layers.

ISOTOPE DISCRIMINATION BY FORM ID RUBISCO FROM THE DIATOM SKELETONEMA COSTATUM.

Phytoplankton 13C values are used to ground-truth and constrain parameters of models of the global carbon cycle. One major influence on 13C values is isotopic discrimination by RubiscoCO2, the Calvin cycle carboxylase. It is often assumed that all Rubiscos discriminate against 13C to the same degree (ε = 25‰, ε = [(13C/12C) - 1] x 1000), which is problematic, since carbon fixation in the ocean is catalyzed by four distantly-related forms of Rubisco (Ia, Ib, Id, II). Many dominant primary producers, including diatoms and coccolithophores, use form ID. Recently, the ε value for form ID Rubisco from the coccolithophore Emiliania huxleyi was found to be surprisingly nonspecific (ε = 12‰). To determine whether other ID enzymes discriminate to a lesser degree, the ε value for Rubisco from the diatom Skeletonema costatum was measured using the substrate depletion method. Like E. huxleyi, S. costatum has a Rubisco that is less isotopically selective than expected (ε = 18.5‰). These lower-than-expected ε values necessitate the re-interpretation of 13C values of phytoplankton, and provide a mechanism for the isotopic enrichment commonly noted for marine biomass relative to terrestrial.

AN ESTIMATION OF DIFFERENT SOURCES OF NEW NITROGEN DURING MONSOON-FORCED UPWELLING OFF THE VIETNAMESE COAST.

The southwest-monsoon induces coastal upwelling off Vietnam, with variable intensity between years. During field-campaigns in July 2003 and 2004, we investigated the importance of nitrate and N2-fixation for supporting productivity. Within the upwelling zone, Ekman velocities ranged from 1.9±10-3 m s-1 (2003) to 2.0±10-3 m s-1 (2004). The product of Ekman velocities and nitrate concentrations in upwelling source waters yielded vertical fluxes of 13±2 mmol N m-2 d-1 in 2003 and 17±2 mmol N m-2 d-1 in 2004. Consistent N demands of primary production were found in 2004 (16±4 mmol N m-2 d-1), but not in 2003 (4±2 mmol N m-2 d-1). For the stratified, oligotrophic offshore zone, diapycnal turbulent diffusivities were calculated using shear- and buoyancy measurements. Values of up to 120 cm2 s-1 in 90 m depth are unrealistically high due to an upwelling-induced undercurrent. Values between 0.35 cm2 s-1 and 0.42 cm2 s-1 were derived from nitrate uptake rates measured in the nutrient-rich, and are consistent with literature values. N2-fixation was insignificant in the upwelling zone, but may have accounted for 15-18% of new production offshore in 2004 and 2003, respectively.

THE WEATHER DURING THE SUMMER OF 2006 IN THE PACIFIC NORTHWEST AND ITS CONSEQUENCES FOR THE COASTAL OCEAN.

The weather of the summer of 2006 was characterized by a persistent ridge of anomalously pressure off the coast of Oregon which led to a long string of days featuring upwelling favorable winds from the north. This appears to have had a number of impacts on oceanic conditions in the coastal zone. Notably, a large area of relatively high nitrate concentrations was found farther offshore and farther north than usual. This water featured relatively low phytoplankton biomass, with assemblages typical of high nutrient/low chlorophyll (HNLC) regions rather than coastal upwelling areas. These effects appear to have been manifested at higher trophic levels, as exemplified by poor catches of juvenile chinook and coho salmon. The atmospheric forcing from late spring through summer of 2006 also can be implicated in the development of record-low oxygen concentrations (hypoxia) on the shelf along the coast. The present paper summarizes the physical, chemical, and biological states of the coastal zone in 2006, and outlines the mechanisms linking the weather to the biological response.

INTERANNUAL DIFFERENCES IN NUTRIENT DYNAMICS DURING BLOOMS OF AUREOCCUS ANOPHAGEFERRIS, A FLOW CYTOMETRY APPROACH.

Chincoteague Bay, MD has been experiencing blooms of Aureococcus anophagefferens since at least 1999. We examined interannual differences in both nitrogen and carbon dynamics during blooms from 2002 thru 2007. During all of these blooms, inorganic nitrogen (e.g., ammonium and nitrate) was taken up but urea was the dominant form of nitrogen (e.g., low chlorophyll (HNLC) regions rather than coastal upwelling areas. These effects appear to have been manifested at higher trophic levels, as exemplified by poor catches of juvenile chinook and coho salmon. The atmospheric forcing from late spring through summer of 2006 also can be implicated in the development of record-low oxygen concentrations (hypoxia) on the shelf along the coast. The present paper summarizes the physical, chemical, and biological states of the coastal zone in 2006, and outlines the mechanisms linking the weather to the biological response.
A real-time coastal monitoring and prediction system was implemented with the Dynamics of the Adriatic in Real-Time (DART) international collaborative project, a focus on the study of the complex dynamics of the swiftly-evolving fronts and eddies in the Western Adriatic Current downstream of Cape Gargano. They were directly observed in real-time through remotely sensed Chlorophyll a and Sea Surface Temperature imagery from MODIS Aqua, and by ship and mooring monitoring.

THE DART EXPERIMENT GARGANO: PREDICTIONS, MONITORING, AND ADAPTIVE SAMPLING DURING EDDIES IN THE WESTERN ADRIATIC CURRENT DOWNSTREAM OF CAPE GARGANO

Tourazz, M., Flinders University of South Australia, Adelaide, Australia; Kaempf, J., Flinders University of South Australia, Adelaide, Australia

MIXING PROCESSES IN THE SUBTROPICAL FRONT
The Subtropical Front south of Australia is characterised by strong density compensation in and below the seasonal mixed layer and small-scale salinity structure at the base of the seasonal mixed layer. High-resolution Upper Ocean model simulations show that on seasonal time-scales, density compensated fronts persist, even in the absence of active atmospheric forcing. Evolution of these fronts is dependent on the relative balance between mixing that maintains the frontal structure and flow patterns that advect and modify the fronts. Our recent work describes the role of the seasonal mixed layer on the formation of these fronts. In the near future, we expect to develop new methods for the observation of these features, and to further improve their prediction. The Subtropical Front is a significant physical feature that controls the transport of matter and energy in the Southern Ocean. Its density structure is responsible for the formation of the Subantarctic Mode Water (SAMW), which is an important source of deep water in the global ocean. The Subantarctic Front is also a key feature for the transport of heat and carbon between the Southern Ocean and the atmosphere.

DOCUMENTING CHANGE ALONG A LOW-ENERGY COASTAL EMBAYMENT WITH FRINGING MARSH: A NEW PROXY-BASED SHORELINE INDICATOR
Lagoon and estuarine shorelines represent a significant portion of eroding shorelines along the U.S. Atlantic and Gulf coasts. These shorelines are often not included in shoreline change studies as delineating a definable, repeatable and reliable proxy-based shoreline indicator is difficult. A new proxy-based shoreline indicator was used to document shoreline change in a low-energy coastal embayment below the HWL. The new proxy was shown to be superior to the FWL for documenting changes to the shoreline. Approximately 9.8km of the HWL, exhibited statistically significant shoreline change compared to 22.5km using the new proxy for the same 40km stretch of shoreline. In addition, the visual cues used to delineate the new proxy were found to be more scientifically defensible than those associated with the HWL delineation along shorelines with fringing marsh. Changes in marsh vegetation below the HWL have implications for sediment transport, water quality, predator-prey relationships, contaminant sequestration and filtration, ecosystem health and other science-based inquires and/or management issues.

INTEGRATING CO2 FLUXES IN THE COASTAL OCEAN: SIMULATING NATURAL VARIABILITY AND ANTHROPOGENIC UPTAKE WITH A GLOBAL MODEL OF 0.5Â° HORIZONTAL RESOLUTION
The coastal ocean represents 7% of the oceanic surface area, but accounts for 20% of the total oceanic organic matter production and 80% of total oceanic organic matter burial. It receives massive inputs of organic matter and nutrients from land and exchanges large amounts of matter and energy with the open ocean. Despite all this, the coastal ocean has been largely ignored in the recent carbon budgeting and in ocean carbon uptake projections over the 21st century. Recent studies have compiled in-situ data from several key coastal environments and clearly indicate the significance of this active region in the global carbon cycle. In this study, we couple the global biogeochemical model PISCES to a 0.5Â° -horizontal resolution version of the NEMO ocean general circulation model. We perform runs over the industrial era (1880-2001) forced by observed atmospheric pCO2 and atmospheric re-analysed fields when available. We present here an evaluation of the simulation of natural and anthropogenic carbon fluxes in the coastal ocean thanks to the recent data compilation. We also show how the coastal ocean carbon flux changes under increasing atmospheric pCO2.
The possible biases associate with incorrectly modeling aggregates as solid particles. We apply this model to recently proposed MPA networks for the central coast of California and show how its output makes quantitative comparisons of different MPA networks. Our approach integrates the patchy spatial distribution of habitat, the spatial scale of larval dispersal, and the fishing level outside of reserves into a calculation of the spatial distribution of equilibrium species. These distributions are summarized in terms of the amount of coastline having high settlement rates for each combination of MPA network, dispersal distance, presence of fishing, and population structure. Results show that while the habitat set aside is a good indicator of persistence for short distance dispersers, presence of longer distance dispersers depends on the spatial distribution of habitat and reserve. We conclude by considering the advantages of this model-based approach relative to route- and habitat-based methods of designing MPAs.

COMBINING MICROCOMIS EXPERIMENT AND ISOTOPIC TRACERS TO STUDY MERCURY TRANSFORMATIONS UNDER REDOX OSCILLATIONS IN COASTAL SEDIMENTS

Major questions are still associated with the fate of Hg species in coastal sediments: first, the methylmercury (MMeHg) formation extent of the fresh pool of Hg and the legacy pool of Hg (endogenous Hg) and secondly, the transformations and partitioning of the Hg species under redox oscillating regimes in surface sediments. In this work, a time course experiment was developed using a microcosm to investigate the surface sediment reactivity of Hg species under controlled redox oscillations. Isotopic enriched species of endogenous Hg and MMeHg were added at the beginning of the experiment. Sampling was done in the solid, aqueous and gaseous phase along the redox oscillations allowing the simultaneous measurement of transformation and partition extents of endogenous and exogenous Hg species. It was found that methylation yields and desorption of inorganic Hg species were controlled by the redox cycles. The model-based approach to assess a network of marine reserves for persistence of populations in coastal ecosystems with a sedentary adult phase and a dispersing larval phase. We apply this model to recently proposed MPA networks for the central coast of California and show how its output makes quantitative comparisons of different MPA networks. Our approach integrates the patchy spatial distribution of habitat, the spatial scale of larval dispersal, and the fishing level outside of reserves into a calculation of the spatial distribution of equilibrium species. These distributions are summarized in terms of the amount of coastline having high settlement rates for each combination of MPA network, dispersal distance, presence of fishing, and population structure. Results show that while the habitat set aside is a good indicator of persistence for short distance dispersers, presence of longer distance dispersers depends on the spatial distribution of habitat and reserve. We conclude by considering the advantages of this model-based approach relative to route- and habitat-based methods of designing MPAs.
PHOTONIC PLASTICITY IN THE FILTERING APPARATUS OF THE PELAGIC TUNICATE, OIKOPLEURA DIOICA, IN RESPONSE TO FOOD LIMITATION.

The frequent repetitive secretion of filter-feeding houses of the tunicate, Oikopleura dioica, represents investment in a substantial proportion of total body carbon. Despite this investment, the filter-feeding strategy of pelagic tunicates in general, has been proposed as an adaptation to oligotrophic environments. We examined the capacity of O. dioica to modify its house renewal rate (HRR) and filter morphology in response to eutrophic vs. oligotrophic food regimes. The HRR remained constant at 0.26 ± 0.08 house 1^{-1} throughout the first life cycle and did not change in response to altered food concentrations. However, there was a small alteration of transcriptional activity of a gene responsible for production of the food concentrating filter (Oikos3) compared to a gene producing the overall house scaffold (Oikos7). The difference in relative contribution of the two structural elements became more evident at the protein level, with a highly significant effect in response to food concentration. These results indicate that although house production rates are not subject to a plastic response, dietary differences drove differential regulation of component proteins of the filter-feeding house.

T., NASA/JPL, Pasadena, USA, liu@pacific.jpl.nasa.gov; Scalectometry DERIVED SURFACE TURBULENT STRESS

Two algorithms are examined to retrieving (1) sea surface turbulent stress and (2) sea surface turbulent kinetic stress. The kinetic stress is equal to the stress divided by atmospheric density. Traditionally, scatterometer have (1) been believed to respond to turbulent stress, and (2) be calibrated in a manner consistent with a response to kinematic stress. We investigated the advantages of considering atmospheric density in the satellite calibration. These consideration could be important in areas of strong temperature gradients and for large scale circulation studies.

Bourque, J. H., Université É de Moncton, Moncton, Canada, ebl2860@umonton.ca; Tremblay, L., Université É de Moncton, Moncton, Canada, luc.tremblay@umonton.ca; BACTERIAL CONTRIBUTION TO THE ORGANIC MATTER OF THE ST. LAWRENCE ESTUARINE SYSTEM.

Bacteria are primary agents of diagenetic alterations and contribute to a unique fraction of detrital organic matter (OM). In this study we measured muramic acid (Mur) and amino acids (AA) in various fractions of bulk OM (ultrafiltered, particulate, and sedimentary). Mur and the D-enantiomers of AA are bacterial biomarkers providing insights on the bacterial contribution to OM and OM diagenetic status. Samples were collected at different locations and depths in the St. Lawrence Estuary, Canada. Bacterial biomarkers were present in every sample and some displayed a major bacterial contribution to the detrital organic carbon and nitrogen. Dissimilarities in biomass marker yields were observed between locations and could be explained by different OM inputs (e.g. soil vs. marine OM). We also observed a general increase of the percentage of D-AA vs. total AA with depth, which can be explained by both bacterial contribution and preferential degradation of L-AA with time. As a result, altered material such as most of dissolved OM exhibited higher D-AA yields. The opposite trend was observed for Mur which appeared very labile.

Diatynal mixing near topography seems to be required to provide the required buoyancy gain of the deep/intermediate waters in order to close the global overturning circulation. Available data from different regions indicate a clear link between high levels of diapycnal mixing and rough topography. The purpose of this work is to explore mixing and its relation to bottom circulation and internal waves near a sill of the axial rift-valley of the MAR in the Lucky Strike segment. A synthesis of regional circulation inferred from the GRAVILUCK and BEMOMAR cruises in 2006-2007 and a few floats will be presented and its variability will be discussed in view of previous observations. Next the variability of the deep circulation will be detailed using data from two 1-year mooring: one close to the sill and one two km downstream from the sill. The measurements are from classical ADCP and currentmeter as well as from high frequency temperature sensors and thermocline sensors. Hence they allow to identify internal waves and high-shear/low Rl episodes and their respective contribution to dissipation and mixing.

M., Sars International Centre for Marine Molecular Biology, Bergen, Norway, eric.thompson@sars.uib.no; Can we massively parallel tag sequencing approach be used to track environmentally induced changes in salt marsh sediments?

The use of high throughput tag sequencing to explore bacterial diversity in different habitats has recently surged. This technology has demonstrated that microbial diversity is vastly greater than indicated by previous methods and that much of that diversity, the "rare biosphere," is at very low abundances. The degree to which this rare biosphere is ecologically relevant is largely unknown, though we hypothesize that these rarer taxa provide ecological redundancy that allows microbial populations to withstand environmental perturbation. We test this hypothesis by first examining local-scale variability in salt marsh sediment samples collected within a 10 cm2 area of salt marsh to assess the degree of patchiness among rare microorganisms. We then use a tag sequencing approach to examine the effects of fertilization on the community composition of salt marsh sediment bacteria. Preliminary evidence from DGGE indicates that fertilization does affect microbial communities in some habitats. Through tag sequencing we can look in more detail at these community changes and the role that the rare biosphere plays in microbial response to fertilization.

Bowen, A. S., Woods Hole Oceanographic Institution, Woods Hole, USA, abowen@whoi.edu; Lozier, M. S., Duke University, Durham, USA, sllozier@duke.edu; EXPORT PATHWAYS OF LABRADOR SEA WATER FROM THE SUBPolar NORTH ATLANTIC OBSERVED WITH RAFOS FLOATS.

The Deep Western Boundary Current (DWBC) in the North Atlantic has generally been considered the dominant export pathway for recently ventilated water masses from the subpolar to subtropical regions. Profiling float trajectories obtained in the 1990s seemingly contradicted this traditional view. To further explore the export pathways and their temporal variability, about 72 acousticallytracked RAFOS floats were sequentially released at the Labrador Sea lip (700 and 1500 m) in the DWBC near 50N in 2003-2006. To date, about two-thirds of the floats have surfaced, with the remainder due to complete their missions by November 2008. Remarkably, the vast majority of floats have been expelled from the DWBC into the ocean interior before reaching the Tail of the Grand Banks (42N). This expulsion occurs most often when the North Atlantic Current (NAC)oodle onto the continental slope, temporarily blocking the southward-flowing DWBC. Once offshore, many floats are carried eastward via the deep NAC toward or over the Charlie Gibbs Fracture Zone, while others drift southward west of the mid-Atlantic ridge, following an interior pathway to the subtropical region. Although these results challenge our notions of the DWBC as a continuous pipeline for newly formed water masses, they are consistent with transit time distributions estimated from tracer measurements.

Bowers, H. A., University of Maryland Biotechnology Institute, Baltimore, USA, bowers@umb.md; THE MANY APPLICATIONS OF REAL-TIME PCR IN THE HARMFUL ALGAL BLOOM WORLD.

Real-time PCR assays have revolutionized a broad spectrum of research areas by providing rapid and sensitive methodology for detecting a variety of targets in a suite of different environments. In particular, these techniques have advanced research on protists in several ways, including identification of unculturable organisms, detection of target species in heterogeneous environments, and aiding in laborious microscopic methods. Here, several applications to the study of harmful algal bloom (HAB) species will be described. Results from a long term monitoring program in the Chesapeake Bay will be presented. Real-time PCR assays have provided data for HAB species present during fish kills and have revealed temporal and spatial distributions of key species in the region. Studies combining real-time PCR with other methods (cell counting, flow cytometry) will also be described. Finally, real-time PCR data tracking parasite-host interaction throughout infection experiments and during bloom events will be presented. This sampling of studies supports the broad applicability of using real-time PCR to address various research interests.

Bowles, K. M., University of Georgia, Athens, USA, kloftis@uga.edu; EFFECTS OF PHYTOCHEMICAL AND MICROBIAL DEGRADATION ON CHEMICAL AND ISOTOPIC COMPOSITIONS OF LINNIN- DERIVED PHENOLS IN GEORGIA COASTAL MARSH PLANTS.

Our previous studies showed that chemical and isotopic compositions of lignin-derived phenols in marsh plants and surrounding sediments varied temporally and the variation between plants and the sediments were different. However, it is difficult to distinguish effects of multiple-source inputs vs. diagenesis on chemical and isotopic signatures of the biomarkers in the field. This study was designed to investigate effects of phytochemical and microbial degradation on the lignin-derived phenol compositions and their δ13C ratios in Georgia coastal marsh plants. Leaves of Spartina alterniflora (C3) and Juncus roemarianus (C4) were incubated in natural seawater under variable light/dark regimes over one year. Preliminary results indicated: (1) presence of light did not promote degradation of plant TOC and lignin-derived phenols; (2) bulk C/N ratios increased initially and decreased after three weeks; (3) major components (aldehydes, ketones, and acids) degraded...
differentially, leading to variations in molecular indices; (4) molecular δ13C ratios of lignin-derived phenols varied in a larger range (~3-5%) relative to those of bulk plant TOC.

ACTIVITY, DIVERSITY, AND RELATIVE ABUNDANCE OF SULFATE REDUCING BACTERIA IN OIL-RICH SEDIMENTS FROM A LOWER CONTINENTAL SLOPE GULF OF MEXICO COLD SEEP

Mississippi Canyon block 118 (MC118) is the site of an on-going, multidisciplinary study of a gas hydrate-rich cold seep. The northern section of MC118 is influenced by advection of gas-charged brine, whereas the southern section is influenced advection of oil and gas (no brine). The two sections are thus ideal for comparing microbial community composition and activity in sediments influenced by varying amounts and types of reduced substrates. Sulfate reducing bacteria (SRB) oxidize numerous hydrocarbons, including methane, higher alkanes and oil. Rates of sulfate reduction were two orders of magnitude higher in the oily sediments of southern MC118 than in the gasy sediments of northern MC118; oily sediments supported the highest sulfate reduction rate reported in cold seep sediments, 26.9 kmol cm-3 day-1. Integrated rates of sulfate reduction in both sections were ~3000 times greater than rates of anaerobic oxidation of methane, suggesting that SRB was fueled by oil and alkanes rather than methane. Microbial diversity of SRB populations was used to evaluate whether distinct microbial communities were present in the two sections.

SEDIMENT INTERACTIONS CONTROLLING GROWTH OF MODERN MARINE STROMATOLITES HIGHLBORNE CAY, BAHAMAS

At Highborne Cay, the well-laminated and easily accessible stromatolite buildups found along the margins of Exuma Sound, Bahamas, form in the back-reef of a 2.5km algal-ridge complex, accrete sediment more rapidly than the pure prokaryotic mats, and are predominantly dominated by filamental cyanobacteria. The prokaryotic mats are dominated by gliding filamentous cyanobacteria and are found chiefly on the low-lying, shallow stromatolite ridges. The mixed euakaryotic-prokaryotic mat communities, sediment-trapping diatoms overlaying sediment binding filamentous cyanobacteria, accrete sediment more rapidly than the pure prokaryotic mats, and are predominantly observed on the algal-ridge headstromatolites. The migration of sand waves across the stromatolite reef is a major control on the distribution of the microbial communities. These migrating sand waves bury and expose the reef episodically for periods of days, weeks, and months. Microbial growth and resultant stromatolite formation at Highborne Cay are controlled by the variations in the duration of these sedimentation events.

RELATIVE ROLES OF RECYCLING AND REMINERALIZATION OF UPPER OCEAN BIOMINERALIC PARTICLES FOR IRON BIOGEOCHEMISTRY

Recycling of particles in the surface mixed layer, and their subsequent remineralization in subsurface waters play important roles in the biogeochemical cycling of many elements in the ocean. The former process drives the regeneration of nutrients on short timescales, whereas the latter eventually increases the inventory of new nutrients deeper in the water column. In the case of iron, pelagic recycling by the biota spins the ‘ferrous wheel’, and remineralization at depth leads to iron re-supply to the subsurface ocean. However, the role of processes such as complexation or photochemistry on iron recycling and remineralization is less clear. Here, we present data on the rate of pelagic iron recycling, relative to that for particulate organic carbon, and the impact of remineralization on the re-supply of both iron and iron-binding ligands at depth in polar and subpolar waters south of Australia. A model of upper ocean iron particle transformations is used to explore further the relative roles of recycling and remineralization on iron biogeochemistry.

EDDIES OVER THE LOMONOSOV’ RIDGE: HORIZONTAL VARIABILITY IN THE THERMOCLINE OF THE CENTRAL ARCTIC OCEAN

Above the Lomonosov Ridge of the central Arctic Ocean is a frontal region between relatively warm, salty Atlantic water flowing cyclonically along the Eurasian side of the ridge and colder, fresher water on the Canadian side. Horizontal variability of this region is examined using CTD data from SCICEX submarine transects that were run across the ridge at fixed depth (214m) in the thermocline. Plots of horizontal density ratio derived from 35 cross-ridge transects run between 83 and 89 degrE on the Asian end of the ridge reveal two modes within the data, at density ratio ~ 1.3 and ~ 0.4. A large, relatively contiguous region of density ratio near 1 (similar to found elsewhere in the mixed layer) is associated with widespread diffusive convective steps above the depth of the Atlantic water core. Eddies of Atlantic water with length scales of 0.15km are found embedded within the high gradient region on the Canadian basin side of the front near 89 degrE. Eddy location appears to be related to underlying ridge bathymetry, suggesting a role for topography in eddy formation.

Bowle, E. A., Massachusetts Institute of Technology, Cambridge, USA, ebowle@mit.edu

VARIABILITY OF IRON IN THE UPPER OCEAN: A BARRIER TO EVALUATING THE ROLE OF Fe IN NITROGEN FIXING BLOOMS

Because nitrogen-fixing organisms require more Fe than other photoplankton, it has been hypothesized that blooms sometimes may be caused by iron from dust deposition events. Although there is evidence consistent with an association of N fixation with higher Fe (e.g. Mills et al., 2004), there are no documented cases where a nitrogen-fixing bloom clearly follows a dust deposition event. Here, I will use Fe data near Bermuda and Hawaii (BTM time-series mooring and shipboard upper water column profiles) to illustrate the problem. For example, in September 2004, a typical late summer Trichodesmium bloom was observed by satellite north of Hawaii. A shipboard cruise to the site showed ~0.2 nmol/kg surface Fe in the bloom. A shallow surface maximum (~0.5 nmol/kg) - and hence clearly a result of atmospheric deposition - was observed near station HOT (west of the bloom). In the blue water to the northeast of the bloom, Fe was ~0.2 nmol/kg. One could construct a story in which the bloom site originally had higher Fe that was removed during the bloom to levels typical of the blue water. But the story could also be that Fe had nothing to do with the bloom, at least not directly. Unless we have time series data preceding and during the bloom, we cannot know which story is correct. The demise of the MOSEAN and BTM biogeochemical moorings makes this impossible for now.

EVALUATION OF THE MEDITERRANEAN OUTFLOW WATER VARIABILITY IN NORTH ATLANTIC HYCOM SIMULATIONS

Several questions remain unanswered about the role and importance of the Mediterranean Overflow Water (MOW) for the Atlantic Ocean circulation and the global thermohaline circulation. Of particular interest is the temporal variability of the MOW and the mechanism(s) responsible for such variability on interannual and decadal scales. Specifically, we seek to determine the extent to which MOW variability is driven by buoyancy forcing changes within the Mediterranean Sea and/or determined by variability in the properties of the entrained waters. To answer this question, we investigate the variability of the MOW using a 1/3 North Atlantic configuration of the Hybrid Coordinate Ocean Model (HYCOM) forced by NCEP atmospheric forcing. The Mediterranean overflow is parameterized using the Price and Yang (1998) boundary condition, which allows for an accurate representation of the outflow properties. The MOW representation in experiments where the T/S properties are either fixed in the Atlantic and/or the Mediterranean are contrasted to a control experiment where the overflow properties are free to adjust.

DEVELOPMENT OF ESCAPE AND FREEZE RESPONSES IN JUVENILE COPEPODS

The ontogenetic escape development of escape responses of Eurytemora affinis, an estuarine copepod ubiquitous in Northern Hemisphere coastal waters, was studied with a focus on comparisons of behavior between nauplii and copepodite. Responses to brief hydrodynamic stimuli were recorded with high-speed 3-dimensional video micrographs. The lengths of stages from early nauplii (<.5 h post hatching or p.h.) to adult copepods (7-9 h.p.). Escape jumps and freeze responses were observed in all stages. These were quantified in comparison to normal, non-escape swimming behavior. Behavioral analysis showed a sharpening in sensitivity to stimuli to elicit an escape from early stage nauplii to early copepodite. Tenebrosa in freeze was much higher in deal stages and was observed in all stages at distances similar to non-responses, such as prior swimming patterns and orientation, in the animal’s discrimination between freezing and non-response. The retention of this freezing behavior over the life of the copepod implies some evolutionary benefit in predator avoidance.

WHICH FACTORS SHAPE BACTERIAL COMMUNITY STRUCTURE IN COASTAL PERMEABLE SEDIMENTS? Bacteria play important roles in the biogeochemistry of coastal sediments. However, factors governing benthic bacterial community composition are scarcely studied. We used automated rRNA intergenic spacer analysis (ARISA) to investigate seasonal and depth-related variability of the whole bacterial community structure on a shallow subtidal flat in the German Wadden Sea. The relationships between bacterial community data and associated sediment parameters were analyzed by redundancy analysis. ARISA community data revealed significant assemblage variations along sediment depth and over the entire sampling period. Sediment at 10-15 cm depth exhibited higher species richness than sediment at 0.5 cm or 5-10 cm depth. Time, depth, chlorophyll a, NO3, wind speed, P. glaucosidase activity and bacterial abundance accounted for 85.5% of the total variation in bacterial community structure. Partitioning of the biological variation revealed strong covariation of the factors depth, P. glaucosidase activity and sediment chemistry (NO3 and chlorophyll a). Also, a considerable part of the seasonal variation could be attributed to changes in total carbohydrate concentrations. Hence, sediment mixing and labile organic matter availability were the major drivers of bacterial diversity in this study.

THE OPTICAL PROPERTIES OF CDOM IN THE MEDITERRANEAN BASIN: EXPLORING THE ROLE OF PHYSICAL AND BIOLOGICAL FORCING. Chromophoric Dissolved Organic Matter (CDOM) regulates the radiative transfer of solar radiation in the water column and is the natural substrate for microbial communities. Data related to the ultraviolet absorption of dissolved organic matter were acquired in the Mediterranean basin. CDOM absorption (10 cm quartz cuvette) was modelled by a bi-aliquot analysis of absorption spectra. Higher spectral slope values were observed in the Mediterranean basin. CDOM absorption (10 cm quartz cuvette) was modelled by a bi-aliquot analysis of absorption spectra. Higher spectral slope values were observed in incoming freshwater. An empirical regression equation, using the percent cover of four different land cover types (coniferous forest, turf, agriculture and developed land), predicts 45 percent of the observed variability in freshwater CDOM concentration in these estuaries. This is nearly the same fraction attributed to cross-site variability. CDOM concentrations were linearly correlated with salinity in the shallow estuaries studied here, but the slopes were not constant over time in any of the estuaries examined. This makes salinity a poor proxy for CDOM over times scales of days or longer. Freshwater CDOM concentrations entering estuaries were highly variable, both among sites and over time within one site, while the seaward end members had fairly uniform CDOM concentrations. Although incoming CDOM concentration is highly variable over time, it is not well predicted by freshwater inflow and no seasonal pattern is apparent.

VERTICAL MASS EXCHANGE ACROSS SUBMERGED AQUATIC VEGETATION CANOPIES USING A NEW EDDY CORRELATION METHOD Hydrodynamics exert an important control on vertical nutrient and oxygen exchanges across submerged aquatic vegetation canopies. Field studies that quantify and parameterize the exchange dynamics are lacking because simultaneous measurements of the controlling physical variables and the mass fluxes are difficult to acquire. Eddy correlation methods are used extensively in the terrestrial science community to model the vertical exchange of heat, water vapor and CO2 fluxes across plant canopies. Here we present an eddy correlation method for measuring vertical mass transport across submerged canopies using injected Rhodamine dye as a tracer. High frequency measurements of the dye concentrations entering and exiting the canopy were obtained with a fiberoptic spectrometer with the probe mounted adjacent to the control volume of an Acoustic Doppler Velocimeter. We describe the method and its validation in flume experiments, method limitations and field applications.

NATURAL FLUCTUATIONS IN COASTAL HYPOXIA: RELATIONSHIPS BETWEEN LARGE-SCALE CLIMATE DRIVERS AND OXYGEN LEVELS RECORDED IN SEDIMENT CORES FROM PUGET SOUND Coastal estuarine systems are often limited to increasing anthropogenic nutrient loading. While this cause-effect relationship holds true for many coastal regions, the Pacific Northwest also receives nutrient-rich waters from coastal upwelling. The relationship between large-scale hydrographic cycle, such as the Pacific Decadal Oscillation (PDO), and the historical record of hypoxia for circa 400 years were evaluated. Paleoclimatological tracers used to reconstruct the record included identification of diatom and foraminifera fossils, pollen, stable isotopes of carbon and nitrogen, biomarkers for terrestrial/marine carbon, and metals that are enriched in sediment during periods of low/no oxygen. Sediment core profiles indicate periods of hypoxia are recorded in the sediment as early as the 1700s. The record...

COMPOSITION OF NEAR-SURFACE PARTICULATE MATTER IN THE NORTH SEA EXAMINED BY NANOSCALE X-RAY SPECTROMICROSCOPY
Coastal regions receive an ever-increasing input of nutrients and anthropogenically-derived organic matter as human populations have expanded along coastal regions. There is considerable evidence that inputs of plastics, combustion-derived organic materials and other contaminants have significant impacts upon coastal ecosystems. How these inputs interact with the carbon cycle, especially in regards to fate(s) of particulate organic matter, remain obscure. We examined suspended organic matter collected from a coast to open ocean transect in the North Sea to examine the influence of Anthropogenic inputs on the composition of this carbon pool. Soft-X-ray Spectromicroscopy, a technique which allows for the identification and quantification of all carbon types within samples at 50 nm resolutions, was employed to examine these samples. The results indicate that, in addition to expected contributions of marine organisms and their remains, significant amounts of micron-sized soot and plastics are found in surface organic particulates. Suchrecalcitrant phases are unlikely to be quantified by laboratory techniques commonly used by organic geochemists. Overall compositional patterns indicate that these non-biogenic organic matter phases can travel significant distances from coastal sources.

COMBINING OCEAN COLOUR SATELLITE OBSERVATIONS WITH COASTAL OCEAN BIOGEOCHEMICAL MODELS IN THE TROPICAL FITZROY RIVER ESTUARY
In the tropical Fitzroy Estuary and Keppel Bay system (FEKB) contingent to the Great Barrier Reef lagoon, we tested how to combine ocean colour datasets with coastal ocean biogeochemical models. As the global algorithms failed for the FEKB system, a new generation of regional specific algorithm was developed for large satellite datasets of the MODIS sensor. Concurrently, a biogeochemical model was developed for the system, built upon a three-dimensional hydrodynamic and sediment dynamic model, and simulating nitrogen and phosphorus dynamics including the dynamics of dissolved organic material as well as pelagic and benthic primary production. Several methodologies for linking of remote sensing observations to model variables were evaluated over a period of one year (2004). After an initial comparison of the model output with satellite datasets using the region-specific algorithm, the effects on simulated concentrations of TSS and CHL of forcing boundary conditions using satellite data was evaluated. The satellite observations were also used to supplement in situ data to improve calibration and parameterisation of the sediment model. Combining remotely sensed observational data into biogeochemical and sediment transport models improved both the models and our ability to interpret the practical significance of the satellite data. Future work will include the direct assimilation of observational data, where available, across the model domain

IMPROVING THE PARAMETERIZATION OF ERRORS STATISTICS FOR DATA ASSIMILATION IN A HYCOM BAY OF BISCAY REGIONAL CONFIGURATION
The SEEK filter (Brassée and Verron, 2006) filter is a sequential method used to assimilate observations into circulation models such as HYCOM. This study focuses on the parameterization of error statistics, usually estimated under assumptions that appear too irrelevant to ocean dynamics. The SEEK has been adapted to a HYCOM model of the Bay of Biscay, nested in a North Atlantic configuration (Broquet et al., 2007). An ensemble method is proposed to provide realistic model error statistics, considering that the imperfect determination of surface fluxes and open boundary conditions are the main error sources. Model error statistics, observability and controllability are characterized using representers, revealing the complex, inhomogeneous and anisotropic response to perturbations in the forcings. In addition, the SEEK filter is modified to incorporate inequality constraints during the assimilation process, assuming that the errors are distributed as truncated Gaussians. This new feature is shown suitable to maintain positiveness of model variables such as layer thickness. Data assimilation experiments with the SEEK filter using these new parameterizations show decisive statistical and physical improvements when compared to more classical schemes.

STEEL AGE AND SALINITY GRADIENTS IN SUBMARINE GROUNDWATER MEASURED IN A SMALL CHESAPEAKE BAY TRIBUTARY
Submarine groundwater discharge (SGD) into Maryland’s Chesica River estuary was investigated as part of a larger study to determine the importance of nutrient delivery to Chesapeake Bay via this pathway. Experiments performed included continuous resistivity profiling (CRP), piezometer sampling, seapage meter measurements, and collection of a radon tracer time series. Results from a detailed study site show a shallow plume of terrestrial groundwater (salinity <15) located within 2 m of the estuary floor and extending >17 m offshore, which is overlain by a thin and variable brackish zone. Deeper low-salin- ity groundwater extends >200 m offshore based on CRP data. Groundwater and surface water were sampled for analysis of nutrients, stable and radioactive isotopes, age tracers, and microbes. Tritium data indicate that young groundwater discharges near shore, but that the age of groundwater increases with depth and distance offshore. Discharge rates were highly variable and strongly influenced by astronomical and wind-driven tides. Better understanding of the distributions of age and chemical composition in groundwater discharge areas such as this could lead to improved models and mitigation strategies for estuarine nutrient over-enrichment.

TRAPPING BOPYRID ISOPOD CRYPTONISCONS FOR TAXONOMY
The northeast Pacific bopyrid isopod crustaceans Ione cornuta Bate, 1864 and Orthione griffenis Markham, 1904 parasite, castrate and sometimes control the populations of their estuarine shrimp hosts. The epicaridian, microniscan and cryptoniscan larval stages have not been described for any eastern Pacific bopyrid because large morphological differences between bopyrid larval stages and the reproductive stage preclude taxonomy by simple, direct comparisons. The inability to distinguish species of bopyrid isopod larvae has precluded most research on their ecology, geography and dispersal. Unidentified reproductive I. cornuta and O. griffenis females transplanted in their hosts, in-situ, were used to attract and, positively identify the cryptoniscans. The trapping method for resolving cryptoniscan taxonomy opens bopyrid larvae for study in marine and estuary ecosystems.

FINE- TO BASIN-SCALE DISTRIBUTIONS OF CALANUS FINNMACRICUS AND ITS PREDATORS IN WILKINSON BASIN, GULF OF MEXICO DURING DECEMBER 1998 AND 1999 FROM VPR DATA

The calanoid copepod Calanus finnmacrincus diapauses in the deep basins of the Gulf of Mexico during late-summer through early-winter. During diapause, predators that co-occur in regions of high copepod abundance may reduce survivorship through predation. Consequently it is important to measure the distribution patterns of C. finnmacrincus and its predators. Two cruises were carried out during the winters of 1998 and 1999 in the Gulf of Mexico. Video Plankton Recorder (VPR) data collected in Wilkinson Basin were used to describe the fine- to basin-scale distribution patterns of C. finnmacrincus and its predators. The locations of individual zooplankton were mapped by towing a VPR, mounted on the towed-body BIOMAPER-II, across the basin. Volumetric distribution patterns were estimated by interpolated abundance data using 3D kriging. The abundance of Calanus was lower in 1998 than in 1999 and this difference is discussed in terms of the spatial distributions and abundances of ctenophores, echinoderms, and crustacean predators.

DO NORTH ATLANTIC RIGHT WHALES COMPENSATE FOR INCREASES IN SHORT TERM AMBIENT NOISE?

Low frequency anthropogenic noise contributes to habitat degradation of the critically endangered North Atlantic right whale (Eubalaena glacialis) by masking acoustic vocalizations. Studies in other mammals have described various compensating mechanisms that allay these affects, including the Lombard effect and frequency shifts. We investigated whether the Lombard effect, an increase in vocalization intensity, and frequency shifts, where signal frequency changes to minimize spectral overlap with background noise, were present in the vocals of two North Atlantic right whale. To test for the Lombard effect, we investigated the relationship between apparent call source levels and ambient noise levels - derived from one second clips before each call. We did not find a statistically significant correlation. To test for frequency shifts, we compared the 1/3 octave bands of calls made at low, moderate, and high ambient noise levels over a range of 15 dB re 1 µ-Pa2/Hz. We found a significant amount of energy in the harmonics of the upcall, regardless of ambient noise level. Our analysis did not statistically support the presence of the Lombard effect or frequency shift as short-term compensation mechanisms, heightening the sensitivity of this species and the need to mitigate anthropogenic impacts.

INFLUENCES OF THE ORINOCO RIVER PLUME IN THE BALANCE BETWEEN PLANKTON PHOTOSYNTHESIS AND RESPIRATION IN THE CARIBBEAN SEA

Planktonic production, respiration and ETS were measured along the Orinoco River Plume dispersal axis (10.3°N-17.6°N) during fall, its maximum outflow season. Planktonic primary production, respiration and ETS were measured along the Orinoco River Plume dispersal axis (10.3°N-17.6°N) during fall, its maximum outflow season.

Feeding occurs through much of the temperate waters of the North Pacific and undergoes zonal feeding migrations across the entire basin. Oceanic habitat accuracies and timing of immigration and emigration into the Eastern North Pacific have not been studied. We used albacore logbook CPEU data for 1999 through 2004 stratified by month, latitude, and longitude (33,662 records) along with satellite-derived environmental variables (Reynolds SST, SeaWIFS SSChl, AVISO SSH, and ERS-1 and QuikSCAT-derived wind stress curl). CPEU was mapped for the main fishing season (May–October) overlaid on environmental maps, and environmental records were extracted for each catch location where fishing occurred using both positive and zero sets. The optimum range (mean and variance) of each variable was estimated based on catch and CPEU was related to all environmental variables using GAM modeling by month. We plotted binary prediction map of distributional range of this species based on optimal habitat for each month and year. Catch varied significantly between years and all four environmental factors were related to the distribution of albacore in this region.

PERSISTENT BEACH MEGACUSPS CONTROLLED BY HYDRODYNAMIC FEEDBACKS AROUND NEARSHORE BATHYMETRY: KITTY HAWK, NC

Understanding spatial variations in alongshore beach and nearshore morphology, such as the formation and disappearance of megacusps and shore-oblique bars, may contribute to our ability to predict anomalous shoreline change rates associated with erosional hotspots. Numerical “forced” models, driven by standing edge waves, and “free” models, driven by atmospheric forcing from random waves, however, are unable to predict 3-D alongshore variations in post-storm bar and beach evolution. Bar and Swash Imaging Radar (BASIR), a mobile x-band radar system, was used to investigate the development and evolution of megacusps in Kitty Hawk, NC. The megacusps were found to be relatively stable through varying energy conditions, and their location correlated with bathymetric features of a nearshore shore-oblique bar field. In addition, wave run-up in the swash zone and wave parameters in the nearshore were investigated to identify the spatial variations in hydrodynamics induced by the shore-oblique bar field. We suggest that the location of these megacusps in Kitty Hawk, NC is neither random nor forced, but is instead controlled by small-scale hydrodynamic alternations created by the shore-oblique bar field.

OBSERVATIONS OF THE INTERNAL TIDE ENTERING MONTEREY CANYON

Internal tides in Monterey Submarine Canyon have been shown to propagate up-canyon from an energy source in deeper waters, but this source has remained somewhat of a mystery. Recent numerical simulations of the Monterey Bay and the nearby shelf and slope (including the canyon) suggest an internal tide source some 40 km to the south at a submarine ridge off Point Sur. We report on a 2006 field survey during the ONR AESOP experiment using a combination of ship-launched, free-falling and expendable measurements of velocity and temperature between this ridge and the canyon, focusing on the plateau midway between the two. Semi-diurnal tidal analysis reveals a northward internal wave energy flow toward the canyon dominated by the first baroclinic mode but also containing complex vertical and horizontal structure. Comparisons with tide-resolving models and ray-tracing calculations are used to investigate this structure.

EXPLORE THE FUTURE OF U.S. OCEAN TIME SERIES

A key issue in oceanography is distinguishing between short-term seasonal or annual variations and longer-term changes in response to natural or anthropogenic forcings. To quantify the temporal variability in the ocean basins, the United States established a number of ocean time series (TS) sites. The Scientific Steering Committee of the Ocean Carbon and Biogeochemistry Program has formed a subcommittee to review three TS sites - Hawaii Ocean Time-Series (HOT), Bermuda Atlantic Time Series (BATS) and Carbon Retention In A Colored Ocean (CARIACO, in collaboration with Venezuela). The subcommittee was charged to assess the importance of TS and to facilitate communication and consistency between the three TS sites under review. Most importantly we must determine the future needs of the oceanographic community for TS observations. Do we need additional measurements at existing sites? How should new technologies be incorporated in the TS program (e.g. gliders and moorings)? Do we need additional TS sites? If yes, where should they be and how will we pay for them?
Invasive species often compete with native species for resources e.g. space, and can alter community structure. Temperature effects on the distribution of marine invasive species are often unknown yet are critical to determine their spread. We used heat rates of four colonial ascidians to associate species (Botryllus schlosseri, Didemnum sp., Botryoides violaceus, and Diplosoma liestoni) as a proxy for health and growth. Heat rates and growth rates correlated with increasing temperature for Botryllus schlosseri, Botryoides violaceus, and Diplosoma liestoni, but not Didemnum sp. Heat rate was determined to be a good indicator for health for all species, and was also a good indicator for growth within a species, but not between species. For example, Botryllus schlosseri had a higher Botryllus schlosseri, but slower growth than Botryoides violaceus. The goal of this study was to determine if increasing temperatures could facilitate the spread of invasive colonial ascidians into colder waters.

The oceanic response to the large riverine flux was examined using SeaWiFS ocean color data of river discharge. The irritation might be due to abrasion or a reaction to bottom sediments present in much of the St. Lucie estuary. Controls revealed abnormalities in gill structures suggestive of irritation from sediments. Analysis of tissues of selected abnormal fish and outwardly normal fish selected as “controls” revealed abnormalities in gill structures suggestive of irritation from sediments. The experiments, which resolves continental slopes, indicate that i) the inflow and outflow are separated in space and do not affect each other to any large degree, ii) the inflow of warm Atlantic water decreases with increasing freshwater forcing but remains, nevertheless, powerful even for very strong freshwater forcing, iii) inflow and outflow of water takes place more or less at same depth level.

The PREVALENCE OF ABNORMAL FISH AS AN INDICATOR OF ENVIRONMENTAL QUALITY

A 9-yr survey of fish in the St. Lucie Estuary system, Florida, and nearby estuarine systems indicated that the prevalence of fish with abnormalities varied by species, system, and part of the system. Prevalence was greater in the St. Lucie compared to the reference systems and greater in the estuaries compared to the inlets. Abnormality prevalence varied over time, reaching an all-time peak in the double-strike hurricane year, 2004, and declining subsequently to the lowest rate observed in the first half of 2007 during a drought. Data summarized by a 3-month period, the prevalence of abnormal fish was negatively related to salinity and negatively related to visibility. Microscopic analysis of tissues of selected abnormal fish and outwardly normal fish selected as “controls” revealed abnormalities in gill structures suggestive of irritation from sediments. These gill abnormalities were present in more than half of the fish examined. Haddock bottom trawls present in much of the St. Lucie estuary are easily resuspended by freshwater discharges and storms. The irritation might be due to abrasion or a reaction to sediment-associated contaminants.

SURPRISING RESULTS OF CDOM PHOTOOXIDATION IN THE BERING SEA: IMPLICATIONS FOR FOOD WEBS

Chromophoric dissolved organic matter (CDOM) absorbs biologically damaging UV radiation in aquatic systems and can provide organic carbon to the microbial community. In past studies, sunlight exposure decreased CDOM absorption of UV independent of source suggesting that sunlight destroys the double bonds in humic substances. On a Bering Sea cruise during the spring bloom (May 2007), we exposed temperature-controlled, water samples to sunlight while monitoring the UV-B dose ( Integrating the effect of the spring bloom, because of diminished ice, will likely alter the pelagic and benthic components of the food web in the Bering Sea.

The emergence of the Arctic Mediterranean, which has dual buoyancy forcing of the basin. The Arctic Mediterranean, which has dual buoyancy forcing, with gently sloping side walls and strong dual buoyancy forcing forms the basis of the study. The experiments, which resolves continental slopes, indicate that i) the inflow and outflow are separated in space and do not affect each other to any large degree, ii) the inflow of warm Atlantic water decreases with increasing freshwater forcing but remains, nevertheless, powerful even for very strong freshwater forcing, iii) inflow and outflow of water takes place more or less at same depth level.

INTERPRETATION AND APPLICATIONS OF SECOND ORDER VARIABILITY IN SATELLITE OCEAN COLOR: THE ROLE OF NON-ALGAL MATTER AND BACKSCATTERING

Empirical algorithms, based on first order relationships between ocean color and chlorophyll concentration ([Chl]; mg m⁻³), are widely used, but do not explain the statistical dispersion (referred to here as anomalies) around the mean trends. We use an empirical approach that removes the first order effect of [Chl] from satellite ocean color imagery, allowing us to observe the influence of other optical constituents and their distributions, which may vary independently of [Chl]. We then present statistical and modeling analyses to interpret the observed anomalies in terms of their optical sources (i.e. absorption and backscattering). With this information, we can examine the global distribution of anomalies in non-algal colored matter, particularly colored dissolved organic matter, and backscattering by particles, which displays significant regional and seasonal trends. We also estimate the backscattering coefficient of particles, and compare our results with other published studies. Potential applications of our results include independent comparisons with inverse models of ocean color and simple corrections for empirical [Chl] algorithms.

The oceans are the dominant source of atmospheric methyl iodide (CH$_3$I), however mechanisms responsible for its production are poorly understood. Experiments were conducted in the laboratory to determine whether Prochlorococcus marinus is a significant global producer of CH$_3$I. CH$_3$I production was measured over time (approximately 30 days) in sealed culture vessels containing P. marinus using purge and trap methods in combination with gas chromatography mass spectrometry (GC/MS). During lag phase, high light adapted P. marinus species (CCMP1986) produced 1.8 x 10$^{-11}$ pmol CH$_3$I cell$^{-1}$ day$^{-1}$, while low light adapted P. marinus (CCMP1427) produced 3.2 x 10$^{-11}$ pmol CH$_3$I cell$^{-1}$ day$^{-1}$, with the lowest CH$_3$I production measured during log phase. The results of this study indicate that Prochlorococcus marinus is a significant global producer of CH$_3$I in the ocean and should be considered in models of CH$_3$I production and atmospheric concentrations.

MAPPING OF HYPOXIC ZONE IN THE MISSISSIPPI RIVER IN THE SUMMER OF 2006 Based upon detection of near-hypoxic waters in early August 2006, two cruises were conducted mid-August to sample a grid of 22 sites south of the Mississippi barrier islands. The prime objectives were to map the extent of the hypoxic region along with the physical environment (temperature, salinity, and currents), Profiles of dissolved oxygen, temperature, pressure, conductivity, turbidity, and currents were measured at each station. Oxygen was measured using YSI 6300 and Sea-Bird SBE 43 probes. Salinity and dissolved oxygen concentrations were measured with a YSI 6820. Bottom-water hypoxia was detected by hydrocasts at seven stations, extending seaward to ~20 m water depth near artificial fishing reef FH2 and extending along the 10-m isobath from Ship Island to Petit Bois Pass. Winkler analyses confirmed hypoxia at four of these stations, with the other three having values ~2.8 mg/L. Eleven stations had values ~3.0 mg/L. The water column was highly stratified throughout the region in some cases with several pronounced pycnoclines consistent with isolation of bottom waters from the oxygenated surface waters.

OCEAN LITERACY ALLIANCE - HAWAII: ESTABLISHING A FRAMEWORK FOR COLLABORATION

The ocean environment is central to many science, technology, engineering, and mathematics (STEM) education initiatives in Hawaii. To ensure the greatest possible success for these activities and to minimize duplication of efforts, we must create new avenues for collaboration among key stakeholders, including scientists, educators, and government-organized programs. Toward this end, we recently founded the Ocean Literacy Alliance - Hawaii. Sponsors include the federal Interagency Working Group for Ocean Education (IWG-OE), National Science Foundation, National Oceanographic and Atmospheric Administration (NOAA), and numerous partners from the University of Hawaii. Our overarching goal is to establish a framework for collaboration in ocean science education in Hawaii. At the inaugural workshop (November 2007), participants review ongoing efforts, strengthen existing collaborations, and develop strategies to build new partnerships. A key outcome will be a resource guide for ocean science education in Hawaii, which we offer as a national model.

COMBINING FLOW CYTOMETRY AND REAL-TIME PCR TO DEMONSTRATE PHAGOTROPHY IN THE TOXIC HAPTOPHYTE PRYMNESIUM PARVUM Studies with phagotrophic organisms are limited by a series of methodological constraints. To overcome problems related to the detection and enumeration of prey fed upon by mixotrophic and heterotrophic organisms, we combined flow cytometry with the sensitivity and specificity of a real-time PCR assay. Flow cytometry was used to detect and score feeding Prymnesium parvum cells based on the fluorescence of the prey (Rhodomonas sp.) as well as for detection of food vacuoles labelled with a pH dependent acidotropic dye, Rhodamine 123. In addition, flow cytometry was used to separate and sort Prymnesium parvum cells from Rhodomonas sp. cells. The sorted cells were collected for DNA extraction and a TaqMan real-time PCR assay: The Ct (cycle threshold) values of Rhodomonas sp. signal from the sorted Prymnesium parvum cells decreased over time, corresponding with the decrease in the ingestion rates calculated based on the flow cytometry results, suggesting that flow cytometry and real-time PCR is a powerful and fast method to confirm phagotrophy among mixotrophic algae.

THE GLOBAL OCEAN TRANSIT TIME DISTRIBUTION COMPUTED WITH AN EDDY RICH GENERAL CIRCULATION MODEL Transit time distributions (TTDs), or age spectra, provide a powerful conceptual framework for evaluating and interpreting the advective-diffusive transport properties of geophysical flows. Most calculations and practical applications of TTDs to date have considered only the case of steady circulations with parameterized turbulent mixing. We are computing the global ocean TTD for the unsteady, but statistically stationary, flow using an ensemble of impulse boundary propagators in an eddy-rich general circulation model. In this presentation we provide an overview of the structure of the computed TTD, consider the convergence properties of the TTD as a function of ensemble size and time-space coarsening, and consider the utility of TTDs as a metric for testing eddy mixing parameterizations in coarse resolution models.

AN OPERATIONAL ARRAY FOR MONITORING THE ATLANTIC MERIDIONAL OVERTURNING CIRCULATION AT 26Â°N The first objective of the RAPID programme is to establish a pre-operational prototype system to continuously observe the strength and structure of the Atlantic meridional overturning circulation (MOC). Observing the Atlantic MOC is the fundamental observational requirement of a programme of research into the Atlantic thermohaline circulation (THC) in climate. The Rapid-MOC array measures: 1. Gulf Stream transport through Florida Strait by cable and repeat direct velocity measurements; 2. Ekman transport by satellite scatterometer; 3. deep western boundary currents by direct velocity measurements; 4. basin-wide interior baroclinic circulation from moorings measuring vertical profiles of density at the boundaries and on either side of the Mid-Atlantic Ridge; and 5. barotropic (reference level) fluctuations using bottom pressure recorders. The system first became operational in late March 2004 and is expected to continue until at least 2014. We show that the zonally integrated meridional flow tends to conserve mass, with the fluctuations of the different transport components largely compensating at periods longer than 10 days. We take this as experimental confirmation that the Rapid array is measuring the MOC.

IRON AND SILICON CO-LIMITATION IN THE EQUATORIAL PACIFIC The roles of Si and Fe as limiting nutrients in the equatorial Pacific were investigated in December 2004 and September 2005 between 100Â°W and 140Â°W longitude. The results of nine mesocosm experiments showed that additions of silicon augmented diatom production and cell division. However, in the Fe-enriched cultures Si uptake was limited, which suggests that the addition of Si to iron-limited cultures may have a stronger effect on phytoplankton growth than addition of Fe. Baines et al. (2007) also found that iron and silicon co-limit growth in some regions of the equatorial Pacific. We conclude that iron and silicon co-limit growth in the equatorial Pacific.

OPERATIONAL OCEAN MODELING AT THE NAVAL OCEANOGRAPHIC OFFICE The Naval Oceanographic Office (NOAVECOANO) provides the Navy with a suite of operational circulation and wave forecast products ranging from the global ocean through the coastal regions to the surf zone. These models forecast ocean properties in 3 dimensions over 27 hours, and all products are updated daily. A number of observation data sources, including sea surface temperature and alitimetry; fixed and floating buoys; aircraft, autonomous profiling systems; and a rowing fleet of gliders, provide real-time data for model assimilation and assessment. NOAVECOANO models rely on atmospheric forcing from Fleet Numerical Meteorology and Oceanography Center (FNMOC). They run on high-performance mainframe computers managed by the DoD’s High Performance Computing Management Office. We will discuss how NOAVECOANO receives, formats, quality controls, archives, and delivers these data; the infrastructure at NOAVECOANO to moves data and products; the resources required; and some of our products. Our tasks extend beyond
Aerosol iron solubility continues to be the subject of intense research because of its importance to the biogeochemical cycling of iron. There have been a variety of analytical methods employed to measure iron solubility producing a wide range of results while evidence of an overarching factor governing iron solubility remains elusive. The goal of this research is to determine what relationship exists between particle size and aerosol iron solubility. The samples described here were collected during summer 2003 over the North Atlantic. Also reported are samples collected from the North Pacific Ocean during summer 2004 and spring 2006. A Multi-Orifice Uniform Deposition Impactor (MOUDI) was deployed during these cruises to collect size-fractionated aerosol samples using a low-volume sampling system. The samples were leached with ultrapure water and the leach solution analyzed by high-resolution ICP-MS to determine the soluble iron fraction. The filters were subsequently analyzed by energy dispersive x-ray fluorescence to measure the insoluble iron fraction. In general, most of the soluble aerosol iron is found on particles between 1 and 3 microns in diameter. Samples collected from within the Saharan Dust Plume do not show any clear increase in the fractional solubility of iron with decreasing particle size. This work will also report the fractional solubility of iron for samples collected in other regions of the North Atlantic, as well as from the North Pacific.

THE BIOGEOCHEMISTRY OF IRON AND COPPER IN ANTARCTIC PENINSULA SHELF AND ANTARCTIC CIRCUMPOLAR CURRENT WATERS IN THE SOUTHERN DRAKE PASSAGE

Samples for dissolved and leachable particulate iron and copper concentrations, as well as for iron and copper speciation, were collected in austral winter 2006 from the southern Drake Passage. These sites were chosen as they document an intensive exchange of watermasses out into low iron Antarctic Circumpolar Current (ACC) waters. Complementary incubation experiments were employed to investigate sources, bioavailability, and photoactivity of strong iron-organic complexes using 57Fe as a stable isotope tracer with added strong organic ligands. The physico-chemical speciation of dissolved iron and copper in all samples and through the entire iron and copper system was examined using competitive ligand and adsorptive cathodic stripping voltammetry (CLE-ACSV) with the added ligand salicylaldehyde. Dissolved and leachable particulate metal concentrations were measured using high-resolution inductively coupled plasma mass spectrometry (HR-ICP-MS) techniques.

VERTICAL STRUCTURE OF MASS AND TURBULENCE IN SEDIMENT-LADEN CHANNEL FLOWS

Suspension-laden flows affected by buoyancy stratification occur in rivers, lakes, and coastal regions during episodic floods, storm surges, and spring tides. We report new observations of the vertical structure of sediment mass and fluid momentum in laboratory channel flows transporting high-density suspensions, and which are thus subjected to buoyancy stratification. Thus far, we have conducted three series of experiments at flow speeds of up to 1.0 m/s in a paddle-driven, open-channel flume: 1) clear-water flows, 2) under-capacity flows with average concentrations of up to 35 g/l of 37-micron silicon carbide, and 3) capacity flows with average concentrations of up to 56 g/l of 75-micron silicon carbide and 52 g/l of 37-micron silicon carbide. Results of our experiments indicate that sediment-laden flows, at undercapacity and thus not significantly affected by bedforms, have a higher velocity, a reduced Reynolds stress, and a reduced vertical velocity fluctuation (w') than clear-water flows at the same nominal paddle speed. These results are consistent with existing notions that high-density sediment suspensions reduce bed friction and suppress vertical turbulent mixing in transporting channel flows.
The portraits of oceanic transport patterns in the Indo-Pacific have been a subject of considerable interest. The zonal (IODZM) and meridional (ENSO) variations have been the focus of much research. In this study, we aim to better understand the internal wave generation mechanisms, local beam overturning, and far field low vertical modes in the Luzon strait. For this purpose, experiments conducted in a laboratory are compared with solutions of the non-hydrostatic version of the Regional Ocean Modeling System (ROMS). In the laboratory experiment a Gaussian mount, representing Lam Yu ridge in the Luzon strait, is oscillated horizontally in a stratified water body. In the ROMS experiment a Gaussian mount is also used, however with real-world dimensions. To facilitate a better comparison between the experiments, non-dimensional parameters such as the excitation parameter, slope parameter, and Froude number are equalized. The experiments are conducted for single and multiple forcing frequencies, various tidal amplitudes, different stratification, and varying bathymetries. Preliminary results indicate a relatively good agreement between the experiments in the locations of the internal wave beams and the phases of the velocities along the beams.

ESTIMATING DECadal CHANGES IN ANTHropogenic CARBON in the INDIAN OCEAN using FCFS and SULFUR HEXAFLUORIDE

As part of the CLIVAR Global Repeat Hydrography Program, a meridional hydrographic section was occupied in the Indian Ocean in 2007, nominally along 85-95oS from 65oS to 26oN. The 2007 section repeated a section occupied in 1995 as part of WOCE. In addition to the suite of WOCE physical and chemical measurements made on both occupations, measurements of dissolved sulfur hexafluoride (SF6) were made coincident with the Chloufrosorubins (CFCs) on the 2007 section. The tracers provide information on the rates and pathways of ventilation in this region, and changes in surface forcing (e.g. anthropogenic carbon dioxide, temperature, salinity) can propagate into the interior of the ocean on decadal time scales along this section. The use of two complementary tracer transients provides information on the impacts of mixing on tracer-derived ages, and on changes in tracer ages. Significant changes in CFC concentrations, CFC-derived ages, and dissolved inorganic carbon (DIC) concentrations were observed between 1995 and 2007 along the section. We used the SF6 measurements and a simple modeling approach to estimate the impacts of mixing on observed tracer-derived water mass ages and changes along the section. The combined CFC and SF6 data also were also used to constrain the transit time distributions (TTDs) and uptake of anthropogenic CO2 in the waters of this region.

INTERNATIONAL VARIABILITY OF SEA SURFACE SALINITY from ARGO PROFILES and HYCOM SIMULATIONS in the TROPICAL INDIAN OCEAN

The Argo salinity profiles and the 1/12° global Hybrid Coordinate Ocean Model (HYCOM) simulations during January 2002 - February 2007 are analyzed to understand the interannual variability of Sea Surface Salinity (SSS) in the tropical Indian Ocean. We have selected 2 boxes located in the eastern equatorial Indian Ocean (EIO: 5 S-5 N, 90 -95 E) and Southeastern Arabian Sea (SEAS: 5 -9 N, 72 -76 E). The HYCOM SSS at the Argo float's location compared well with Argo SSS in each box. HYCOM SSS lies within the range of Argo SSS in all the years, except in 2006 when the positive Indian Ocean Dipole/Zonal Mode (IODZM) event developed off Sumatra. In the EIO box, Argo SSS dropped sharply from April to December 2006 giving rise to peak interannual Sea Surface Salinity Anomaly (SSA) of -4.9 in December 2006. This anomalous SSA is related to the advection of low salinity waters from the eastern Bay of Bengal into the EIO due to the anomalous surface circulation during IODZM 2006. In the SEAS box, more freshening (negative SSA) is noticed during January - February 2006 prior to the IODZM 2006 that developed off Sumatra coast during July - December 2006. In contrast to the negative SSA variation in the EIO box, the SSA is more positive in the SEAS during IODZM period.

ASSESSMENT OF INDICES OF INTERANNUAL and INTERDECADAL VARIABILITY in the EQUATORIAL PACIFIC

The equatorial Pacific is vast and few long monthly records of climate variability exist. One record is the more than 150 year long record of the sea surface temperature (SST) index NINO3.4, based on the analysis by Kaplan et al. (1998). Another, since 1883, is the Tahiti minus Darwin Southern Oscillation Index (SOI) and a third is the O19, coral proxy of NINOS3.4 SST from Palmyra (Cobb et al. 2003). These records are closely related physically and therefore should be highly correlated. Decadal and longer variability of NINOS3.4 and SOI indices agrees well after 1950 (r=0.92), but not before 1950 (r=0.12). The correlation, which does not care about imprecise measurements before 1950, shows that both the NINOS3.4 and the SOI decadal indices may be in error before 1950 because both individually are well correlated with the coral after 1950, and less so before 1950. We have used an improved data set (Rayner et al. 2005) and constructed equatorial SOI and night time air temperature series over the NINOS3.4 region to obtain better agreement before and after 1950.

EVIDENCE FOR ATMOSPHERIC VARIABILITY OVER THE PACIFIC ON DEcadAL TIMESCALES

An index of Pacific decadal variability (PDV) based on a multivariate empirical orthogonal function (EOF) analysis of NCEP reanalysis is used to extract associated signals in satellite-based measurements of atmospheric parameters. This index captures the 1975-1977 ENSO-like warming shift of sea surface temperatures (SST) as well as a more recent transition of opposite sign in the 1990s. Utilizing satellite measurements of water vapor, wind, precipitation, long-wave radiation, as well as surface observations, our analysis evidences evidence of the atmospheric changes that accompanied ENSO-like inter-decadal SST changes. Our analysis suggests changes in atmospheric circulation, forced in the tropics, effect near-southern subtropical SSS via changes in water vapor, clouds, and radiation, with no indication in the wind speed that these changes are due to changes in the regional heat flux. Together, these results suggest that there are decadal-scale changes in the atmosphere involving circulation, water vapor, clouds and radiation that may play a role in PDV, and are worthy of further study.

COMPARISON of TIDAL CURRENTS in the H UDSON RIVER DURING SPRING and FALL 2006

NOAA's National Current Observation Program deployed 20 bottom-mounted acoustic Doppler current profilers at 10 stations during both the spring and fall of 2006. Moorings spanned the length of the upper river from Poughkeepsie to the locks at Troy at 15 to 30 river kilometers spacing. Data collected was used to investigate the influence of freshwater flow on tidal currents in the Hudson River as requested by the Hudson River Pilots. A long-term station was placed at the George Washington Bridge to determine tidal forcing near the mouth of the river. Tidal currents were semidiurnal and rectilinear. In the spring, the flow tends to decrease flood speeds and increase ebb speeds by about 15 cm/s on average at 5 meters depth. This results in delaying the slack before flood and advancing the slack before ebb 15 to 45 minutes. These speed and timing effects increase from the midriver to the locks. Results of the harmonic analyses and the nonlinear influence on the variability of the resultant harmonic constituents are presented.

ASSESSING the DRIVING FORCES of Submarine GROUNDWATER DISCHARGE

Submarine groundwater discharge (SGD) represents an unquantified pathway for nutrients and other dissolved constituents from land to the coastal ocean. It is now recognized that a considerable amount of seawater, in addition to terrestrial freshwater, is also recirculated through coastal aquifer systems. However, we still lack an adequate understanding of the relative importance of SGD driving processes. Predictive capabilities require a higher level of insight than is now available. We have been evaluating SGD forcing parameters at the Northwest tip of Mexico by a combination of long-term radionuclide measurements, hydrogeological/geochemical investigations, and numerical modeling. Our results indicate that tidally-driven seawater recirculation accounts for ~95% of the fluid flow through these sediments. Numerical modeling and field assessments show that the total (fresh and saline) 24-hour average flow per meter width of shoreline ranges from ~5 to 85 m3/day
with higher flows during spring tides and wet periods. If SGD nutrient fluxes from this site are extrapolated to the Florida Gulf coast, they are comparable to regional rivers, although SGD likely accounts for only a small amount of "new" nutrients.

MANAGING MANGANESE IN DRINKING WATER: AN ASSESSMENT FOR MICROBES AND METALS

Manganese can be released and cause aesthetic problems in the drinking water systems worldwide. The relationships between metals and microbes; at the sediment-water interface; have already been established to assess microbiological implications in natural water systems. Studies have been conducted on the oxidation and reduction of manganese by microbes, but their implications in drinking water systems have not been understood thoroughly. Five microbial strains that were recovered from the filtration and sedimentation basins of a water treatment plant in Blacksburg, Virginia were selected to conduct this research. The strains were found to be capable of performing oxidation of Mn (II) to Mn (IV) when inoculated in a Mn-oxidation selective broth medium. Mn (II) present at concentrations equal or less than 0.05 mg/l in the broth medium used for this study had no effect on the growth of the five strains evaluated. Mn(II) inhibited growth of these strains when present at a concentration of 0.08mg/l. The results from this research suggest that microbial manganese oxidation takes place in drinking water systems and that it could encourage manganese being released and deposited.

ROLE OF SALINITY ASSIMILATION IN A HYBRID COUPLED MODEL FOR THE TROPICAL PACIFIC

With the ever-increasing number of Argo data, the targeted launch date of Aquarius in March, 2009 and the soon-to-be available Soil Moisture and Ocean Salinity (SMOS) satellite observations in fall 2008, important work still needs to be done to investigate the impact that salinity will have on ENSO forecasts. In previous work, we have shown that assimilation of salinity along with other key variables improves the initial state and the ENSO prediction (e.g. Hackert et al., 2007). For example, retrospective hindcasts of subsurface temperature along the thermocline, sea level in the western Pacific, and SST in the NINO3 region are all improved when assimilating salinity. Here we will present results that show that Ensemble Reduced Order Kalman Filter (EROKF) data assimilation of salinity leads to more accurate ocean forecasts using a Hybrid Coupled Model (Zhang et al., 2006). In particular, we will show results of sea level, SST and zonal wind stress for recent El Nino cases (1997, 2002 and 2006).

CARBON DIOXIDE AIR-SEA FLUX PATTERNS IN THE NORTHEAST PACIFIC: 1993-2007

Air-sea carbon dioxide flux estimates for the coastal Northeast Pacific have been highly variable and uncertain. By analyzing data collected over the last 14 years in a region extending from Vancouver Island to the Baja California Peninsula and extending out 300 km from the North American coast, we will attempt to reduce this uncertainty and explain the patterns and variability seen in sea surface pCO2 measurements. This is the most comprehensive set of pCO2 measurements gathered for this area, taking data from fixed moorings and shipboard observations. Seasonal variability within 150 km of the coast is largely dominated by wind-driven coastal upwelling, while seasonal temperature cycles are primarily responsible for offshore variability. Multi-year variation is primarily due to the El-Nino Southern Oscillation. Additionally, we expect that the North-South gradient of pCO2 can be partially explained by the level of preformed nitrogen in upwelling source waters resulting from lateral differences in initial water mass formation. Despite periods of high sea to air CO2 fluxes in the Northeast Pacific coastal region, the overall net air-sea CO2 flux appears to be nearly balanced.

SATELLITE-BASED MEASUREMENTS OF OCEAN CLIMATE VARIABILITY IN THE AGULHAS CURRENT SYSTEM

Interzone leakage from the Agulhas Current constitutes an important pathway in the Atlantic meridional overturning circulation. As this Indian Ocean source of thermocline and intermediate water is saltier and warmer than Pacific Ocean waters entering via the Drake Passage, the characteristics and volume of the Agulhas leakage will influence global salt and heat balances; it thus constitutes a significant benchmark of ocean climate. Occurring over fairly large spatial scales, the Agulhas leakage demonstrates significant temporal and spatial variability on the mesoscale, presenting difficulties for in situ sampling programs. Satellite altimetry provides one of the most promising sources of observations for monitoring such oceanic variability and its long-term trends. We investigate the Agulhas leakage and evaluate our ability to measure it with satellite altimetry. Our study synthesizes information from the Jason and T/P altimeter missions and profile data. Historic profiles are combined into a streamfunction climatology, allowing heat, salt, and mass transports to be estimated from steric height in the study region. These are compared with in situ estimates from a recent field program, the Agulhas-South Atlantic Thermohaline Transport Experiment (ASTTEX).

UNLOCKING ROLE OF THE EAST CHINA SEA CURRENT SYSTEM IN THE COCHLODINIUM POLYKRIXIOIDES BLOOM CONUNDRUM OF THE SOUTH EAST OF KOREA

The first severe Cochlodinium polykrikoides harmful algal bloom occurred in the coastal waters of the South Sea of Korea in 1995. Surprising this red tide started offshore, unlike most algal blooms which commonly start in eutrophic coastal waters. Its subsequent development and movement towards the shore caused US$95.5 million losses in the Korean aquaculture industry, including the devastation of coastal fin-fish and shellfish farms, and devastating natural ecosystems. Recent red-tide blooms have become an annual summer-mertime event since the 1995 outbreak, causing massive marine organism mortalities and considerable financial losses. In this study, we suggest a possible hypothesis for the mechanism responsible for annual summertime Cochlodinium polykrikoides red-tide bloom outbreaks in the South Sea of Korea (SSK). We explain the main outbreak processes in the SSK through a large-scale understanding of the summer current circulation system of the East China Sea from observed data and a model simulation combined with information on the ecological and physiological characteristics of C. polykrikoides.

MECHANISMS OF INTERANNUAL VARIATIONS OF THE MERIDIONAL OVERTURNING CIRCULATION OF THE NORTH ATLANTIC OCEAN

We investigate the nature of the interannual variability of the meridional overturning circulation (MOC) of the North Atlantic Ocean using an ECCO (http://www.ecco-group.org) assimilation product for the period of 1993-2003. The time series of the 1st Empirical Orthogonal Function (EOF) of the MOC is found to be correlated with the North Atlantic Oscillation (NAO) index while the associated circulation anomalies correspond to cells extending over the full ocean depth. Model sensitivity experiments suggest that the wind is responsible for most of this interannual variability, at least south of 40N. A dynamical decomposition of the meridional stream function allows us to look further into the mechanisms. In particular, we examine the contributions associated with (1) the Ekman low and its depth-independent compensation, (2) the vertical shear low, (3) the barotropic gyre lowing over zonally varying topography. The Ekman dominates shorter time scales (1.5 - 3yr) while vertical shear is important for longer time scales (>10yr). The latter is primarily caused by heaving of the pycnocline in the western subtropics associated with the stronger wind forcing.

POPULATION DYNAMICS AND NUTRITIONAL VALUE OF EPHITIC ALGAE IN ARTIFICIAL REARING PONDS ASSOCIATED TO THE REINTRODUCTION OF THE PUERTO RICAN CRESTED TOAD

Bufo lemur is the endemic toad of Puerto Rico. This species was declared endangered in 1987. To assist in its recovery, five rearing ponds were built during 2005-2006 as part of the species reintroduction program. Three rearing ponds are located in the north (Arecibo) and two in the south near Coamo and Guimimas, Puerto Rico. This research focuses on the nutrition requirements of Bufo lemur’s tadpoles during rearing. We will assess the nutritional value of periphrayan, the major observed food source of the Bufo lemur tadpoles. For a period of two months, four of the five artificial rearing ponds will be examined for algal biomass growth (as ash-free dry mass and chlorophyll a) and community composition. Nutritional analyses of the periphyton (dry matter, fiber, crude protein, amino acids, fat, pigments, fatty acids, macro and micro minerals) will also be performed. The results from this study could be used to improve the feeding of B. lemur tadpoles raised in captivity and could also improve the environmental conditions of the rearing ponds in Puerto Rico.
SURFACE AND SUBSURFACE GEOSTRICTIC CURRENT VARIABILITY FROM ALTIMETRY

Satellite altimetry data from TOPEX/POSEIDON and Jason-1 were used in conjunction with GRACE geoidal data as well as historical hydrographic profiles from the World Ocean Atlas 2009 to calculate the mesoscale and submesoscale currents at the surface and subsurface levels in the Indian Ocean basin during Indian Ocean Dipole periods: 1994-95, 1997-98, 2002-03 and 2006. The results of this method were validated with currents measured with Acoustic Doppler Current Profiler (ADCP) moorings. The measured and computed currents compared reasonably well. Seasonal features such as the Wyrtki Jets and Equatorial Undercurrents are visible in the computed currents. The purpose of this study is to observe the influence of the Indian Ocean Dipole on subsurface circulation.

THE EVOLUTION OF COASTAL OPTICS ASSOCIATED WITH A TURBID PLUME AND FEEDBACKS ON NEARSHORE PHYSICS

The optical properties associated with a turbid coastal plume and their feedback on nearshore physics and ecosystem dynamics are examined using a three-dimensional bio-physical model.Visible satellite imagery of the New York-New Jersey Bight in April 2005 shows distinct regions of highly turbid water of differing optical properties associated with the Hudson River plume, bulge and coastal current circulation driven by a freshwater discharge event in excess of 4000 m$^3$ s$^{-1}$. Water types characteristic of the river plume and open shelf are parameterized as variable light attenuation length scales, and simulations of April 2005 conditions are evaluated against field observations in terms of upper ocean temperature structures, baroclinic circulation and biological productivity. Increases in chlorophyll concentration in the upper water column decrease the transmission of light and result in a change in water temperature. Compared with the open shelf, the river plume simulations result in a deeper and warmer surface mixed layer (~1 m), a sharper temperature gradient, colder bottom water and enhanced productivity, highlighting the importance of biogeochemical feedbacks on nearshore physics in coastal systems.

SPATIAL AND TEMPORAL VARIABILITY OF CARBON DIOXIDE SIGNALS AND THE BIOGEOCHEMICAL CONTROLS IN THE SOUTH ATLANTIC BIGHT

The US South Atlantic Bight is shallow and the water column is generally vertically well mixed. The system has abundant inputs from rivers and salt marshes on the landside and active exchanges with the Gulf Stream on the seaside. We synthesize the inorganic carbon records based on six cruises of regional measurements of pH, pCO$_2$, DIC, TALK and DIC-δ13C. pCO$_2$ show dramatic seasonal and spatial variability, particularly in the inner shelf, as results of sharp changes in temperature and terrestrial inputs. DIC production as a result of organic carbon remineralization in the inner shelf and its biological removal in the mid and outer shelf as well as in the surface slope water also show large seasonal and spatial variability. We discuss the seasonal, cross-shelf, and alongshore variability of surface water pCO$_2$, DIC dynamics, and the underlying biogeochemical controls using field data and simple model analysis. The carbon cycling pattern and the underlying bio-geochemical driving forces revealed here may have broad implications to research in other western boundary current shelves.

QUANTITATIVE DETERMINATION OF COLLOIDAL ORGANIC PHOSPHORUS IN RIVER WATER AND SEAWATER FROM THE GULF COAST REGION

The abundance and variations of colloidal phosphorus (both inorganic/organic) in natural waters remain largely unknown. Samples were collected from the Mississippi River (MR), Pearl River (PR, Mississippi), and Bay of St. Louis (BSL) for ultrafiltration and measured. The concentration of inorganic phosphorus (CIP) was negligible in the MR and BLS (3%), although CIP became significant in the PR, a forested, black water river (~3%). In contrast, CIP dominated in the bulk DOP pools as high as 50-87% with the highest abundance in the PR, followed by BSL and MR. Measurable CIP in the PR likely resulted from pedogenic sources. High CIP abundance in both freshwater and seawater points to the importance of colloidal phase in the biogeochemical cycling of phosphorus in aquatic environments.

DEVELOPMENT OF A PALEO-ICE DURATION PROXY IN THE BERING SEA: PRELIMINARY RESULTS BASED ON DIATOM ASSEMBLAGES AND SEDIMENT GRAIN SIZE

The dramatic reduction in ice extent seen this summer in the Arctic Ocean highlights the need to understand natural rates of change of declining sea-ice extent and duration. To address this, we are developing a quantitative proxy for paleo-ice duration in the Bering Sea. A suite of surface sediments taken onboard the USCGC Healy 0601 and 0702 expeditions from a grid of stations across a gradient of sea-ice duration (historically ranging from four to nine months of ice cover per year) were analyzed for sediment grain size and diatom assemblages. These sites were then combined with a diatom assemblage dataset of surface sediments previously taken from the Bering Sea (Sancetta, 1982). This combined dataset now includes sites representative of a full sea-ice duration gradient (zero to twelve months of ice per year). Several methods of machine based learning will be applied to the dataset to correlate these and other surface sediment variables (including diatom assemblages and morphometry, sediment grain size, and the concentration of an organic compound associated with sea ice diatoms) with mean annual duration of sea ice.

A CHARACTERIZATION OF BENTHIC MACROFAUNAL COMMUNITIES PRESENT AT ANTRHOPOCENICALLY IMPACTED ENVIRONMENTS WITHIN NARRAGANSETT BAY, RI

Benthic communities were examined over a six year period along a gradient of anthropogenic stress in Narragansett Bay, RI. Historic models of faunal succession describe predictable changes in the structure of benthic assemblages with spatial or temporal distance from a disturbance. These models have been repeatedly tested and appear to be universally applicable for most physical, chemical, or biological disturbances in littoral soft-bottom habitats. Benthic infaunal communities present at four depositional environments within the upper Narragansett Bay were characterized and inter-station differences in species composition and abundance were examined. Our analysis has identified significant anthropogenic impact on the structure of benthic macrofaunal communities of Narragansett Bay. The magnitude of this impact was greatest in Mt. Hope Bay where exposure to multiple stressors has resulted in persistent low faunal diversity characteristic of early stages of species succession.Mirroring what was expected based on historic models; the successional status of benthic assemblages in Narragansett Bay was found to be inversely proportional to the gradient of anthropogenic stress and this relationship appears to have persisted over time.

FEATURE-ORIENTED REGIONAL MODELING AND SIMULATIONS (FORMS) FOR THE WESTERN SOUTH ATLANTIC, SOUTHEASTERN BRAZIL REGION

The multi-scale synoptic circulation system in the southeastern Brazilian (SIBRA) region is presented using a feature-oriented approach. Prevailing synoptic circulation structures, or “features”, are identified from previous observational studies. These features include the southward flowing Brazil Current (BC), the eddies off Cape Sapo Tome (CST) and off Cabo Frio (CF), and the upwelling region off of CST. Their synoptic water-max (T-S) structures are characterized and parameterized to develop temperature-salinity feature models. Following the Gangopadhyay et al. (2003) methodology, a synoptic initialization scheme for feature-oriented regional modeling and simulation (FORMS) of the circulation in this region is then developed. First, the temperature and salinity feature-model profiles are placed on a regional circulation template and then objectively analyzed with available background circulation data. These initialization fields are then used for dynamical simulations via the Princeton Ocean Model (POM). A combination of different feature models and climatology fields were then used to dynamically understand the relative importance of baroclinic and barotropic instability mechanism for the growth of the BC meandering. Our future plan includes the application of these feature models with satellite, in-situ data and advanced data assimilation schemes.

A CHARACTERIZATION OF BENTHIC MACROFAUNAL COMMUNITIES PRESENT AT ANTRHOPOCENICALLY IMPACTED ENVIRONMENTS WITHIN NARRAGANSETT BAY, RI

Benthic communities were examined over a six year period along a gradient of anthropogenic stress in Narragansett Bay, RI. Historic models of faunal succession describe predictable changes in the structure of benthic assemblages with spatial or temporal distance from a disturbance. These models have been repeatedly tested and appear to be universally applicable for most physical, chemical, or biological disturbances in littoral soft-bottom habitats. Benthic infaunal communities present at four depositional environments within the upper Narragansett Bay were characterized and inter-station differences in species composition and abundance were examined. Our analysis has identified significant anthropogenic impact on the structure of benthic macrofaunal communities of Narragansett Bay. The magnitude of this impact was greatest in Mt. Hope Bay where exposure to multiple stressors has resulted in persistent low faunal diversity characteristic of early stages of species succession. Mirroring what was expected based on historic models; the successional status of benthic assemblages in Narragansett Bay was found to be inversely proportional to the gradient of anthropogenic stress and this relationship appears to have persisted over time.
ited to coarse size particles having the material properties of quartz immersed in water. However, in the grain size analysis of coarse to fine sand the grain-grain interactions transition from being best described as inertial to viscously damped. As grain size is decreased further to clay-size particles, electrostatic forces of attraction and repulsion become dominant. Additionally, one might include the influence of biogeochemical effects from polymers and polysaccharides, among others. Likewise, shear induced lift forces need to be accounted for to produce suspended loads with fine grains. Here we propose a new modeling framework based on DPM for sediment transport in heterogeneous environments that uses a multi-scale, multi-physics approach. Specific improvements include adding a shear induced lift term and modeling viscous dissipation at grain-grain contacts through an effective coefficient of restitution as a function of Stokes number. Comparisons are made with laboratory U-tube measurements for bulk transport rates and time-dependent concentration profiles.

GENERATION OF SUBMESOSCALE VORTICITY FILMMENTS AND THEIR IMPACT ON PRIMARY PRODUCTIVITY IN AN ISLAND WARE

Strong mesoscale eddies are characteristic in regions of large Eddy Kinetic Energy. Elongated submesoscale filament are generated by the straining of the eddying flow and affected by their interaction with the wind field and topographic features. Such filament are associated with large vertical velocities and can act as important pathway for the vertical exchange of fluid between the nutrient-rich waters below the euphotic zone and the sun-lit upper ocean. The steep topography of the Hawaiian Island chain, located in an oligotrophic region far from the inshore influence of strong spatially varying and temporally varying wind forcing, make it an ideal site for a systematic study of the generation of submesoscale features and their environmental impact. Previous model results show an asymmetric behavior between cyclones and anticyclones (Calil et al. 2007). Cyclones break down into vorticity filaments as they evolve while anticyclones maintain their coherence and strength for longer times. Large strain and relative vorticity rates, as well as nonlinear Ekman and advective effects, play an important role in such behavior. Model simulations at higher resolutions and subject to different forcing fields will be used to investigate the potential role of environmental factors in generating submesoscale vorticity filaments. Implications for mixing will be evaluated through the use of Finite-Size Laxunum Exponents. Coupled biological models will be used to understand the potential effects on the Biology.

RESPONSES OF BENTHIC MACROFAUNA AND BIODIGEOCHEMICAL FLUXES TO VARIOUS LEVELS OF MUSSEL BIODEPOSITION: AN IN SITU BENTHOCOSM EXPERIMENT

An in situ experiment was done to determine the influence of differing levels of mussel biodeposition on the structure of sandy benthic communities and bicochemical fluxes. Natural benthic communities within sediment cores (benthocosms) were exposed in situ over 50 days to 7 different levels of mussel bio-deposition. Although bio-deposition rates increased linearly with mussel density, sediment % organic matter was not correlated to mussel density. Despite the high variability between replicate samples, macrofaunal community showed trends in relation to increased bio-deposition. Important increases in the abundance and biomass of opportunistic species (Capitella sp.) were observed in the benthocosms exposed to the greatest bio-deposition. Sensitive species (e.g. Tellinula ovalis) tended to decrease in abundance and biomass with increasing mussel density. Benthic organisms may have contributed to the recycling of organic biodeposits. Oxygen consumption, ammonium, phosphate and nitrite fluxes did not vary significantly between treatments. Only the flux of silica was positively correlated to bio-deposition. This study presents some useful information on the dose-response relationship (bio-deposition - benthic communities and bicochemical fluxes) to help set mussel production density limits to ensure that the environmental carrying capacity are not surpassed.

NUMERICAL MODELING OF CROSS-SHORE SEDIMENT TRANSPORT AND SEASONAL BAR MIGRATION EVENTS

The cross-shore sediment transport on a barred beach is studied by a numerical model. The goal is to make simulations of morphological evolution on a seasonal time scale for onshore and offshore bar migration events. The numerical model consists of a spectral wave driven, REF/DIF/S - a quasi-3D nearshore circulation model, SHORECIRC, and a generic energetics based sediment transport model. Simulations are based on a series of nearshore field tests conducted near Grays Harbor, WA in which monthly nearshore bathymetric surveys show the onshore migration of the sandbar during spring 2001. The model is used as a profile model by excluding the longshore variations and successfully replicates the behavior of the bar between monthly surveys. We have shown in a previous study that wave skewness is one of the mechanisms contributing to onshore bar migration. This study extends the analysis for the effect of wave skewness to much longer time scales. The model is also used to help understand the mechanisms of sediment transport causing the migration of the bar by analyzing the effects of waves, currents and bed slope.

SYNOPTIC ANALYSIS OF CORAL HABITATS AND COASTAL OCEAN CHEMISTRY TO INFORM REEF CONSERVATION IN PACIFIC PANAMA

Pacific coral habitats were surveyed to chemically characterize euphotic zone water masses while studies of naturally occurring patterns of reef architecture, diversity, and benthic morphology. Multi-scale, spatially contiguous data were collected in the Gulf of Chiriqui using conventional SCUBA methods in concert with a towed chemical sensor platform and a stereo camera dive sled. Acoustic bathymetry, 3-D optical imaging, in-situ underwater mass spectrometry, CTD, chlorophyll, and CODM, coupled with precision navigation, enabled high resolution comparisons of coastal and island habitats. Salinity/ CDOM / CH4 / CO2 relationships suggest abrupt, complex mixing of terrigenous and anthropogenic input near oligotrophic waters being mitigated by cold, hypsalsine pulses that potentially affect sessile assemblages. Spatially dense chlorophyll data collected over 300km transects permitted thorough SeaWiFs ground-truthing. Chemical measurements and reef mosaics were integrated into a GIS to create thematic water chemistry and benthic habitat maps for the Republic of Panama. Ecological information was extracted in order to identify threatened areas and prioritize conservation objectives for surrounding islands and coastal marine provinces outside of the protective domain of Coiba Island National Park, a UNESCO World Heritage Site.

TRAINING THE NEXT GENERATION OF OCEAN SCIENTISTS: AN UPDATE ON THE MASTER OF GEOSCIENCES CERTIFICATE IN OCEAN OBSERVING SYSTEMS AT TEXAS A&M

Many important global issues facing oceanographers, such as climate change, maintaining healthy ecosystems, and sustainable use of marine resources, require long-term observations. Therefore, there is a need for trained professionals knowledgeable in oceanography, in situ ocean observations, remote sensing technologies, data analysis and display (including geographic information systems and remote database administration), analytical techniques and modeling tools, and who can and do operate the ocean observing systems of today and the future. The mission of the Master of Geosciences-Ocean Observing Systems Certificate program at Texas A&M University is to provide a fundamental understanding of oceanography and the statistical and technical training. The two-year 24-credit-hour program consists of five foundation courses and three elective courses. The training program in Ocean Observing Systems is interdisciplinary and includes: in situ ocean observations, remote sensing technologies, data analysis and display, geographical information science (GIS), as well as numerical modeling. To date, we have graduated our first class of students. The program offers the student scientific and technical expertise, thereby targeting a major obstacle in recruiting, and retaining U.S. workers for technological and operational careers, such as ocean exploration.

A COUPLED AIR/OCEAN/WAVE MODELING SYSTEM - DEVELOPMENT AND CASE STUDY

Using the Earth System Modeling Framework (ESMF) a coupled air/ocean/wave modeling system has been developed. The system integrates the atmospheric model from the Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS®) together with the NRL Coastal Ocean Model (NCOM) and WAVESATIVIII into a single executable application. The exchange of fields between the components, which execute on non-overlapping sets of processors, is handled by the reordering and inter-processor communication methods provided by ESMF. Details of the implementation of the coupled system are presented along with results for two region test cases.

VORTEX DYNAMICS AND ENERGY DISSIPATION IN OSCILLATORY FLOW PAST COMPLEX BOUNDARIES

The interaction of oscillatory flows with obstacles is a predominant scenario in coastal hydrodynamics. Coherent vortical structures are ubiquitous in these flows, and their dynamics affect fundamental problems such as sediment transport, wave energy dissipation and pollutant dispersal. In this study, the transition towards three-dimensionality and turbulence is investigated experimentally in the moderate Reynolds number regime, 100
CALDEIRA, K.

Comparison of the theoretical and simulation results shows a good agreement.

Meso-scale topography conditions, mean currents and surface forcings. The numerical experiments were performed in a channel with a wide range variability in the mesoscale kinetic energy (and therefore, mesoscale diffusivity) reaches its maximum in mesoscales in the ML is a critical problem for coarse resolution OGCMs. In the ML, Eddy-resolving computations by Oschlies (2002) show that mesoscale eddies affect the... potential to provide insights about the biogeochemical sources, transformation, and fate of organic matter, which are critical for understanding the effects of natural and human potential to provide insights about the biogeochemical sources, transformation, and fate of organic matter, which are critical for understanding the effects of natural and human-induced environmental change. In this session, we will present a review of recent advances in the development of new biomarker tools including: (1) the use of intact polar lipids for tracing microbial sources of organic matter; (2) the use of δ7D, δ13C and δ15N stable isotopes with organic biomarkers, and new methods for characterizing polar constituents associated with dissolved organic matter. Additionally, we will describe new applications of classical biomarkers to research questions in the fields of ecology, biogeochemistry, geochemistry and paleo-studies.

MODELING MESOSCALES IN THE MIXED LAYER

Eddy-resolving computations by Oschlies (2002) show that mesoscale eddies affect the depth of the mixed layer (ML) by inducing a strong re-stratification. Thus, modeling mesoscales in the ML is a critical problem for coarse resolution GCMs. In the ML, the mesoscale kinetic energy (and therefore, mesoscale diffusivity) reaches its maximum which makes the widely used tapering schemes unphysical. We have developed a dynamical mesoscale model for the ML as an extension of the mesoscale model previously developed for the deep ocean, and which has no adjustable parameters. The new ML model was validated using fine resolution (4km horizontal, 40-50 vertical levels) simulations with more than 40 numerical experiments under different conditions and situations. Most of the numerical experiments were performed in a channel with a wide range variability in initial, lateral and bottom topography conditions, mean currents and surface forcings. Comparison of the theoretical and simulation results shows a good agreement.

OCEAN ACIDIFICATION, CORAL REEFS, AND CO2 STABILIZATION

When atmospheric CO2 dissolves in the ocean, it increases the concentration of hydrogen ion (H+ or pH), which acts to decrease the concentration of carbonate ions. This decrease in carbonate ion concentration decreases the saturation state of calcium carbonate minerals including aragonite, the material of which coral skeletons are made, posing significant risks to their survival. Here we predict ocean chemistry conditions for existing coral reef locations and conclude that the chemical environment associated with pre-industrial coral reefs is disappearing rapidly as atmospheric CO2 concentration increases. Before the industrial revolution, more than 98% of corals reefs were found in waters that were >3.5 times saturated with respect to aragonite. If atmospheric CO2 is stabilized at 550 ppm, there will be no place left in the ocean with such aragonite saturation levels. Temperature, light, and other environmental factors affect coral growth. Nevertheless, the loss of ocean water with high aragonite saturation is cause for concern.

Spatial and Temporal Variation in Primary Production in the Lower Mississippi River

Although the Mississippi River is the largest river in North America, relatively little is known about the potasposkinni community metabolism. This research investigated temporal and spatial patterns in phytoplankton biomass, primary production, and plankton respiration in the Lower Mississippi River. The study occurred over a twenty month period at two locations approximately 420 river km apart. Every 2-4 weeks, we measured primary production at a series of light levels from which production versus irradiance (P-I) curves were generated. From these P-I relationships, and data for photic zone depth, surface light intensity, biomass, and algal and bacterial respiration, we created a model for autotrophic and respiration and production for a representative segment of river water. Variations in phytoplankton carbon flux across time and location are compared.

Role of Frontogenesis in Energy Transfers at Ocean Surface

Recent observations have shown that surface oceanic flows at mesoscales are associated with an inverse kinetic energy (KE) transfer, which contradicts standard arguments of quasi-geostrophic turbulence. Here we demonstrate that Surface Quasi-Geostrophic dynamics (SQG) may explain this behavior. SQG is the QG representation of mesoscale flows near vertical boundaries. In this system, the nonlinear transfers of surface KE promote an inverse cascade. However, they are locally compensated for by a KE source. This source can be linked to the surface frontogenesis mechanisms and to conversion of potential to kinetic energy at smaller scales. We provide evidence from numerical simulations of SQG and primitive equations models that this mechanism is relevant for the ocean.

DIATROPHS AND DIATROPH OF THE MEDITERRANEAN DYNAMIC SITE Nitrogen fixation has been implicated as a factor leading to anomalies in nitrogen stable isotope distributions and nitrate and phosphate ratios in the Mediterranean basin. However, there are relatively few studies which have provided direct observational data for the presence and activity of diatrophs. During three cruises to the central Mediterranean DYNAMED time-series station between Nice and Corsica, in Oct 06, Jan and Jul 07, we collected samples to enumerate and identify diatrophs by microscopic and molecular methods and to calculate rates of nitrogen fixation at several depths and in different size fractions in the upper water column. An experiment testing the response of nitrogen fixation to phosphate additions was also carried out. Nutrient concentrations were generally low (about 1 uM in Jan) to unmeasurable in the upper water column in July. nifH sequences were amplified from about half the samples and are being sequenced for identity. The distributions of diatrophs will be considered in relationship to the observed rates.

USING QUIKSCAT SURFACE WIND MEASUREMENTS TO UNDERSTAND WIND SPEED VARIABILITY AND SURFACE FLUX IMPLICATIONS

Surface momentum and energy fluxes are non-linearly dependent on wind speed and are thus sensitive to its distribution. Our sensitivity studies have detected large momentum flux increases from using wind speed PDFs versus means. When accounting for feedbacks, significant surface flux changes are realized. Thus, neglecting to represent sub-grid scale winds within a GCM can lead to surface flux and climate biases. We have conducted an unprecedented wind speed PDF comparison between QuikSCAT and a state-of-the-art GCM. Our findings include positive mean wind speed biases in the northern hemisphere trades and southern hemisphere storm tracks. Seasonally-persistent negative shape and mean wind speed biases were found along the ITCZ. Parameterizing...
wind speed variability using an empirical formulation reduced these GCM biases. A wind speed PDF converted from this formulation has a high degree of stability from one wind speed categorical improvement. Thus, the breadth of this physically-based wind speed PDF will be a function of turbulence kinetic energy. We hope to improve the modeled PDF with respect to observations in regions where modeled and observed mean wind speeds agree.

ENHANCED OPTICAL COMMUNICATION THROUGH THE SEA-AIR INTERFACE

For Homeland Security, AUVs have been developed with advanced sensors to acoustically and optically inspect our ports, harbors, and infrastructure. Optical and acoustic imagery from such systems must be rapidly classified, implying that high-rate data streams are required. Target ports can be frequency-saturated in the radio frequency (RF) spectrum, but optical communications may be effectively employed to provide data links in port-security operations. For an optical link to be practical in such an application, it must support communications with both above water and underwater systems. Maintaining reliable optical communications through the air-sea interface is challenging due to ever-changing surface characteristics. We present one option for establishing an optical data link which mitigates the effects of waves diverting optical beams, with an aerial platform relaying signals to the home base. We discuss a beam-redundancy method that has demonstrated an improvement in data transmission rates across the sea-air interface by a factor of three during daylight. We also discuss a spatial-filtration method that is expected to increase the signal-to-noise ratios, and thus data rates, by at least another factor of ten.

PRELIMINARY ASSESSMENT OF STREAM GEOCHEMISTRY IN WEST CENTRAL NICARAGUA DURING BASEFLOW CONDITIONS

A series of water samples was collected from streams in west-central Nicaragua at the end of the dry season in April, 2007. Filtered samples were analyzed, using ion chromatography and ICP-OES, for major cations, anions and nutrients. Streams in volcanic watersheds had lower mean Ca2+ and Mg2+ concentrations and slightly higher Ca/Mg ratios than streams in marine carbonate rocks. Dissolved Si concentrations averaged 1.12 mM L-1 in the 15 streams sampled, indicating a very high degree of silicate mineral weathering. Mean Si, Ca, and Mg concentrations in these streams are higher than those measured in volcanic rock dominated watersheds in Panama and in first and second order streams flowing through basaltic in Costa Rica. These differences may reflect the lithologies and the ages of the rocks. N/P molar ratios vary from 6.4 to 1 in the Nicaraguan stream waters, suggesting these streams may be N-limited. In general, the highest phosphate concentrations were associated with lower CI values, implying that at least a portion of the P is derived from chemical weathering sources, although anthropogenic sources cannot be ruled out.

A NEW GLOBAL CLIMATOLOGY OF OCEAN TEMPERATURE AND SALINITY STATISTICS FOR DATA ASSIMILATION

A global ocean temperature and salinity climatology was developed as a replacement for the Navy's GDEM and MODAS climatologies. Designed to cover both shallow shelves and deep water, the new climatology is constructed from both temperature-only profiles (XBTs and AXBTs) and profiles having both temperature and salinity and is designed to minimize errors in vertical gradients caused by construction of historical profiles having a large range of terminal depths. Used operationally, it supports explicit construction of profiles as functions of geographic position, depth, time of year, and any subset of the following: mixed layer depth, surface temperature, surface salinity, and geopotential anomaly. It also provides the required statistical relationships and fields of expected errors to support data assimilation by optimum interpolation or 3-D variational methods. Robust
The Arctic climate has changed dramatically within the last several decades, but the effects of these changes on Arctic marine ecosystems remain largely speculative. Observation of ecosystem responses to decadal-scale climate variations (i.e., oscillations) may help elucidate the impact of climate change on the structure and function of these ecosystems. We analyzed annual growth and shell mineral contents (Mg, Sr, Ba, Mn) of the circumpolar Greenland cockle, Serripes groenlandicus and linked their patterns to environmental variations in the Norwegian-Russian Arctic area of the Barents Sea. The dataset comprises 53 individuals from different regions of the Barents Sea and Svalbard and spans 117 years (1878–1995). Absolute growth rates differed among regions, reflecting overall differences in environmental conditions, but at all sites growth had an oscillatory pattern alternating between above and below average growth on a decadal scale. Mineral ratios elucidate seasonal and interannual patterns, reflecting different ecological controls. Preliminary analyses reveal that growth rates of bivalves in the Pechora Sea are strongly and negatively correlated to the North Atlantic Oscillation Index (NAO), indicating mechanisms of bio-physical coupling in the region.

COASTAL TRENDS ISSUES AND THE FORMATION OF SCIENCE-EDUCATION PARTNERSHIPS

From catastrophic storms to sea level rise and rapidly eroding shorelines, to harmful algae blooms, expanding dead zones and declining fisheries, we are becoming increasingly aware of our changing coastal oceans and how they impact our lives. Although we find these and other disturbing trends in the coastal ocean featured every day in news articles all around us, their causes and consequences are still poorly understood by the general public. Research scientists are increasing understanding of these processes, however, the science associated with these issues often does not reach the broader community. A New Center for Ocean Science Education Excellence, is addressing issues facing our changing coastal oceans through unique partnerships among research scientists, formal and informal educators, students and science communicators. We use a visual approach to communicate these key messages, and develop resources which will be available on the web for educators to use in a variety of formats. To develop these communication resources, this program utilizes a team approach to formulate “coastal trends modules for the K-12 classroom and for the general public through research-based activities.

Carson, M. L., University of Washington, Seattle, USA, carson2@u.washington.edu; Harrison, D. E., NOAA / Pacific Marine Environmental Laboratory, Seattle, USA, D.E.Harrison@noaa.gov

IS THE UPPER OCEAN WARMING? COMPARISONS OF 50-YEAR TRENDS FROM DIFFERENT APPROACHES

Ocean temperature trends at depths from 50 m to 1000 m are examined, based on observations gridded on a 3° x 3° latitude grid. Most of the ocean does not have 50-year trends that are significant, even at the 90% confidence level (CL). In fact only 30% of the ocean at 50 m has >90% CL trends, and the percentage decreases significantly with increasing depth. There is much spatial structure in 50-year trends, with areas of strong warming and strong cooling. These trend results are compared with trends calculated from data interpolated to standard levels and from a highly horizontally interpolated version of the dataset that has been used in previous nutrient content trend studies. The regional trend results can differ substantially, even in the areas with statistically significant trends. Trends based on the more interpolated analyses have more warming. 20-year trend variability is also high in all datasets. These results suggest that upper ocean heat content integrals and integral-trends may be substantially more uncertain than has yet been acknowledged. Further exploration of uncertainties is needed.

EFFECTS OF A LARGE-SCALE EUTROPHICATION AND OLGOTROPHICATION EXPERIMENT IN DANISH ESTUARIES AND COASTAL WATERS

The Danish monitoring program was established with the aim of identifying trends and drivers for a variety of ecosystem variables, particularly with respect effects of nutrient inputs from land. After 30 years of monitoring covering periods of both eutrophication and oligotrophication there should be sufficient data and variation to link drivers and impacts, but the trends are also confounded with signatures of global warming and potential regime shifts in addition to the large variations inherent to all ecosystem data. Despite large intra-system differences generic relationships can be obtained by pooling data from several coastal ecosystems. Reductions on land-based nitrogen inputs by almost 50% and phosphorus inputs by more than 80% have resulted in some ecosystem recovery for the pelagic variables, whereas benthic vegetation has stronger resilience to nutrient reductions. Highlights from a long-term analysis of a regional ecosystem undergoing both increases and reductions in nutrient inputs are presented.

THE EFFECTS OF INLET CHANNEL MODIFICATION ON THE BENTHIC INFANNA IN THE VICINITY OF BOGUE INLET, NORTH CAROLINA

Infuna are useful bioindicators of natural and anthropogenic disturbances. In this study we examine responses of benthic infuna to inlet channel modification. Sampling data is assessed using a BACI design for identifying seasonal trends and changes in the population dynamics of the benthos following dredging activities. Sites were core sampled for three years to determine macrourviverte community structure in the Bogue Inlet complex. Four baseline monitoring events provided pre-construction macrourviverte community structure data including spatial and temporal fluctuations. Inlet channel realignment occurred in March and April 2005, followed by seasonal monitoring at each site throughout 2006 and 2007. Results show the abundance of both taxa and organisms as significantly higher post-construction. Diversity was significantly lower at one year post-construction. By use of multivariate analysis, the effects of inlet relocation on the macrourviverte community are assessed, as well as the inherent temporal and spatial variation occurring within these communities. Patterns of succession are also evaluated.

AN INVERSE MODEL TO SEPARATE MIXING FROM GAS EXCHANGE IN THE REGION OF AAW FORMATION

Intermediate and mode waters have the potential to operate as rapid feedbacks to climate change via entrainment of greenhouse active species due to their comparatively fast turn-over times. Estimating the gas exchange that occurs during formation of these masses is complicated by biological activity and the complex mixing of the source waters during subduction. In this study we estimate gas exchange using hydrographic data collected on a cruise to a region of suspected intermediate and mode water formation (the region contained by 62° S, 105° W and 45° S, 75° W) during the late Austral winter of 2005. An optimum multiparameter inverse model with Redfield-type biology, simple mixing, and no parameterization for gas exchange was used to obtain a modeled distribution of properties. The difference between this modeled distribution and the observed distribution then provides our estimate for the net effect of gas exchange over the timescale of mixing. Average rates of exchange are thus determined for deep mixed layer waters and waters representative of AAIW over this timescale.

FORTNIGHTLY VARIATIONS IN BAROCLINIC TIDAL FLUXES AT THE HAWAIIAN RIDGE

A high-resolution primitive equation model is used to study the temporal variation in semidiurnal baroclinic tidal dynamics due to astronomical forcing. The one-hundredth of a degree domain covers a region of the Hawaiian Ridge from Niihau to Maui, including one of the three main internal tide generation sites along the Hawaiian Ridge. The domain-integrated barotropic to baroclinic conversion increases from 1 GW at neap tide to 5 GW at spring, with flux divergence and dissipation varying by approximately a factor of three. The fortnightly range of baroclinic flux is spatially variable, with range being proportional to the magnitude of the M2 flux. The model output is used to place flux measurements from the Absolute Velocity Profiler (AVP), taken as part of HOME, in context of the fortnightly cycle. Although the AVP measurements were taken in a relatively small area south of the ridge (<50km X 50km), the spring/neap variation at the survey locations varies by a factor of eight.

NAVY OCEAN MODEL COMPARISONS IN THE GULF OF OMAN

NAVOCEANO deployed 4 profiling floats in the Gulf of Oman (GOO) during summer 2007 to improve our understanding of oceanographic processes and evaluate the forecast models in the region. The area, which is important to Navy operations, is quite complex with sub-surface salinity related to the Arabian Gulf, temperature inversions, and a complex eddy structure. The models we are evaluating include the Navy’s Modular Ocean Data Assimilation System (MODAS), Shallow Water Analysis and Forecast System (SWAFS), and Global Navy Ocean Model (GNCOM). A 2-month study to comparing observations with model products will help us better understand model skills and weaknesses and improve our ability to support Navy activities in this challenging environment.

The approach is to compare modeled temperature, salinity and sound speed profiles with float observations. Analysis and forecast skill scores are assigned and the results are discussed in terms of important features, locations, and times. We will provide a statistical assessment of these comparisons. For example, it was immediately determined that more levels were needed to represent the complex ducting system in the GOO.

SALINITY, FRESHWATER FLUX, AND CLIMATE

This is a study of year-to-year sea surface salinity (SSS) variations -- their causes and their connection to climate. While observations from remotely sensing instruments together with an expanded suite of in situ observations are expected to provide global estimates of SSS anomalies in the near future, our current understanding is limited. Why, for example, do SSS and SST in the subtropical North Atlantic vary in phase on decadal timescales, while they vary out of phase in the tropical Pacific? This study presents results from a suite of IPCC AR4 GCAMs together with an ocean reanalysis to diagnose the complex relationship between salinity, freshwater flux, and the overlying atmospheric circulation on sub-seasonal timescales.

REMOTE SENSING OF INTERNAL WAVES IN THE MID-ATLANTIC BIGHT

Both satellite synthetic aperture radar (SAR) and electro-optical (EO) sensors image internal waves on the ocean surface. From July through September 2006, both EO and SAR imagery were collected from the SpotImage satellites, Radarsat-1, the European Remote Sensing Satellite (ERS-2) and Envisat-1 ASAR satellites. These satellite observations provided good temporal coverage for tracking the propagation of internal waves. A total of 58 SAR and 68 EO images were acquired and used to identify 2901 internal waves grouped into 472 packets. The data show persistent and repeated presence of internal waves parallel to the bathymetry. The images show refraction of internal waves over the shallower bathymetry and complex patterns arising from wave-wave interactions and reflections. The images are used to characterize the distribution, wavelength, number of oscillations and propagation speed of internal waves. The satellite observations were complemented by two research vessels equipped with WAACO marine radar systems and environmental moorings that measured near-surface and wave properties perpendicular to the bathymetry. The ship and mooring measurements were used to calibrate the radar backscatter measurements.

UPTAKE OF PHOSPHATE AND ATP BY FLOW-SORTED CYANOBACTERIA, PICOCYRKYAROTIDES AND NANOEUARYOTES IN THE SUBTROPICAL WESTERN NORTH ATLANTIC

Orthophosphate and ATP are biologically labile sources of phosphorus, a macronutrient known to seasonally limit primary production in the oligotrophic North Atlantic and Pacific gyres. While information on bulk community assimilation of these two compounds is common, there is very limited information on specific cyanobacterial and eukaryotic assimilation. Radioactive phosphorus tracers were used in conjunction with Fluorescence Activated Cell Sorting to quantify average cell-specific phosphorus uptake rates in Prochlorococcus, Synechococcus, and pico- and nano-eukaryotes in the western North Atlantic Subtropical Gyre. While information on bulk community assimilation of these two compounds is common, there is very limited information on specific cyanobacterial and eukaryotic assimilation. Radioactive phosphorus tracers were used in conjunction with Fluorescence Activated Cell Sorting to quantify average cell-specific phosphorus uptake rates in Prochlorococcus, Synechococcus, and pico- and nano-eukaryotes in the western North Atlantic Subtropical Gyre. All measured phosphorus uptake rates were greater near the deep chlorophyll maximum than at the surface, but mean cell-specific ATP uptake rates were consistently ~ 2.5 times lower than phosphate uptake regardless of depth. While average cell-specific rates increased with cell size, at the population level Prochlorococcus, Synechococcus, pico-eukaryotes and nano-eukaryotes contributed 40, 16, 24, and 20% to measured phosphate and 41, 60, 8, and 10% to measured ATP uptake, respectively. These data suggest that while Prochlorococcus can assimilate SRP and ATP equally, Synechococcus is actually a better competitor for phosphorus derived from ATP.
and estuaries in particular has been hampered by the limitations of using a few discrete

lateral movement of density surfaces within the subpolar gyre over the last 50 years. We
and temporal variability in the northward penetration of the MOW and the position of
westward, allowing MOW to penetrate into the subpolar gyre. We investigate the spatial
waters in the subpolar gyre block the northward flowing MOW, preventing its entry into
mid-depth property fields of the North Atlantic, questions remain regarding its influence
on subpolar waters. The salinity signature of the Rockall Trough has been conjectured
possibly linked to the NAO. It has been hypothesized that during persistent periods of strong winds, when the subpolar front moves eastward,
water in the subpolar gyre block the northward flowing MOW, preventing its entry into the
subpolar gyre. Conversely, during persistent periods of weak winds, the front moves westward, allowing MOW to penetrate into the subpolar gyre. We investigate the spatial and temporal variability in the northward penetration of the MOW and the position of the subpolar front. Using historical hydrographic data, we test this hypothesis by analyzing the temporal variability of salinity at locations north of the Strait of Gibraltar and the lateral movement of density surfaces within the subpolar gyre over the last 50 years. We present trajectories from a 1/12 FLAME model that show strong interannual variability, possibly linked to the NAO.

EFFECTS OF INCREASING SURFACE AREA OF PERiphyton SUBSTRATES IN TILAPIA RENDALLI YIELDS IN SWINE MANURE FERTILIZED PONDS
Since over half of the operational costs in commercial aquaculture systems are related to feed, developing commercial systems that are able to produce marketable-sized fish while minimizing feed costs by incorporating natural production techniques should be interesting avenues to explore. Fertilization stimulates both the autotrophic and heterotrophic production chains, which in turn enhance fish production. Laboratory studies by Dempster, et al. (1993) have demonstrated that ingestion rates by tilapias are up to 25 times greater when algae are presented as periphyton than when given as phytoplankton. It has also been demonstrated that by supplying different substrate areas for periphyton, ponds supported fish production levels close to 70% greater than their respective controls (Azim et al., 2002). We believe an increase in substrate area may increase the amount of periphyton available as feed resulting in possible higher yields and marketable size fish. As such, we will be evaluating the effect that a substrate equivalent to 0, 100 or 200% of the surface area will have on growth in ponds fertilized with the same levels of swine manure.

Florida St. Petersburg, St. Petersburg, USA HI-RESOLUTION MAPPING OF THE SPATIAL VARIABILITY IN CO2/O2/N2 CDOM, & CHLOROPHYLL FLORESCENCE IN COASTAL RIVERS Monitoring and modeling the impacts of point and non-point pollution as well as water- shed driven use changes of the North Atlantic, regulations to distinguish natural spatial pat-
terns from anthropogenic ones. Yet these spatial patterns are strongly influenced the scale of their sampling program. Extensive sampling of shallow habitats as coastal rivers and estuaries in particular has been hampered by the limitations of using a few discrete grab samples to characterize large surface areas, and displaying them solely as means
and variability. We demonstrate off-the-shelf technological advances that substantially improve this situation - Integrated geographic collection and 2D mapping of chlorophyll, CDOM, dissolved gases, temperature, turbidity, and conductivity. These parameters are efficiently integrated through an inexpensive unmanned multi-instrument surface vehicle (USV), CTD/sondes, near real-time wireless multi-instrument data acquisition, GIS formatted data, and geospatial techniques. Several under appreciated natural features (i.e. tributary confluences, submarine groundwater upwelling, riparian land use patterns, and an estuarine transition) added substantial spatial heterogeneity (lateral and longitudinal) to this coastal system that might have led to mischaracterizations.

The concentration of oxygen (O2) in the surface ocean mixed layer reflects both biological and physical processes. Estimating the efficiency of photosynthesis as well as setpoint measurements of the inert gas argon (Ar). We report continuous onboard measurements of O2/Ar derived net community productivity (NCP) by equilibrator inlet mass spectrometry (EIMS) in the Australian sector of the Subantarctic zone. Based on these continuous measurements, we estimate NCP during the austral summer 2007 in the Subantarctic zone to reach around 70 mmol O2 m-2 d-1. Gross primary productivity (estimated from the oxygen triple isotope anomaly) and NCP both show significant spatial variability, with larger productivities near the Subtropical front, and a general trend of northward increase in productivity. These measurements are presented with respect to other observations which we have performed during theustral summer. We also evaluate the potential application of continuous surface ocean pCO2 measurements by EIMS based on a comparison with standard pCO2 measurements made using a sheeter type equilibrator and infrared gas analyser.

A ThermoSalinoGraph (TSG) is an autonomous instrument designed to provide sea surface temperature and salinity along the track of a vessel when connected to the sea- water intake system of the ship. NOAA supports thermosalinograph operations on ships of the NOAA fleet and on commercial vessels participating in the Ship Of Opportunity Program. The NOAA/AOML TSG program is a collaborative effort with several other institutions. For example, in collaboration with the University of Miami one TSG is oper-
ated in the Strait of the Sea of Royal Caribbean Cruise Line. Also, and in cooperation with the Semester At Sea Program another TSG is operated in the M/V Explorer. Additionally, several cargo ships are equipped with TSGs. Most of the ships use SEAS 2000 software, developed at AOML, to acquire and transmit data in real-time. These data are quality controlled following the standard procedures recommended by the Global Ocean Surface Temperature Data (GOSUD) and disseminated globally via the GTS for climate and weather model initialization. We present here a summary of the TSG activities, relevant results, and future plans.
Castelao, R. The first sustained glider observations in the Middle Atlantic Bight are used to describe the seasonal evolution of hydrographic fields off New Jersey. Near-surface temperatures respond to variations in insolation, while waters at depth are primarily influenced by advection of cold waters from the north in the cold-pool during spring/summer, and warming due to mixing during fall. The thermocline thickens offshore. Salinity varies pri-
marily due to river discharge and wind variations, with low-salinity waters spanning 100 km across the shelf from May to September in a 10 m thick surface layer. Surface velocity maps, satellite imagery and drifers’ trajectories revealed the existence of a jet directed offshore and to the south, from near the Hudson River mouth toward the study region, which provides a direct pathway for transporting freshwater and biogeochemical material across the shelf. Stratification increases from April through June, peaking with a maximum of 80 km from the coast. The pycnocline deepens in late summer, while the passage of storms during fall rapidly reduces the stratification. The glider high-resolution observations al-
lowed for unprecedented detailed characterization of the scales of variability.

CONNECTIVITY IN AN OCEANIC SEAMOUNT SYSTEM: COMPARATIVE PHYLOGEOGRAPHY OF GASTROPODS WITH CONTRASTING REPRODUCTIVE STRATEGIES

Marine benthic invertebrates possess a species-specific mode of larval development. Species with planktotrophic development have larvae that spend an extended period of time in the water column, and it is commonly accepted that such species have higher levels of dispersal and gene flow than species with non-planktotrophic development. Because of the acceleration of the growth of the gastropod shell, it is possible to infer the mode of larval development of a species from the morphology of its protoconch, which is ideally retained at the top of the adult shell. For these reasons, gastropods are a good model to test connectivity between seamounts. Earlier studies have suggested that trapped water circulation generated by seamounts

COMPARISON OF SEA SURFACE TEMPERATURE DERIVED FROM MODIS TERRA/AQUA AND SUBLITTORAL MEASUREMENTS FROM THE INNER LAGOON AND OUTER BARRIER REEFS OF SOUTHERN BELIZE

Corals are fundamental for the biodiversity and overall health of reef ecosystems. Bleaching events have occurred in the past, with widespread effects on ecosystem quality and local economy. Thermal stress has been regarded as the primary cause of bleaching in coral reef environments. In order to be able to accurately predict damaging events, it is important to have accurate data for scientific and management purposes. This study assesses the effectiveness of satellite data in providing information on the subtidal thermal environment at two distinct reef locations. Ambient seawater temperatures adjacent to corals at 3-5 m depth were measured every 15 min in the inner lagoon and outer barrier reef in southern Belize from 2002-2007. MODIS data from Terra and Aqua platforms, with a spatial resolution of 4 km, acquired during the day and nighttime, were used for comparative purposes. Our study suggests consistency in differences between remotely sensed and in situ measurements for both satellite and locations. However, daytime and nighttime satellite overpasses yield contrasting results. This study provides insights into the use of satellite versus in situ data to estimate thermal stress in corals.

EVALUATION OF MODEL-DERIVED LOOK-UP TABLES FOR ESTIMATION OF DIURNAL WARMING IN SATELLITE-DERIVED SEA SURFACE TEMPERATURE PRODUCTS

Efforts to reference satellite sea surface temperature (SST) retrievals to a common depth and merge retrievals from multiple sensors require accurate compensation for diurnal warming effects. The use of look-up tables (LUT) derived from more detailed diurnal warming models provides a method for estimating the warming from a limited set of input fields. This paper explores the applicability and accuracy of this approach. Two different numerical models are used to generate LUT relating the surface and subsurface temperature as a function of conditions such as wind speed and insolation. The models include the warm layer portion of the COARE flux model and a version of the Kantha and Clayson parameterizations as a function of conditions such as wind speed and insolation. The models include numerical models are used to generate LUT relating the surface and subsurface temperature as a function of conditions such as wind speed and insolation. The models include numerical models are used to generate LUT relating the surface and subsurface temperature as a function of conditions such as wind speed and insolation.

THE FATE OF THE RHONE RIVER DELIVERY TO THE COASTAL OCEAN: BOTTOM WATER AND SEDIMENT RECYCLING COUPING

Actual carbon budgets in the Rhone prodelta show large uncertainties about the fate of the particulate river inputs, especially about the processes occurring in intermediate and bottom water. Indeed, most particles undergo a rapid deposition in the sediments near the river mouth and secondary transport occurs very frequently during wind surge and river flow variations which promote resuspension. The concentration and fate of the unconsolidated sediments. These processes create a strong coupling between sediments and the lower water column and play a key role in biogeochemical transformations of Rhone river particulate inputs. In April and September 2007, oxygen profiles were measured in the sediments of the Rhone river mouth using an in situ microprofiler unit. At the same time, Suspended Particulate Matter (SPM), Particulate Organic Carbon (POC) and Dissolved Organic Carbon (DOC) measurements were performed in bottom water together with core incubations and DCR (Dark Community Respiration) experiments. All the data show a South-Western gradient reflecting the intense organic matter degradation near the mouth and the particle dispersion through the main South-East current.

CAN KILL MIX THE OCEAN?

Previous in situ microstructure profiles of turbulent dissipation rate and estimates based on krill swimming speeds, suggest that krill-generated turbulent flow motions make a significant contribution to local and global mixing of the ocean. In the current study, we measured the velocity fields around free swimming individuals of two species of krill, Euphausia pacifica and Euphausia superba, using an infrared Particle Image Velocimetry (PIV) system. The velocity field data are used to directly calculate the turbulence characteristics in krill-generated flow fields. The krill-generated flow is characterized by a jet directed downward and to the rear with relatively large velocity magnitude in the vertical flow and smaller velocity magnitudes in the horizontal directions. This study focuses on the wake of the krill at a maximum value of 1.5 W-m-3 for Euphausia superba and 1.0 W-m-3 for Euphausia pacifica. Estimates of the turbulence generated by krill will be used to make comparisons to previous in situ observations.

CAUSSEY, B. D., NOAA/National Marine Sanctuary Program, Key West, Florida, USA, Billy.Caussey@noaa.gov

THE ROLES OF REGIONAL CONNECTIVITY, CLIMATE CHANGE AND BIOGEOGRAPHY IN SHAPING THE CORAL REEF COMMUNITIES OF THE FLORIDA KEYS

Biogeographically, the Florida Keys are situated in a crossroad between the warm-temperate waters of the Gulf of Mexico and the tropical waters of the Caribbean. While this environmental setting has set the stage for higher biodiversity in the Keys, as compared to the other major parts of the Caribbean, these same environmental conditions have made the Keys coral reef community more vulnerable to natural and anthropogenic impacts. While the overarching threat to the coral reef community of the Florida Keys has been increasing sea surface temperatures due to climate change, the affect of thermal stress on the coral reef community of the Keys has been exacerbated by secondary sources of anthropegenic pressure on the ecosystem. However, some coral reef habitats in the Keys have resisted major change in living coral cover, diversity and recruitment as compared to other coral habitats. This paper will describe how the biogeographic distribution of coral reefs in the Florida Keys have been recently influenced by a changing climate, in a region where connectivity is a major force in shaping the biodiversity of the area.

INTEGRATING CLIMATE AND ECOSYSTEM DYNAMICS: CIRCUMPOLAR ANALYSES OF SOUTHERN OCEAN ECOSYSTEMS

Integrating Climate and Ecosystem Dynamics in the Southern Ocean (ICED) is a new multidisciplinary international programme, launched to address the challenges of integrating research on Southern Ocean ecosystems, biogeochemistry and climate at the circum-polar scale. This decade-long programme will initiate, coordinate and integrate three main areas of activity: historical data synthesis, fieldwork and model development. The ultimate goal of ICED is to improve predictions of ecosystem dynamics, including responses to climate change and harvesting. This will be achieved by developing a hierarchical set of models of ocean circulation, biogeochemical cycles and the end-to-end operation of foodwebs with differences in spatial, temporal and trophic resolutions. Understanding the processes driving ecosystem responses to climate change and harvesting is of fundamental importance in both developing management strategies for the Southern Ocean and elucidating the role of the Southern Ocean in the Earth System. For the duration of the International Polar Year ICED is operating as ICED-IPY and will provide a legacy for large-scale understanding of Southern Ocean ecosystems.

THE IMPACT OF DISSOLVED ORGANIC MATTER (DOM) ON THE GROWTH OF ALEXANDRIUM TAMARENSE IN LABORATORY CULTURES

Several algal species responsible for harmful algal blooms (HABs) have recently been found to mixotrophic under certain environmental conditions. One such organism, Alexandrium tamarense, is found in red tide blooms which cause paralytic shellfish poisoning (PSP) in the Gulf of Maine. The ability to switch between photosynthetic and hetero-
trophic modes of nutrition may play a role in the timing and severity of HABs in coastal regions. Studies up to this point have linked increases in inorganic nutrient concentrations to HABs, but have been unable to develop a consistent method of predicting HABs and PSP outbreaks based solely on inorganic nutrient inputs. In this study we looked at the impact of nutrients found in dissolved organic matter (DOM) on the growth of Alexandrium tamarense cultures. DOM is a reservoir of organic forms of nutrients, like nitrogen and phosphorus. It is ubiquitous to all natural waters and plays a role in global nutrient cycling. Based on changes to DOM character in laboratory cultures, we hypothesize that Alexandrium uses DOM to enhance growth in the coastal zone during HAB events.

CROSS-SHORE DIFFERENCES IN MESOZOOPLANKTON EXAMINED USING DIGITAL IMAGE ANALYSIS
As part of the California Current Ecosystem Long-Term Ecological Research (CCE-LTER) site, mesozooplankton samples were analyzed along a cross-shore transect off of Point Conception, California to determine if there are predictable spatial patterns in assemblage composition, size distribution, and/or abundances. By understanding spatial differences in mesozooplankton, we hope to be able to better interpret and predict how patterns may change through time, including over climate scales. Preserved samples were analyzed using a digital scanner (ZooScan) combined with image analysis software to define regions of interest (ROIs), make morphometric measurements, and classify images. A training set was created by manually classifying more than 10,000 images. This training set was used in a Random Forest algorithm to classify all scanned images. Preliminary results suggest that there are changes in cross-shore abundances, although patterns differ among taxa and between years. Copodops are the most numerically abundant organism at all stations along the transect. However, they make up a lesser portion of each sample when compared by relative biomass. The use of digital imaging leads to more efficient analysis of plankton samples.

A COUPLED WAVE-CURRENT MODEL FOR STORM SURGE PREDICTION
The storm surge generated by a hurricane can cause significant flooding at the coastal areas as megarides. Waves are to be considered as the storm surge if the essential conditions to produce them exist. One such case was during the peak surge period of Hurricane Isabel when the surface wave was propagating with the flood currents and the significant wave height was as high as the surge height, reaching up to 2 meters, with a period of 5 seconds at York River. Forecasting inundation and flow conditions during such a complex incident will require modeling the interactions between waves and currents. In order to accomplish this goal, the unstructured three-dimensional hydrodynamic model UnTRIM is coupled with the third generation unstructured wave model UnK-Model. The effect of waves on wind stress, bottom shear stress, and radiation stress is accounted in storm surge and inundation modeling while the effects of water levels and currents are included in the wave model with a two way coupling. The ability of the coupled model is tested with a rare dataset taken during Hurricane Isabel.

MIXING INDUCED IN OCEANIC OVERFLOWS AND DENSE GRAVITY CURRENTS: A NEW ENTRAINMENT PARAMETERIZATION
This study proposes a new empirical parameterization for entrainment in dense currents that has been obtained using a data set which includes oceanic and laboratory data. The proposed parameterization presents two novelties compared to the present available parameterizations. First, it depends on both the Froude number, Fr, and Reynolds number, Re, of the flow and it accurately predicts both ocean and laboratory estimates of mixing. Second, it takes into account subcritical (Fr>1) mixing. The subcritical mixing observed in previous laboratory experiments could be of fundamental importance when determining the final water mass characteristics of a dense current descending the continental slope. A weak, but non zero entrainment can substantially change the final density and location in the open ocean water column of important water masses, such as the North Atlantic Deep Water. To test this new entrainment parameterization, we used a stream tubemodel employing both the new and classical parametrizations. The stream tube model predictions are consistent with previous laboratory observations when the new entrainment parameterization is used.

NUTRICLINE DEPTH, MIXED LAYER DYNAMICS, AND THE BALANCE BETWEEN DIATOMS AND COCCOPLATHOPHORIDS IN THE OCEAN
Over the past fifty millions of years, the balance between diatom and cocolithophorid production has played a key role in marine biogeochemical cycles, controlling the rate of carbon transfer between the atmosphere and the ocean, and contributing to stabilize long-term atmospheric carbon dioxide levels. Here we analyze phytoplankton community composition across latitudinal gradients in the Atlantic Ocean to show that the balance between diatoms and cocolithophorids is dependent upon the nutrient depth, a proxy of nutrient supply into the euphotic layer. We find a clear shift from diatom- to cocolithophorid-dominated assemblages as water column stratifies and nutrient deepens in the ocean (i.e., increasing nutrient stress). Consistent with their divergent life-histories, our analysis reveals that this compositional shift is a result of dramatic changes in diatom biomass and diversity with cocolithophorids exhibiting a reduced response to environmental variability. These findings highlight a strong mechanistic linkage between upper ocean turbulence, nutrient exchange dynamics, and phytoplankton community composition with profound implications on Earth’s climate.

SUBANTARCTIC MODE WATER AND ANTARTIC INTERMEDIATE WATER FORMATION
The formation of Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW) is analyzed using WAM淋al analysis for years 2005 and 2006. Air-sea heat fluxes in the Southern Ocean (SO) are not well known. Therefore we examine several heat flux estimates (HF) and ECMWF products. Coastal mixing and the effects of SOCE and ECMWF input variables as well as HF from the Southern Ocean State Estimate (SOSE; Mazloff, Heimburg and Wunsch, 2007). For the sea surface density field we use NCEP ECMWF and Advanced Microwave Scattering Radiometer SST and the best available surface salinity estimates (combination of float data and climatology). SOSE provides its own sea surface density. SAMW is formed on the equatorward flank of the Subantarctic Front by progressive cooling in winter months. Global formation rates obtained from WAM淋al analysis for 805 to 2055 at 14 deg C, 10 - 11 deg C and 4-5 deg C, corresponding to SAMW in the Atlantic, Indian and Pacific respectively: SOSE formation rates are 3 Sv (36 Sv) of 14 deg C water, 15 Sv (2.5 Sv) of 10 - 11 deg C and 15 Sv (5.25 Sv) of 4-5 deg C in years 2005 (2006). Both NCEP HF with SOSE SST and Coare with NCEP input variables have similar peaks as SOSE; Coare and SOSE formation rates are comparable, but NCEP HF formation rates are much higher due to excessively high heat loss during intense cooling episodes. Formation of progressively colder waters is apparent in the monthly analysis for the Atlantic and Pacific.

THE PATHOGENIC EFFECTS OF VIBRIO SPECIES ON CLONAL SYMBIODINIUM
Genetically similar Vibrio strains coupled with thermal stress are pathogenic in Caribbean and Pacific coral species, causing an impairment of the relationship between coral host and its endosymbiotic zooxanthellae. Vibrio isolated from corals with yellow band disease (YBD) specifically target isolated clones of zooxanthellae. Symbiodinium clade subtypes C1, D, and B1 were inoculated with four yellow-band causing Vibrio spp and a single Vibrio str. Toxicity during thermal stress and Vibrio infection was highest in CLADE C1 when compared to D1 and B1. These data suggest that initially, V. strain K has a stimulatory effect on the cell cycle zooxanthellae compared to the Vibrio consortium in this in vitro study. However, over time the toxicity of these Vibrio strains are severely impairing to the cell-cycle of all Symbiodinium CLADE sub-types in vitro. Cytological examinations of all treatments show a decrease in chlorophyll, cell size, cell lysis, degenerative cells are more evident in heat treated zooxanthellae, compared to controls. These data suggest that metabolically weakened symbiotic algae are not more susceptible to Vibrio infection coupled with thermal stress and that toxin production and pathogenicity is further evident within a Vibrio consortium.

AN ENERGY-CONSTRAINED PARAMETERIZATION OF EDDY BUOYANCY FLUX
A parametrization for eddy buoyancy fluxes for use in coarse-grid models is developed and tested against eddy-resolving simulations. The development is based on the assumption that the eddies are adiabatic (except near the surface) and the observation that the flux of buoyancy is effected by barotropic, depth-independent eddies. Like the previous parametrizations of Gent and McWilliams (GM) and Visbeck et al. (VMHS), the horizontal flux of tracer is proportional to the local large-scale horizontal gradient of tracer, through a transfer coefficient assumed to be given by the product of a typical eddy velocity scale and a typical mixing length. The proposed parametrization differs from GM and VMHS in the selection of the eddy-velocity scale, which is based on the kinetic energy balance of baroclinic eddies. The three parametrizations are compared to eddy-resolving computations in a variety of forcing configurations and for several sets of parameters. The VMHS and the energy-balance (EB) parametrizations perform best in the tests considered here.

CIRCULATION AND DEMOGRAPHIC MODELING OF THE STRUCTURING OF MARINE POPULATIONS ON REGULAR COASTLINES

Headlands in alongshore coastal flows create filaments and downstream recirculations advecting planktonic larvae away from or retaining them over suitable habitat. Coastal circulations and larval dispersal were modeled using the Regional Ocean Modeling System along Gaussian shaped headlands patterned after the Central California coast with larvae characterized after the larval life history traits of kelp bass. Numerical simulations are used to understand how unidirectionally seeded fish larvae disperse and settle around headland locations. For small, 5 km headlands, we find no preferential settlement distribution around headlands. For larger, 10 km headlands, spatial patterns of enhanced settlement around headlands emerge. The spatial settlement patterns continue to change with larger amplitude headlands. The impacts on marine populations of the spatial settlement patterns induced by the flow are explored with a demographics model parameterized to consider abiotic (settlement patterns) and biotic (density dependence, harvest, fecundity) factors.

BLENDED SEA SURFACE TEMPERATURE DATA SET FROM MULTIPLE SATELLITES AND IN-SITU OBSERVATIONS FOR COASTAL OCEANS

A two-dimensional variational (2DVAR) method for blending sea surface temperature (SST) data sets from multiple observing platforms is presented. The method produces globally continuous fields and has the capability of blending multiple satellite and in-situ observations together. The method allows specification of individual characteristics and background correlations, which are a common feature of coastal ocean regions. The blended SST fields for August 2003 covering the central California coastal region at high spatial (6 km) and temporal (6 hours) resolution were produced to demonstrate and evaluate the methodology. A comparison of these fields with independent observations revealed root mean squared errors of less than 1°C, comparable to the errors of conventional SST observations. The blended SST fields clearly reveal the fine-scale spatial and temporal structures associated with coastal upwelling in this region, demonstrating their utility in the analysis of fine-scale flow structures. In addition, we will produce a 5-km SST data set using this method and compare it with the existing the Global Ocean Data Assimilation Experiment (GODAE) merged product from the UK Met Office. Plans to produce a higher resolution SST product on the order of 1-km will be discussed.

EFFECTS OF SHORT TERM STABILITY VARIABILITY ON WATER COLUMN AND NEAR BOTTOM BIOCHEMICAL PROPERTIES OF THE WESTERN LOUISIANA SHELF

We present observations of water column stability, current velocity profiles, and hydrographic parameters taken at several long-term (12-36 hours) stations on the western Louisiana shelf during spring and summer of 2005 and 2007. The stations were in 20 m total depth and at locations historically known to experience hypoxia. Richardson number estimated from a bottom mounted RDCP and lowered CTD system show considerable station to station variability and super-inertial temporal variability related to physical forcing. On several occasions, oceanographic fronts associated with freshwater plumes emanating from the Mississippi or Atchafalaya Rivers passed over the observation location and dramatically changed the water column stability. Subynophycous dissolved oxygen concentrations fell and nutrient concentrations increased, consistent with local benthic oxygen demand and nutrient remineralization. Stations were observed to go from non-hypoxic to hypoxic and back to non-hypoxic in just a few hours. Longer term moored observations confirm these results and show significant variance and stability-bottom oxygen coherence at diurnal and higher frequencies. The results can have implications and impact on management and monitoring strategies for the Louisiana Deadzone.

Using QRT-PCR of the FE STRESS RESPONSE GENE ISIB TO RELATE N FIXATION RATES AND GROWTH UNDER DIFFERENT FE CONDITIONS IN TRICHODIEMUM

To aid in defining the threshold of iron (Fe) required by Trichodesmium in situ, we have developed a molecular diagnostic for Fe stress using quantitative reverse transcription PCR (qRT-PCR) of the Fe stress response gene isiB. Trichodesmium sp. are the dominant nitrogen [N] fixing cyanobacteria in the tropical and subtropical oceans, regimes frequently characterized by low Fe concentrations. Trichodesmium sp. have been shown to require higher amounts of Fe than other non-diazotrophic photoautotrophs, and Fe-limited laboratory culture experiments have shown that Fe availability can affect N fixation rates. Despite these data, there is limited information about the mechanisms and controls of Trichodesmium Fe acquisition and what levels of Fe in the ocean correspond to a reduction in N fixation capabilities. Using qRT-PCR analysis of isiB expression we have shown that detected gene expression levels correspond to specific reductions in N fixation rates in Trichodesmium.

TRACE METAL BIOGEOCHEMISTRY IN KARSTIC SOUTHERNFLA ESTUARIES

Despite being a major vector for the land–ocean transport of materials, the role of groundwater in oceanic elemental mass balances has been poorly characterized. And where groundwater has been explicitly considered, most studies have not quantified the importance of chemical transformations that occur during the mixing of meteoric water with saline pore water (the subterranean estuary or STE) prior to surface water discharge. Here we examine the importance of karstic coastal hydrogeology on the flux of trace elements from STEs. Data from two field sites will be presented: the Yucatan Peninsula and southwest Florida. There exists an interesting contrast with aluminosilicate-dominated STEs where the freshwater discharge is high enriched in labile anions with evidence for removal during mixing with ocean water. These subterranean karstic systems tend to be reducing environments, which appears to be a common thread among many other STEs regardless of the aquifer lithology; the geochemistry of uranium, iron, and other redox sensitive trace metals will also be discussed. Lastly, radium isotopes and radon-222 will be used to quantify the potential oceanic fluxes of these elements that may be occurring due to submarine groundwater discharge.

HOW DO PLANETARY WAVES INFLUENCE THE PRIMARY PRODUCTION IN THE NORTH ATLANTIC OCEAN?

Planetary waves play a major role in the dynamics of the oceans, but their role is not limited to the physics. In fact, several studies (e.g. Machu et al., 1999; Copilotti et al., 2001; Uz et al., 2001; Charría et al., 2006) have shown that these waves have a distinct signature on surface chlorophyll concentrations. These observations, made possible by the advent of remotely sensed ocean colour data, prompt several important questions: How do planetary waves influence surface chlorophyll concentrations? Which vertical or horizontal coupled processes are involved? Have planetary waves a measurable influence on primary, new and exported production? Is that influence significant within the global ocean carbon cycle? The aim of this study is to quantify the impact of these waves on primary production; to this purpose, a 3D coupled physical/biogeochemical model is implemented in the North Atlantic. Results so far show local primary production increases associated to the chlorophyll wave crest at different latitudes. The net impact of these waves on primary production is estimated by filtering out the planetary waves in the coupled simulations.

GLOBAL OCEAN PREDICTION WITH THE HYBRID COORDINATE OCEAN MODEL (HYCOM): AN OVERVIEW

A broad partnership of institutions has been collaborating over the past few years in developing and demonstrating the performance and application of an eddy-resolving real-time global and basin-scale prediction systems using HYCOM. The partnership is addressing the Global Ocean Data Assimilation Experiment (GODAE) goals of three-dimensional depiction of the ocean state and real-time and provision of results for regional conditions for coastal and regional models. This presentation will highlight the achievements made by the HYCOM consortium and summarize the lessons learned along the way.

INTER-ANNUAL VARIABILITY AND SHELF WATER ENTRAINMENT OF GULF STREAM WARM-CORE RINGS

An analysis of satellite-derived sea surface temperature observations of Gulf Stream warm-core rings (WCRs) has been completed between 75° and 50°W from 1978 – 1999 to understand (1) inter-annual variability of WCRs occurrences, and (2) role of WCRs in entraining shelf water from the outer continental shelf to the Slope Sea (SS). Results indicate a significant response between WCR formation and large-scale atmospheric variations related to the state of the North Atlantic Oscillation (NAO). Adjustment to NAO-induced wind forcing is hypothesized to impact the eddy kinetic energy distribution and related baroclinic instability structure of the Gulf Stream, thus affecting WCR formation rates. A quasi-geostrophic approximation of the potential vorticity equation is used to determine volume fluxes of shelf water entrained by WCRs into the SS. The total mean annual shelfwide WCR-induced shelf water transport is 23700 km³ year⁻¹ (0.75 Sv), which accounts for 25% of the total transport in the SS region adjacent to the outer continental shelf. Results suggest that increased (decreased) occurrences of WCRs observed during positive (negative) phases of the NAO create higher (lesser) WCR-induced shelf water fluxes.

OBSERVATIONS OF STRONG SUBMESOSCALE ANTICYCLONE AND ASSOCIATED FRONTogenesis NEAR AN ISLAND

Observations of surface currents by high-frequency radio current meters, and satellite altimeters, scatterometers and radiometers, are used to document the generation and evolution of a strong submesoscale anticyclone west of Oahu, Hawaii in October 2002. It may have been caused by Ekman pumping associated with island orographic effects on the trade winds, or by boundary layer shear along the coast due to the mesoscale jet. Within three days, the anticyclone reached an extremum negative surface vorticity of 1.5 × 10⁻⁵ s⁻¹, with a solid-body core of 17 km radius and azimuthal velocity of u ≈ 35 cm/s. It slowly decayed to less than 5 days later, possibly as a result of centrifugal instabil- ity. It was in cyclogeostrophic balance to first order. During this period, the anticyclone was trapped between the coast and a larger cyclone to the west, and a second cyclone to the southeast. A front developed between the western cyclone and the anticyclone, as warm water from the southwest was advected northward, and cold water from the north- east southward. The front was divergent (u = 0.2 m/s) and anticyclonic (u = 0.25 m/s) on its warm side, and convergent (u = 0.25 m/s) and cyclonic (u = 0.15 m/s) on its cold side, counteracting the production of density gradient by eddies straining the temperature field. Finally, as the western cyclone drifted westward, the front disappeared and the anticyclone broadened and weakened.

BREAKING NEW GROUND: USING REMOTE SENSING AND MODELING IN OPERATIONAL FORECASTING OF FISHERIES

Ecological forecasting of fishery yields in the face of climate variability has eluded resource managers for decades. Recent advances in observing systems, computational power and understanding of ecosystem function offer evidence that the variability of the ocean eco-system and its impact on fishery yield can be forecast with enough lead time to be useful to society. Accurate and timely forecasts can provide the information needed to maintain the long-term sustainability of fish stocks and protect the ecosystem, while maximizing social and economic benefits and preventing wasteful overinvestment of economic resourc-es. In this contribution we present efforts to enhance the current decision support system for the small pelagic fishery and upwelling ecosystem in the coastal ocean off Peru with remote sensing information and state-of-the-art coupled physical-biogeochemical three-dimensional ocean models. This region has the world's largest single-species fishery, the Peruvian anchovy, which is supported by the world's most variable ocean ecosystem. No other ocean region has this combination of environmental observations, fish resources, fisheries monitoring and well validated climate forecast models for forcing high-resolution operational ecosystem models.

AN UNSTRUCTURED GRID, FINITE-VOLUME COASTAL OCEAN MODEL (FVCOM): APPLICATIONS TO MULTI-SCALE COASTAL AND ESTUARINE SYSTEMS

A team of University of Massachusetts-Dartmouth and Woods Hole Oceanographic Institution researchers has developed a new prognostic, unstructured-grid, Finite-Volume, free-surface, 3-D primitive equation Coastal Ocean circulation Model (called FVCOM) for physical and coupled physical/biological studies in coastal and estuarine regions char-acterized by complex coastlines and bathymetry and diverse forcing. Both hydrostatic and non-hydrostatic versions of FVCOM have been applied to study multi-scale dynamical processes observed in coastal oceans and estuaries. Several examples will be presented here to illustrate how well an unstructured-grid model can capture complex dynamics and kinematics characterized by multi-scale interaction in realistic settings. An integrated interdisciplinary-atmospheric-ocean model system including WRF/AMM, FVCOM, un-structured-grid, finite-volume versions of SWAN, CICE (ice model), generalized biologi-cal model, and sediment transport model as well as advanced data assimilation modules will be introduced along with hindcast validation experiments in the Gulf of Maine/New England Shelf region. Some critical issues relevant to data assimilation, model assessment, and hindcast time forecasting that we have learned from the development of the Northeast Coastal Ocean Forecasting System (NECoFS) are also discussed.

ESTIMATES OF SPREADING IN A NEAR-FIELD RIVER PLUME FROM OBSERVATIONS AND MODEL SIMULATIONS

Data collected from the near-field region of the Merrimack River (Massachusetts) plume were analyzed to examine the plume spreading. Estimates of the plume spreading rate were derived from the CTD and ADCP data using a control volume method, and a direct assessment of the spreading of clustered surface drifters. Additionally, plume spreading...
It has been previously shown that saxitoxin resistance in bivalves is linked to a single experimental data. Implications of the results for the improvement of ocean simulations

...ary model that acts as an functional domains of the protein. This insertion is very close to an "IFM" or "MFM" mutation, one (type 1) has a three-amino-acid insertion between the third and the fourth functional domains of the protein. This insertion is very close to an "IFM" or "MFM" (Isoleucine, Methionine, Valine), Phenylalanine and Methionine motif that acts as an inactivation gate, opening and closing the channel. The insertion may change the position of this motif when it is plugged in the channel, thereby affecting the sodium ion flow into the cell, and accounting for toxin resistance. If so, this mutation represents a different mechanism of resistance from that found in bivalves.
A simple conceptual analysis indicates that the existence of a horizontal density gradient develops Rossby waves dynamically and vertically. For the stratified northern RG, we find the eddy dissipation effect to be important as well.

AXIAL WIND EFFECTS ON STRATIFICATION AND LONGITUDINAL SALT TRANSPORT IN IDEALIZED, PARTIALLY MIXED ESTUARIES

A 3D hydrodynamic model (ROMS) is used to investigate the axial wind control on stratification through straining of longitudinal density field and the associated longitudinal salt transport. The model mimics a straight, 400km-long estuarine channel connecting to a shelf sea. Modifying the horizontal Richardson number by incorporating the Wedderburn number (2\sigma/\rho g H), the ratio of wind stress to baroclinic pressure gradient, to include wind straining effects is shown to better represent the subtidal variations in stratification. When \( W < \sigma(1) \), axial wind has negligible effects on stratification. When \( W – O(1) \), down-estuary wind strain enhances stratification, whereas up-estuary wind reduces it. At the onset and end of the wind events, the subtidal cross-sectional averaged volume fluxes resulting from barotropic adjustment drive strong transient salt fluxes. During a down-estuary wind event, subtidal shear dispersion increases due to enhanced stratification and vertical shear. The opposite effect occurs during an up-estuary wind event. The adjustment time for the salt structure is much longer than the event time scale. Supporting observations from upper Chesapeake Bay are provided.

2DH MODELING OF WAVES, CURRENTS AND SEDIMENT TRANSPORT AT FRF DURING HURRICANE ISABEL

Hurricane Isabel is regarded as the most significant storm event in the 27-year history of the USACE Field Research Facility (FRF) at Duck, North Carolina. Large waves together with high suspended and nearshore currents and significant morphological changes at the FRF. The bathymetric changes during the storm event were estimated from the pre- and post-storm profile measurements and indicated a 2D feature of bathymetric evolution. In this study, we developed a 2D modeling framework that couples the wave model SWAVE, a quasi-steady nearshore circulation model STCIRC and a sediment transport model for simulations of nearshore waves, currents and sediment transport at the FRF during the storm. The coupled nearshore model is nested in a large-scale storm surge model, supplying large-scale forcing such as wind-induced currents and tidal currents as boundary conditions for the nearshore model. The sediment model is based on the transport algorithm developed recently by Kobayashi (2007). It presents the basic mechanics of sand suspension and bedload movement on beaches and calculates bedload and suspended load sediment transport by waves and currents. The model is applied to a 7-day simulation of the storm event. The model results are compared with available data at the FRF.

DETECTION OF HARMFUL ALGAL BLOOMS FROM SPACE: A METHOD USING ARTIFICIAL INTELLIGENCE AND MODERN REMOTE SENSING

There has been considerable amount of effort attempting to identify harmful algal blooms (HABs) using satellite remote sensing, whose synoptic and repeated coverage provides unique and timely information for HAB studies. Due to uncertainties associated with the satellite data products and algorithms, however, the results are not always satisfactory. In particular, it has been fundamentally difficult to estimate chlorophyll-a concentrations (Chl), an index for phytoplankton bloom, in optically complex coastal waters. Using fluorescence line height (FLH) and spectral reflectance data from the MODIS satellite sensor as well as Karenza brevis concentration data from in situ survey on the west Florida shelf, we find a fuzzily developed and improved a fuzzy clustering algorithm. MODIS FLH can effectively differentiate phytoplankton blooms from non-biogenic waters (e.g., waters rich in colored dissolved organic matter or CDOM), while the spectral reflectance data are used to differentiate highly turbid waters caused primarily by sediment resuspension. The validity of the method is tested against in situ sampling results.

IMPACT OF TEMPERATURE AND SALINITY ASSIMILATION ON THE GLOBAL BIOGEOCHEMICAL PARAMETERS DISTRIBUTION

This is a study examining the impact of data assimilation on multidecadal timescales. The model we examine is the NCEP CSM ocean General Circulation model with Donny et al. (2003) biogeochemistry. The experiments presented span the 20 year period 1985-2004. The problem we consider is determining the impact of data assimilation, which clearly improves representation of physical processes, on the evolution of biogeochemical processes. The results show that the assimilation (based on SODA) has considerable impact, including increases in surface chlorophyll concentration in the North Atlantic during the spring bloom due to mixing across the thermocline, as well as increases in the tropical Pacific and Indian Oceans in response to enhanced upwelling. CO2 uptake in the North Atlantic is reduced, but outgassing in the eastern Pacific increases. On decadal timescales near surface total carbon varies strongly due to increasing in vertical exchange in the extratropics and increasing upwelling near the equator. Further experiments are being carried out to elucidate these processes.

A SYNOPSIS VIEW OF THE VORTICITY BALANCE OF THE SUBANTARCTIC FRONT IN THE SOUTHEAST PACIFIC

In late austral winter 2005, the formation of Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW) was observed in deep mixed layers adjacent to and north of the Subantarctic Front (SAF) in the southeast Pacific. The SAF presents a relatively strong barrier to meridional exchanges, but it provides a salinity cutoff for SAMW and AAIW from the Pacific to the Atlantic through the Drake Passage. The regional dynamics of the SAF in the southeast Pacific are diagnosed through its vorticity structure. The SAF is characterized by meanders of wavelength about 300 km over the relatively smooth to rough topography upstream of Drake Passage. The barotropic or depth-averaged vorticity exhibits a balance between advection of planetary vorticity and relative vorticity, as would be seen in a Doppler-shifted short barotropic Rossby wave in a mean flow. The depth-dependent vorticity balance implies a surface divergence which is balanced at depth by a divergence of the opposite sign.

RECENT ADVANCES IN REMOTE SENSING OF ESTUARINE WATER QUALITY: AN EXAMPLE IN TAMPA BAY, FLORIDA, USA

Using Tampa Bay as an example, we present some latest advances in the remote assessment of several key water quality indices (turbidity, colored dissolved organic matter (CDOM), and water clarity) in estuarine waters using MODIS and SeaWiFS. After proper calibration and data quality control, MODIS remote sensing reflectance (Rrs) at 645 nm (250m) showed high correlation with in situ turbidity (0.8-0.8 NTU), with RMSE of ~ 28% in the modeled turbidity. Res ratios of 469/555 (500m) and 488/551 (1km) were highly correlated with in situ CDOM or PCU color measurements. Application of a semi-analytical algorithm to SeaWiFS data significantly improved estimates of the attenuation coefficient at 490 nm (Kd(490)) over the traditional band-ratio algorithm, as indicated by the high correlation with in situ Secchi Disk Depth. In addition, light penetration depth was also estimated reliably from SeaWiFS using a novel algorithm. These algorithms are robust and consistent for most of the Bay waters in all seasons, and thus greatly facilitate time series analysis for monitoring environmental changes. However, estimating chlorophyll concentrations in Tampa Bay is still a challenging task.

buoy and biological/chemical tracers) are assumed. Such an inverse Lagrangian prediction problem is difficult to solve due to: uncertainty in current and wind fields, chaotic trajectories over convergent and divergent flows, deployment constraints, and multi-modal drift characteristics. We seek a solution using an ensemble of simulated trajectories describing a set of possible deployment locations/times. A simple ensemble of backward trajectories often leads to a distribution too diffuse to be practical, due in part to deficiency in the number of trajectories to sample the true distribution adequately. We propose a method that constrains the ensemble's spread sequentially and show that it can lead to a multi-modal distribution of several hot spots that may be more practical to base a deployment strategy. Demonstration based on actual problems (e.g., search-and-rescue) will be given.

REDUCED EQUATIONS FOR QUASI-3D LANGMUIR TURBULENCE

"Langmuir turbulence" is a wind and wave driven flow that dominates vertical transport within the ocean surface mixed layer. Observations suggest that Langmuir turbulence is constrained, in that vertical structures elongated in the wind direction are preferred. By exploring the Craik–Leibovich (CL) model of Langmuir circulation in the strong wave-forcing limit, we identify the source of this slow downwind variability. We leverage this limit using multiple-scale asymptotic analysis to derive a reduced set of PDEs governing quasi-3D Langmuir turbulence. Linear and secondary (i.e., nonlinear) stability analyses show that the reduced equations economically capture the key 3D instabilities. The derivation of this reduced model is a first step in an effort to investigate the interaction of mesoscale eddies with mixed-layer turbulence.

DEGRADATION OF DISSOLVED ORGANIC CARBON IN PERMEABLE SEDIMENTS

Coastal sea water is characterized by high concentrations of dissolved organic matter (DOM) and is pumped by bottom currents through the upper layers of permeable sand sediments that cover large portions of the continental shelf. Within these sediments, DOM is exposed to enzymes of a large and diverse microbial community that colonize the sand grains. We tested the hypothesis that a fraction of the DOM is degraded while passing through the sediment. Through a combination of in-situ measurements in the Gulf of Mexico and laboratory column reactor experiments, we examined the role of filtration process on DOM transformation. Our results suggest that filtration through permeable shelf sediments promotes the degradation of DOM.

EULERIAN AND LAGRANGIAN STATISTICS AND DISPERSAL IN NUMERICAL MODELS

Dispersion in the ocean is intimately bound up with Lagrangian and Eulerian timescales. Thus implicit in numerical methods for simulating larval dispersal in the ocean is the assumption that the time and length scales of currents in the models reflect reality. We compare Lagrangian and Eulerian statistics from two models (a numerical model and a ‘hybrid’ model, where currents are derived from satellite altimetry) with direct observations from Global Drifter Program surface drifter and Topo-Poseidon altimeter data to see how well the models reflect reality. Middleton (1985) suggests that under certain conditions the Lagrangian and Eulerian velocity autocorrelations and spectra are linked by simple transformations in terms of the ratio of Lagrangian to Eulerian timescales. The ratio of Lagrangian to Eulerian timescales is a measure of eddy length scales in the ocean. Our previous work has suggested that this ratio is about 0.1 in the Tasman Sea. We find that the ratio of Lagrangian to Eulerian timescales in the models tends to be higher than in reality, but that overall dispersal is not too different from the real ocean.

DYNAMICS AND INTERNAL STRUCTURE OF THE CROSS-SHELF CIRCULATION DURING WIND-DRIVEN COASTAL UPWELLING

A two-dimensional theory of wind-driven coastal upwelling is developed that is comprised of a surface Ekman layer; an interior frictionless layer, and a frictional bottom boundary layer. The theory is built upon the Lentsh-Chapman upwelling theory, which has been used to demonstrate the importance of nearshore cross-shelf momentum flux divergence during upwelling. The new model retains spatially-varying structure in the interior density and velocity fields. The dynamical model for the interior flow is based upon the nonlinear upwelling theory of Pedlosky, which maintains thermal wind balance between the cross-shelf density gradient and the vertical shear in the alongshelf velocity while retaining the cross-shelf advection of density and alongshelf momentum. The structure of the cross-shelf circulation is studied as a function of alongshelf wind stress and Burger number $N = \alpha / \xi$, where $\alpha$ is the topographic slope, $N$ is the buoyancy frequency, and $\xi$ is the Coriolis parameter. Predictions of the dynamical model are compared with two-dimensional numerical model simulations. During upwelling winds, the dynamical model predicts interior onshore flow high in the water column for large Burger number, and offshore flow in the bottom boundary layer for small Burger number, consistent with the numerical model and with observations.
Leg 171, Site1049) or core photos. Our exercises illustrate essential Earth and Physical Science concepts, and the hope is to allow students to make the connection between the concept and the evidence observed in the sediment. These include the relationship between climate and sediment type, isolation, classification of grain size, and the Cretaceous A Tertiary boundary. The target ages range from middle and high school, to early undergraduate, although all can be adapted for use at any level.

OPTIMAL SPECTRAL DECOMPOSITION (OSD) FOR RECONSTRUCTING SURFACE OCEAN CIRCULATIONS FROM SATELLITE ALTIMETRY

The Ocean Surface Current Analyses - Real Time (OSCAR) data for world oceans (59.5 S to 59.5 N) are derived from satellite altimeter (JASON-1, GFO, ENVISAT) and scatterometer [e.g., QuikSCAT] for various uses including research and operations. The methodology for OSCAR combines geostrophic, Ekman and Stommel shear dynamics, and a complementary term from the surface buoyancy gradient. A major weakness of the OSCAR dataset is its inability to represent the currents near the lateral boundary. The most evident western boundary currents such as the Gulf Stream and Kuroshio are missing. Besides, the data are quite noisy. To improve the OSCAR data, the optimal spectral decomposition (OSD) method is used to reconstruct the OSCAR data. The basis functions are the eigenfunctions of the Laplacian operator with the given boundary conditions. A cost function used for poor data statistics is introduced to determine the optimal number of basis functions. After the OSD analysis, the reconstructed OSCAR data show realistic surface circulations including western boundary currents such as Gulf Stream, Kuroshio, Brazil Current, Somali Currents, and eastern boundary currents such as California Currents, Peru Currents, etc. Comparison of the reconstructed OSCAR data to in situ current measurements and OGCM model results is also provided.

LATERAL EXPORT FLUX OF ORGANIC CARBON IN THE EAST CHINA SEA

The East China Sea (ECS) has been regarded as a potential sink for carbon dioxide. Simply speaking, the adsorbed carbon must be exported from the ECS to maintain a carbon balance of the ocean. Several studies have revealed that the lateral carbon transport is significant in the ECS. Corresponding to particulate organic carbon (POC), dissolved organic carbon (DOC) and POC export flux were measured along several cross-shelf transects in 2006 and 2007. Strong spatial carbon gradient across-shelf was found in both summer and winter suggesting that carbon in the ECS can be exported via horizontal transport. Vertical export flux of POC in the ECS is estimated from 0.1 to 0.8 gC/m²/d. In addition, both size-fractionated particulate and dissolved organic carbon (POC and DOC) export fluxes of Th-234 and carbon were measured in the ECS and the results demonstrated that the ECS may be exported via horizontal transport. Vertical export flux of POC in the ECS was estimated from 0.1 to 0.8 gC/m²/d. In addition, both size-fractionated particulate and dissolved organic carbon (POC and DOC) export fluxes of Th-234 and carbon were measured in the ECS and the results demonstrated that the fraction of small particles accounted for at least 50% of total Th-234 and carbon fluxes. The estimated lateral POC flux in the ECS was about 5 Mm²/yr if the fraction of small particles (<0.5 mm) is assumed to be long-distance transportable particles. The result implies that the lateral carbon transport is significant in the East China Sea.

VIGOROUS GROWTH OF SYNECHOCoccus spp. IN THE EAST CHINA SEA DURING AN ASIAN DUST STORM EVENT

Investigations focused on the effects of dust storms on the ecology of phytoplankton have been limited. The aim of this study was to reveal the succession of pico-phytoplankton in the oligotrophic waters of the East China Sea during Asian dust storms. According long-term observation, Synechococcus is dominant in the water columns over the continental shelf, and Prochlorococcus is restricted to the outer edge of the East China Sea where the Kuroshio Current flowed-through. In spring, 2007, we conducted cruises to a station located at the shelf break of the East China Sea (25°05′N, 123°15′E). We found that vigorous growth of Synechococcus from 1.4 × 10⁴ to 1.0 × 10⁶ cells ml⁻¹ occurred during Mar. 16 to Mar. 18, and then decreased to 4.1 × 10⁴ cells ml⁻¹ at Mar. 19, 2007. Phylogenetic analysis of 665 rRNA sequences revealed that the most of these newly appeared Synechococcus belonged to Clade II. Furthermore, all of mRNA levels of 3 nutrient stress markers including idaA (Fe stress marker), mtcA (N stress marker), and psP (I stress marker), decreased from prominent values to non-detectable levels during the dust storm. These results suggested that the contribution of Fe, N, and P by the dust deposition from dust storm or by turbulence jointly promoted the growth of Synechococcus on the outer edge of the East China Sea.
correlated to temperature anomalies within the mixed layer during the summer. The winter-to-winter recurrence of surface temperature anomalies is also confirmed using an independent SST dataset.

MICROBIAL SYMBOYSIS OF SPORES AND QUORUM SENSING

Bacteria release a wide range of chemical compounds, some of which function as signals. These chemical signals are often involved in monitoring and responding to microbial population density, a process described as quorum sensing. Acylated homoserine lactones (AHLs) are well-studied quorum sensing signals, usually produced via AHL synthases of the LuxP family. LuxR-type transcription factors usually recognize the AHLs and in turn regulate target gene expression. Tissues of marine sponges are densely colonized by diverse bacteria which may play important nutritional and protective functions for the host. A significant portion of the sponge microbiota from the strawberry vase sponge and the black ball sponge produce AHL signals. Members of the Silicibacter-Ruegeria (SR) subgroup of the Roseobacter clade are the most prominent AHL-producing microbes. There are at least two different LuxR-type genes we have isolated from the SR sponge isolate KL1H11. These genes, designated saxl and sbbl, direct synthesis of different AHLs, and are adjacent to genes encoding LuxR-type proteins, saa1 and sbbl, respectively. Sha1 activates expression of the saxl gene via interaction with a conserved DNA binding site upstream of this gene. Mutation of saxl in KL1H11 leads to loss of all detectable AHLs in laboratory culture, while an sbbl mutation does not change the AHL profile. One of the regulatory targets for these systems in the SR symbionts appears to be flagellar motility.

PRETTY IN PINK: SURFZONE DYE DISPERSION IN VARYING CONDITIONS DURING THE HB06 EXPERIMENT

Terrestrial runoff containing bacteria and human viruses often drains directly onto the shore where it is entrained in the surfzone and spread by nearshore waves and currents. Tracer dispersion is key to understanding the fate of polluted surfzone water, however dispersion rates and mechanisms are poorly understood. During the HB06 experiment at Huntington Beach, California, high-resolution surfzone dye dispersion observations were combined with extensive in situ measurements of the waves and currents thought to control dispersion rates. The evolution of plumes and patches of fluorescent dye (Rhodamine W-T) was observed on 8 days during the experiment, in wave conditions ranging from low energy with weak alongshore currents to moderate energy with strong alongshore currents. Recently adapted dye sampling techniques, including fixed (frame mounted) and mobile (jet ski mounted) fluorometers, were used to sample dye within and seawards of the surfzone. shore. Show more samples were acquired simultaneously at 7 or more alongshore locations. Observations with these techniques will be compared. Surfzone dye diffusivity estimates in varying conditions will be contrasted.

SIMULTANEOUS N-ASSIMILATION, NH4+ REGENERATION AND NITRIFICATION IN THE EUPHOTIC ZONE: IMPLICATIONS FOR NEW PRODUCTION ESTIMATES USING THE F-RATIO

Using 13N methods, rates of N-assimilation, NH4+ regeneration and nitrification were measured simultaneously at 55% N of the Spanish Iberian Peninsula. Stations ranged from coastal upwelling to oligotrophy with day-time and night-time measurements. NO3- and [NH4+] peaked at 700 and 150 ng-at-N L-1 in upwelling stations, decreasing to < 4 and < 80 ng-at-N L-1 at oligotrophic stations respectively. N assimilation rates were consistent with those described as quorum sensing. Nitrification rates peaked at 700 and 150 ng-at-N L-1 in upwelling stations, decreasing to < 4 and < 80 ng-at-N L-1 at oligotrophic stations respectively. Nitrification rates were consistent with those described as quorum sensing. LuxR-type transcription factors usually recognize the AHLs and in turn regulate target gene expression. Tissues of marine sponges are densely colonized by diverse bacteria which may play important nutritional and protective functions for the host. A significant portion of the sponge microbiota from the strawberry vase sponge and the black ball sponge produce AHL signals. Members of the Silicibacter-Ruegeria (SR) subgroup of the Roseobacter clade are the most prominent AHL-producing microbes. PLANETARY WAVE PROPAGATION OFF CALIFORNIA AND ITS EFFECT ON ZOOPLANKTON

Analysis of CalCOFI daily temperature and SeaDoo sea level data shows that the dynamic height propagates westward at 4.1 cm/s, about double the speed of the large-scale, low-frequency Rossby wave (2.2 cm/s). Internally filtered along-track TOPEX/Poseidon/Jason sea level height verifies the westward propagation (4.3 cm/s). Because of the westward propagation, interannual variations in alongshore geostrophic surface current are proportionate to the time-derivative of sea level. The anomalous alongshore flow advects particles, the anomalous northward alongshore particle displacement being proportional to sea level. Since nutrient concentration is lower in the south, the anomalous alongshore particle displacement results in lower nutrient concentration when the sea level is anomalously high and higher nutrient concentration when the sea level is anomalously low. Vertical displacement also results in a similar relationship between nutrients and sea level, so we expect that negative sea level anomalies are strongly related to fluctuations in zooplankton population. Consistent with the westward propagation, the logarithm of the zooplankton population averaged over the CalCOFI region is well correlated (r=–0.67) with coastal sea level anomalies and lags it by 2 months.

INTERACTIVE HABITAT DATABASE FOR THE PACIFIC COAST OCEAN OBSERVING SYSTEM (PACOOS): AN ECOSYSTEM OBSERVING TOOL FOR THE CALIFORNIA CURRENT

Recognizing the need to develop an ocean observing system covering the entire California Coastal Ocean System (CCES), NOAA and its partners are establishing PACOOS as a west coast observing ecosystem "backbone" for the U.S. Integrated Ocean Observing System (IOOS). PACOOS long-term objective is to develop and maintain an integrated distributed data access, transport, and analysis system serving data and products and meeting research and management needs for multiple users in the CCE. Building on databases assembled for the development of an Essential Fish Habitat Environmental Impact Statement for west coast groundfish, we have developed a data portal that links several remote servers and delivers a variety of habitat relevant data including benthic, biological and oceanographic data, and allows multilayer query and reporting and query comparisions (http://pacoos.coas.oregonstate.edu/). The data portal provides for data discovery, direct client access to data, custom/interactive view environments, as well as developing integrated decision support tools for Ecosystem Based Management. Our long-term goal is to bring the 2-D geospatial world and the 4-D oceanographic world closer to seamless exploration by examining interoperability between these two inherently different data structures.

CLASTRE, H., Laboratoire d'Océanographie de Villefranche, Villefranche sur mer, France, clastre@ocean-lab.fr; Niewiadomska, K., Laboratoire d'Océanographie de Villefranche, Villefranche sur mer, France; D'ORIENTZIO, F., Laboratoire d'Océanographie de Villefranche, Villefranche sur mer, France; PRIEUR, L., Laboratoire d'Océanographie de Villefranche, Villefranche sur mer, France; SUBMESOSCALE PHYSICAL-BIOGEOCHEMICAL COUPLING ALONG THE LIGURIAN CURRENT (NORTHWESTERN MEDITERRANEAN) USING A BIO-OPTICAL GLIDER

A bio-optical/biogeochemical glider was developed with the purpose of characterizing the signatures of biogeochemical processes at physical forcing at submesoscale. The glider was deployed across the permanent Ligurian current (North western Mediterranean Sea) allowing unprecedented observations of the tight physical-biogeochemical coupling to be recorded. Among the various biogeochemical variables, three of them (backscattering, Chlorophyll a concentration, CDOM) have completely independent behaviour with regards to meso and sub-mesoscale dynamics. Near-isopycnal tongues of elevated Chlorophyll a/Oxygen concentration are recorded down to a depth of 180 m and are the likely signature of a converging horizontal and downwelled water flow. Intrusions of elevated CDOM concentrations together with signatures of smaller particles are the likely features of a local divergence and upwelled waters from subjacent aphotic layers. These tongues are a recurring feature which is observed at various seasons. Such biogeochemical signatures clearly allow the identification of upwards and downwards physical motions not observed by current technologies, reinforcing the need for coupled high-resolution physical-biogeochemical studies, not only for investigating biogeochemical processes themselves but also for resolving physical process at these scales.

SMALL CHANGES IN MORPHOLOGY LEAD TO LARGE CHANGES IN MOVEMENT AND TRANSPORT IN TURBULENCE FOR LARvae OF THE SAND DOLLAR DENDRASSTER

Larval swimming mechanics are determined by larval morphology, interacting with small-scale flows such as shear within turbulent eddies. Empirical and theoretical approaches were used to examine effects of morphology on swimming performance of larvae in shear flows. Movement of various larval morphologies (stages) of the sand dollar Dendraster excentricus in shear was quantified experimentally by simultaneously tracking and mapping the flow field around each larva. Sensitivity of larval swimming performance to changes in water flow is to bring the 2-D geospatial world and the 4-D oceanographic world closer to seamless exploration by examining interoperability between these two inherently different data structures.
changes in certain morphological characteristics was examined theoretically by embed-
ning a hydrodynamic model of plankton larvae in simulated shear flows. Experimental and
model results both indicate that larvae exist in a very sensitive part of parameter space,
where small changes to larval morphology lead to large differences in larval movement.
Because larval morphology responds to environmental conditions, environmental changes
(e.g. eutrophication, acidification) may affect larval movement. Model predictions also
indicate that changes in larval movement strongly influence vertical positions of larvae.
Because environmental factors, including horizontal currents, vary with depth, effects
of morphology on vertical position can influence growth, survivorship and dispersal through
the planktonic larval period.

AN OVERVIEW OF SEAFLUX: NEW SCIENCE AND METHODS IN AIR-SEA FLUXES

In this talk I will present an overview of the SeaFlux program and its history and goals.
Methods and comparisons of satellite-derived air-sea fluxes with in situ research vessels,
buoys, and numerical weather prediction models will be described. Comparisons with
global climate models and future directions for cross-cutting research will be discussed.
New methodologies that are being explored with respect to improved global high-resolu-
tion air-sea fluxes suitable for climate analyses will be detailed, including improved surface
flux models, improved sea surface temperature fields, and possibilities for improved fluxes
in coastal regions and at high wind speed regimes will be explored.

ON THE PROCESSES CONTROLLING SHELF-BASIN EXCHANGE AND OUTER SHELF DYNAMICS IN THE BERING SEA

We use a 9-km pan-Arctic ice-ocean model to better understand the circulation and
exchange in the Bering Sea, particularly near the shelf break. Only limited observations
exist for this region, which is why very little is known about how water from the deep
basin reaches the Bering shelf. To address this issue we examine the relationship between
the Bering Slope Current (BSC) and exchange across the shelf break as well as resulting
mass transports onto the shelf. Previously, it was thought that the BSC advected
amounts of deep water northward via a branch near the Siberian coast. Our model results
indicate a significantly different circulation scheme whereby water from the deep basin
is periodically moved onto the shelf by mesoscale eddies, along the shelf break. We find that
submarine canyons are prone to high eddy activity and, therefore, show higher rates of on-shelf transport. In addition to eddy activity, the sea ice cover greatly influences
the dynamics on the Bering Sea shelf through interannual variability in its extent, distribu-
tion, and timing of melt/freeze.

CONSTRAINING THE TROPICAL ATLANTIC OCEAN CURRENT BY ASSIMILATING SATELLITE ALTIMETRIC OBSERVATIONS: INSIGHTS FROM OBSERVING SYSTEM SIMULATION EXPERIMENTS

Two main issues are developed here regarding our capacity to monitor the tropical
Atlantic Ocean variability. First, the data assimilation system poses specific challenges
especially because of the importance of the wind forcing error in the tropics. Secondly, we
will wonder how much observational information is required for an accurate representa-
tion of the circulation. To evaluate how errors due to wind forcing may be corrected, we
performed twin experiments using an ocean general circulation model (OgCM). Resolution
is 1/4 on a 20 S to 17 N domain, with radiative boundaries. The assimilation model is

BRINGING OCEAN SCIENCE RESEARCH TO THE MIDDLE SCHOOL CLASSROOM

An ongoing collaboration between ocean scientists at the Coastal Observing Center at the
University of New Hampshire and teachers at King Middle School in Portland, Maine has

resulted in the implementation of a hands on ‘Unit Expedition’ that includes a field study
program focused on understanding fluxes. We will provide an overview of methods and
students will be introduced to the work on climate change. The UNH science team has lead customized teacher trainings and participated in
learning team brainstorming sessions to help create and test ideas that are now being used with
in local schools unique to the marine science curriculum framework. Students are now using
field protocols that UNH and other regional plankton programs use and get to work with
UNH scientists directly during visits to the classroom. This successful partnership has created
new opportunities for both middle school teachers and students and UNH scien-
tists and educators through the sharing of information, ideas and experiences. This ‘unit
expedition’ is now in its second year.

DYNAMICS OF CDOM AND CARBON IN THE GULF OF MEXICO

The Gulf of Mexico receives CDOM and DOC inputs from one major and minor
tidal rivers. The traditional approach to prediction of river inputs in coastal regions has been to
determine river endmember concentrations of dissolved constituents and model distribu-
tions of these in nearshore areas based on salinity observations. Satellite observations
extend modeling efforts to the use of CDOM color signature with greater spatial and tem-
poral resolution. Modeling efforts require an understanding of variability on both small and
large temporal scales, and thus require long-term regional studies for best results. We
have conducted ongoing studies in the eastern Gulf of Mexico for the past ten years, and
characterized river signatures for CDOM, chlorophyll, and DOC. Regional summer
CDOM intensities generally increase from the Mississippi River to the dark waters of the
SW Florida coast. Distributions are dominated by river discharge, and thus show a
strong negative correlation with salinity most of the time. However, a large variability in
color, concentration and optical properties is observed due to climatic events such as
wet and rainy seasons and between flood and drought years. Chi and DOC concentrations
also vary regionally, and are only strongly correlated with river discharge during high flow
periods.

THORIUM-234 AND POC FLUXES AND EXTRACELLULAR ENZYMATIC ACTIVITY IN THE LAPTEV SEA

We have used the water column 234Th deficit, coupled with measurements of the POC/234Th ratio on filterable particles >70 µm, to estimate late summer POC fluxes at two shelf stations in the Laptev Sea. Fluxes at an outer shelf station (270 m) showed an attenuation factor of ~2 between 25 and 100 m. Fluxes were higher with less attenuation in the upper 60 m of a station (112 m) closer to the Lena River delta. Particles >70 µm at the outer shelf station also were characterized by a greater fraction of marine organic matter (estimated from 8D). Rates of extracellular enzyme (protease and glucosidase) activity in the >70 µm fraction were greater at the outer shelf station by factors of up to ~7 and ~25 (respec-
tively). The weakly related negative correlation between protease and glucosidase activity, suggesting that protease activity is linked to preferential loss of N from the particles. These results generally support the hypothesis that extracellular enzyme activities contribute significantly to attenuations of POC flux in the Arctic.

MAPPING SUSPENDED SEDIMENT CONCENTRATION ON A FRINGING CORAL REEF USING AIRBORNE MULTISPECTRAL REMOTE SENSING AND IN SITU SAMPLING: MOLOKAI, HAWAII

A major threat to the coral reef on the south coast of Molokai is the large amount of fine
sediment delivered to the reef from the uplands due to land-use changes. Sediment is
introduced to the reef through erosion and storm runoff, and is then resuspended in a
daily cycle influenced by tides, wind, and waves. High levels of suspended sediment can
have a direct influence on coral health by inhibiting photosynthesis and smothering coral.
We investigated using airborne imaging to generate a high-resolution map of suspended
sediment concentration (SSC) levels on the reef. A multispectral camera system with
three bands (green, red, near IR) was used to acquire images with approximately 15 cm
pixel resolution, along with SSC measurements from in situ water sampling, to quan-
tify the POC fluxes from the surface sediments to the water column. The results indicate a
strong negative correlation with salinity most of the time. However, a large variability in
color, concentration and optical properties is observed due to climatic events such as
wet and rainy seasons and between flood and drought years. Chi and DOC concentrations
also vary regionally, and are only strongly correlated with river discharge during high flow
periods.

DYNAMIC MODE VARIABILITY IN THE DEEP GULF OF MEXICO
Low frequency vertical current structure at the northern edge of the Loop Current during
edly shedding events is observed using concurrent hydrographic, moored, and satellite
alimetry data from 2005. Dynamic modes are calculated at three deep, full water-column
ings in the Gulf of Mexico. Time-series of the barotropic and first two baroclinic
odes are found using a least squares minimization that fits derived modes to moored
velops velocity data. EOF analyses show the majority of observed variance is explained by a
 oracle-trapped mode that is highly coherent with temporal amplitudes of the first baroclinic
ode, and a low percentage of variance is captured in bottom-intensified modes. The first
aroclinic mode is prevalent throughout deployment and an assessment of this mode is
es for higher order modes is quantified. Ageostrophic events are
nted to the or
ogthalan change in sea surface height to illustrate local dominance of geostrophy. When
correlation is small, energy in higher order modes is quantified. Ageostrophic events are
vestigated by correlating specific forcings to higher modes. This work is funded by the

Increasing seafood consumption will putatively improve human health and save lives. To meet the demand for seafood, there are more cultured and imported products available, but surveillance of products is minimal. At the same time, risks, or perceptions of risk, are changing because coastal areas are subject to habitat contamination by chemical and biological agents. The complexity of this situation results in a “seafood dilemma,” which may lead to reduced seafood consumption, and resultant loss of presumed health benefits. To address this, we recommend that integrated program is needed to provide: sustained and systematic monitoring of both wild and cultured seafoods; consistent regulatory and guidance criteria; increased analytical capacity, both for harmful and beneficial substances; publicly accessible and user-friendly data on benefits and risks of seafood consumption; and a seafood tracking system. This program should be advised by representatives from the seafood and aquaculture industries, environmental interest groups, and the public health community. While the development of this program will not be a trivial task, the benefits to public health and well being make such an effort well worthwhile.

The effects of oxygen, temperature, and microbial inhibition on remineralization rates of particulate organic carbon, San Pedro Basin, CA

Sedimenting material was captured in San Pedro Basin, CA throughout the late summer and fall 2007 using a floating sediment trap deployed at 100m. Our goal was to understand the controls on remineralization of Corg sinking through the oxygen minimum zone. Total mass, carbon, and biogenic silica flux measurements were made. Additionally, particles were incubated and shaken in the dark in 30L of filtered seawater at 10°C and at 25°C. Aliquots of water were sampled every 12-48 hours and TCOD was measured as a proxy for Corg remineralization rates. Average k values were calculated and ranged from 0.7 to 0.01 day^{-1}, with the 25°C experiments producing higher k values. Inhibition of bacteria by formaldehyde stopped respiration of Corg at both temperatures. Material fall ing from 100m to 500m, if decaying with a Martin function b value of -0.86, would exhibit a k value of 0.15 day^{-1}, similar to values found in our incubation experiments. Further experiments will be conducted examining the effects of low oxygen concentrations, similar to what particles experience in the oxygen minimum zone of San Pedro Basin.

SIMULATION OF FLOW AND NUTRIENT TRANSPORT FROM AN AQUIFER

Transient 3-D modeling was used to simulate ground-water flow from the top of the ground-water flow cell to a coastal embayment at Cape Cod National Seashore, Massachusetts. Simulating in the subterranean estuary also was simulated by a finely discretized 2-D model. Simulations showed that freshwater discharge from the aquifer to the embayment varied from 500 m3/d when ground-water levels were low (November to December) to 2500 m3/d when ground-water levels were high (May to June). Modeled freshwater fluxes agreed with those calculated from salinity and flow measurements made over multiple tidal cycles at a channel connecting the embayment to a larger estuary. Salinity measured in ground water in the intertidal zone used multilevel samplers detected movement of the salt/fresh interface on a tidal and seasonal basis that was consistent with simulation results. Fluctuations in simulated nitrogen loads corresponded with water flux variations. Little nitrogen loss occurred during transport in the aerobic subterranean estuary. Although most nitrogen discharging to the embayment was in the form of nitrate, most nitrogen leaving the embayment through the tidal channel was organic nitrogen. Freshwater release from the Arctic to the deepwater convective regions of the North Atlantic since the mid-1960s appears to be related to changes in the export of freshwater from the Arctic, and the persistence of a high North Atlantic Oscillation (NAO) during this period. To investigate the response of the Arctic to changes in the NAO we use a high resolution regional version of the ocean-only MITgcm forced with daily NCEP reanalysis data from 1992-2001. After creating a control simulation, we performed two calculations with repeated wind fields of two contrasting NAO years for the extreme negative and positive NAO phases of 1969 and 1989, respectively. Our results highlight a clear response in the Arctic freshwater budget to NAO forcing. Repeat NAO negative wind forcing results in virtually all freshwater being retained in the Arctic. In contrast, repeat NAO positive forcing increases the freshwater export out of the Arctic, primarily via the Fram Strait (54%) and Canadian Archipelago (29%), and results in a total loss of freshwater storage of 14,000 km$^3$. We find that the freshwater export via these two pathways increases by virtually the same amount (~700 km$^3$) between the two forcing scenarios, highlighting the important role that the Canadian Archipelago plays in redistributing the freshwater of the Arctic.

RESPONSE OF THE ARCTIC FRESHWATER BUDGET TO EXTREME NAO FORCING

The National Oceanic and Atmospheric Administration has a long history of developing operational products and services. Many of these operational products have traditionally revolved around weather forecasts but increasingly operational ecological forecasts are being developed to address critical ocean and coastal management issues. The development and transition to operations of ecological forecasts however present additional and unique research and institutional challenges to the agency which must be addressed before these valuable management tools can be fully realized. Some of these challenges include, modeling complex physical, biological, chemical and behavioral interactions; characterizing uncertainty in forecast products; communicating forecast results to users; and testing, validating, running, and improving developed forecasts. This presentation will discuss these challenges from the perspective of ongoing efforts to develop new operations of forecasting tools and products related to harmful algal blooms. Also discussed are lessons learned which may be applicable to other ongoing ecosystem forecasting efforts targeted at different ocean and coastal management issues.

LATITUDINAL DEPENDENCY OF TERRESTRIAL CDOM: IOP DIFFERENCES BETWEEN WATERSHEDS THAT SUPPLY THE WEST FLORIDA SHELF

Given that spectral properties of CDOM are source dependent, and that CDOM is a useful proxy for chemical structure, ecosystem health, and Dissolved Organic Carbon (DOC) in coastal environments, there is a critical need to establish its spatial and temporal variability in rivers and estuaries. This is especially true for river-dominated margins, like the West Florida Shelf, where freshwater originates from numerous rivers, and the ability to understand regional carbon dynamics is necessitated by establishing CDOM variability in said rivers. Rivers that supply the shelf have latitudinally dependent terrestrial CDOM, where southernmost rivers have higher concentrations and exhibit distinct differences in optical properties compared to northern watersheds. Discussed here will be how properties, such as absorption coefficients, spectral slopes, fluorescence efficiencies, intensity, ratios and DOC vary spatially and temporally for Florida watersheds and how these properties are altered as freshwater mixes with seawater in the estuaries. Findings were also compared to historical CDOM values (1974-2005) to examine long-term trends in the color of water, where regions have experienced a tripling of concentrations during the last 30 years.

THE POTENTIAL FOR INTERACTIONS BETWEEN ABIOTIC AND BIOTIC FORCING ON THE CONTROL OF THE FRESHWATER HUMAN PATHOGENS CRYPTOSPORIDIIUM PARVUM AND GIARDIA LAMBILIA

Recent research has shown significant negative effects of abiotic forcing through high solar ultraviolet radiation (UVR) on the infectivity of the human pathogen Cryptosporidium parvum. Further research has demonstrated a negative effect of biotic forcing, the zooplankton grazer Daphnia pulicaria, on the viability of both Cryptosporidium parvum and Giardia lamblia. Here we discuss the potential for recently observed global increases in chlorophyll biomass, water mass structure and particulate sedimentation on the sea floor to induce sedation, the duration of sedation, and the recovery time were noted by observing postural orientation and the response to touch stimuli. Anesthetizing shrimp is particularly useful for behavioral work because it allows for the identification of gender and species, as well as counting parasites, without causing damage by physically constrain the organism.

Cooper, L. W., University of Maryland Center for Environmental Science, Solomons, USA, cooperl@cmes.umd.edu

USE OF CLOVE OIL AND CARBON DIOXIDE AS AN ANESTHETIC FOR THE GRASS SHRIMP PALEMNONETES PUGIO

Anesthetics are commonly used in aquaculture to immobilize animals in order to make handling easier. This decreases animal stress, which otherwise may result in physical injury or death. Anesthetics should be easy to administer and induce sedation quickly. Small crustaceans are rarely anesthetized; however, the constant movement of some invertebrates, particularly while assessing morphological features using a microscope, can cause injury to the animal or result in decreased observational accuracy. The purpose of this study was to determine an effective anesthetic for the daggerblade grass shrimp Palaemonetes pugio. Clove oil and carbon dioxide were tested on grass shrimp to determine a concentration range that would immobilize but not kill them. The time required to induce sedation, the duration of sedation, and the recovery time were noted by observing postural orientation and the response to touch stimuli. Anesthetizing grass shrimp is particularly useful for behavioral work because it allows for the identification of gender and species, as well as counting parasites, without causing damage by physically constrain the organism.

RECONSTRUCTING TRENDS IN HYPOXIA USING MULTIPLE PALEOECOLOGICAL INDICATORS RECORDED IN SEDIMENT CORES FROM PUGET SOUND, WA

In the last decade, the frequency and severity of fish kills associated with hypoxic events in Puget Sound has increased, resulting in unprecedented environmental and economic impacts. The relationships between anthropogenic activities (i.e., landscape alterations and increased population) and a suite of paleoecological and geochemical indicators preserved in sediment cores from the main basin of Puget Sound and the subbasin of Hood Canal were examined for the period of 120-400 years B.P. The reconstructions were slightly different between the two basins, but both showed shifts in the dominant diatom and foraminiferan fossils, pollen grains, stable isotopes of carbon and nitrogen, biomarkers for terrestrial/marine carbon, and redox-metals enriched in sediment during periods of hypoxia/anoxia. The redox-metal profiles indicate periods of hypoxia are recorded in each of the last four centuries, with a significant event in the early 1700s. These natural cycles of hypoxia do not increase in frequency in the last century; however, the other indicators record shifts in diatom species, dominant pollen grains, and carbon/nitrogen isotopes and ratios following the onset of significant basin-wide anthropogenic activities beginning in the 1900s.

ULTRAHIGH RESOLUTION MASS SPECTROMETRY OF DISSOLVED ORGANIC MATTER: THE PATH TO GEOMICS

Electro spray ionization combined with high-field Fourier transform ion cyclotron resonance mass spectrometry (ESI FT-ICR MS) can now identify individual compounds in complex dissolved organic matter (DOM) mixtures. Such analyses provide molecular data on DOM that was thought to be “uncharacterizable” just a decade ago. This ultrahigh resolution mass spectrometry (UHR-MS) also represents a new approach to the analysis of ecosystem geochemistry. For example, UHR-MS from ice to Antarctic Bottom Water in the Weddell Sea (Antarctica) estimated control parameters reflect the limitations of this method, and can be post-processed to verify how well these models simulate surface fronts. In this presentation we compare, for 2004, the probability of finding sea surface temperature (SST) fronts in the 4-km MODIS SST product with that of finding fronts in the corresponding Hybrid Coordinate Ocean Model (HYCOM) North & Equatorial Atlantic Ocean Prediction System runs. The multi-im age edge detection algorithm developed at the University of Rhode Island was applied to the daily fields of both data sets and annual frontal probability fields were computed. The difference between the two annual probability fields provides a measure of HYCOM’s ability to reproduce the high gradient regions observed in the MODIS data. In general, HYCOM tends to overestimate the number of fronts found by approximately 50% with the exception of a band across the Atlantic at approximately 10 N and two regions near the northern model border where HYCOM underestimates the frontal probability.

Cornillon, P., Florida State University, Tallahassee, USA, pcornillon@fsu.edu; Eichmann, A., University of Rhode Island, Narragansett, USA, aeich@uri.edu; Howe, P., University of Rhode Island, Narragansett, USA, phowe@uri.edu; Ulloa, D., University of Rhode Island, Narragansett, USA, dulloa@uri.edu.

AN EVALUATION OF THE PERFORMANCE OF HYCOM IN SIMULATING SURFACE THERMAL FRONTS

Eddy-resolution ocean models depict sharp ocean fronts, however, except for comparisons with the mean path and path variability of western boundary currents, little has been done to verify how well these models simulate surface fronts. In this presentation we compare, for 2004, the probability of finding sea surface temperature (SST) fronts in the 4-km MODIS SST product with that of finding fronts in the corresponding Hybrid Coordinate Ocean Model (HYCOM) North & Equatorial Atlantic Ocean Prediction System runs. The multi-image edge detection algorithm developed at the University of Rhode Island was applied to the daily fields of both data sets and annual frontal probability fields were computed. The difference between the two annual probability fields provides a measure of HYCOM’s ability to reproduce the high gradient regions observed in the MODIS data. In general, HYCOM tends to overestimate the number of fronts found by approximately 50% with the exception of a band across the Atlantic at approximately 10 N and two regions near the northern model border where HYCOM underestimates the frontal probability.

4DVAR DATA ASSIMILATION IN THE TROPICAL PACIFIC

A variational data assimilation system has been implemented for the tropical Pacific Ocean for an eddy-permitting regional implementation of the MIT general circulation model (MITgcm). The model uses realistic topography with parameterizations for the surface boundary layer (KPP) and open boundaries at the south and north, as well as in the Indonesian throughflow. The model uses realistic topography with parameterizations for the surface boundary layer (KPP) and open boundaries at the south and north, as well as in the Indonesian throughflow. The strong constraint 4DVAR method is used to adjust the model to observations in the tropical Pacific region using control parameters which include initial temperature and salinity, temperature, salinity and horizontal velocities at the open boundaries, and twice-daily surface fluxes of momentum, heat and freshwater. The model is constrained with most of the available datasets in the tropical Pacific, including climatologies, TAO, ARGO, XBT, and satellite SST and SSH data. The adjoint of the model is used to estimate the steepest-descent directions in a conjugate-gradient descent method which includes pre-conditioning by an approximate Hessian. The estimated control parameters reflect the limitations of this method, and can be post-processed to refine the solution without significantly increasing the cost function.

COMMUNITY COMPOSITION, PHOTOSYNTHETIC CAPACITY, DIAZOTROPH ABUNDANCE AND NITROGENASE ACTIVITY OF PHOTOTROPHIC PLANKTON IN THE ORINOCO RIVER PLUME

We examine chlorophyll-specific, size-fractionated phototrophic plankton community biomass, photosynthetic capacity, diazotroph abundance and nitrogenase activity along the
The Kalman filter is a data assimilation algorithm that optimally estimates a system state given a model, past, and current observations. This is suitable to initialize numerical predictions. The smoothers also consider future observations in the assimilation process. Therefore, more radiation (KdPAR) is needed to build reanalyses. A smoother designed for oceanic analyses is introduced. It is derived from the Singular, Evolutive, Extended Kalman (SEEK) filter and the fixed-lag Kalman smoother. The major difficulty in the derivation lies in the management of model error. Then, extending the SEEK filter with the smoother function is straightforward. The additional computational cost is tiny, what makes the smoother suitable for applications with large data. The SEEK smoother is tested in twin experiments. The model is an ocean general circulation model in a 1/4 degree double-gyre configuration and simulated satellite observations of Sea Surface Height are assimilated. The smoother slightly but significantly improves the filter results. To conclude, an outlook to forthcoming real data assimilation experiments and reanalyses making will be presented.

THE NUTRIENT TYPE DISTRIBUTION OF METHYLMERCURY IN THE MEDITERRANEAN WATERS: RELATIONSHIPS WITH PHOSPHATE

Methylated mercury species (MeHg) are bioactive molecules, which play the major role in the biomagnification of mercury in aquatic food webs. Sources of MeHg in the open oceans are still on debate. High definition vertical profiles of MeHg have been performed in the open waters of the Mediterranean Sea in spring 2004. MeHg concentrations ranged from 0.008 to 0.430 pm (mean: 0.171 pm, standard deviation 0.130 pm for 66 determinations). Systematically the MeHg vertical distributions exhibited nutrient type profiles with the highest concentrations occurring in the PO4 maxima. For the ionian sea the relationships between MeHg and phosphate were highly significant: MeHg(pM) = 0.996 PO4(pM) + 0.037 (R = 0.975, n=6) for the Open Northwestern Mediterranean; MeHg(pM) = 1.237 PO4(pM) + 0.034 (R = 0.993, n=10) for the Open Tyrrhenian Sea; MeHg(pM) = 1.241 PO4(pM) + 0.010 (R = 0.926, n=7) for the Open Ionian Sea; MeHg(pM) = 0.868 PO4(pM) + 0.015 (R = 0.960, n=9) for the Ionian Sea off Catania and MeHg(pM) = 1.312 PO4(pM) + 0.056 (R = 0.951, n=7) for the Strait of Otranto. The results indicate that the MeHg cycle is involved in the organic matter regeneration processes and suggest that its formation in this region of the Ocean is the result of microbiological activity in the upper part of the water column.

HABITAT SELECTION AND COMMON HOT SPOTS OF 3 SEAL SPECIES IN THE WESTERN ANTARCTIC PENINSULA

We carried out a comparative study that examined the foraging behaviour of 30 adult female southern elephant seals, Mirounga leonina (2005, 2006 & 2007). 43 crabeater seals, Lobodon carcinophaga (2001, 2002 & 2007), two Weddell seals, Leptonychotes weddelli (2007) foraging in the Western Antarctic Peninsula (WAP). Southern elephant seals dove the deepest (356 m 20.2 min) and made the longest excursions. Some individuals remained within the WAP along the continental slope, while others foraged into the Antarctic Circumpolar Current. Crabeater seals some 5400 km west. Crabeater seals moved along the continental shelf, remaining closer to shore than elephant seals. Some moved considerable distances (666 km to northeast, 1147 km to southwest), but most remained within 300 km of their tagging location. Average dive depths were 118 m, and lasted 6.5 min. Crabeater, seals remained deep within the pack ice throughout the winter. The Weddell seals remained within 300 km of where they were tagged and made surprisingly shallow dives 89 m that lasted 12.4 min (deepest 455 m, longest 27.5 m). Our results suggest considerable differences in the foraging behaviour and habitat utilization between these 3 species and confirm significant differences between elephant and crabeater seals.

LIGHT FROM AMAZONIAN WATERS AND HUMAN EFFECTS ON IT: A LARGE-SCALE MONITORING APPROACH

We quantify the light field from large rivers of the Amazon Basin by reporting both above and in water in situ hyperspectral reflectance, diffuse attenuation, scalar irradiance measurements and accompanying water optical constituents. Sampling was done along a 500 km transect of the Amazon River and in six of its larger tributaries in high and low water seasons. The results showed that water and white waters, the photosynthetically active radiation becomes dominated by red light as a result of high attenuation by colored dissolved organic matter and suspended particulate matter and blue radiation is non-existent below 0.5 m depth. Clear waters are markedly different with blue light penetrating to a depth of 2.5 m and the occurrence of a unique mid-spectra green light peak at depth. The
spectral light availability was analyzed together with above water reflectance measurements and CHERS satellite imagery to define a large-scale model to monitor Amazonian water affected by injection of sediment from small-scale gold mining.

NUTRIENT CONCENTRATIONS AND N SPECIATION IN AN UNPOLLUTED TROPICAL FORESTED WATERSHED, PANAMA

Human activities have considerably increased the availability of reactive nitrogen. Now, many streams carry large nitrate loads to inland and coastal waters. Nevertheless, mass balance studies have shown that a significant portion of the terrestrial N load does not reach coastal systems, suggesting the existence of important N removal processes. Denitrification has been suggested as an important sink of N in inland waters, which is true in temperate regions of the Northern Hemisphere where most streams contain high nitrate concentrations. However, the global distribution of reactive nitrogen is far from uniform. Recent studies have shown that nitrogen loss from pristine watersheds occurs mainly in dissolved organic compounds, and that the amount of inorganic nitrogen is only a fraction of the total dissolved nitrogen. Herein we present chemistry data from streams within the upper Rio Chagres watershed, a pristine, densely forested watershed in the humid tropics of central Panama. Contrary to that observed in temperate watersheds of the Northern Hemisphere, DIN concentrations in the Rio Chagres and tributaries were low (mostly <2.6 µM), while organic nitrogen concentrations were mostly >10 µM.

THE INFLUENCE OF GEOLOGIC FRAMEWORK ON BEACH MORPHODYNAMICS ALONG THE SOUTHEAST COAST OF FLORIDA

The Southeast Coast of Florida is characterized by the presence of relatively straight barrier islands that developed on an undulating Pleistocene substrate. Major hydrodynamic factor shaping coastal morphology in this area is the wave action which is influenced by northeasters and hurricanes. Two airborne light detection and ranging (LIDAR) datasets collected before and after the 2004 hurricane season were examined to determine the three-dimensional response of beach to storms along the 130 km coastline. The coverage of the pre-hurricane data set reached approximately 1000 m offshore, while the coverage of the post-hurricane data set reaches 600 m offshore. The results from a change analysis show a high longshore variability, which appears to be associated with relict reef tracts offshore. The size and distance to the shoreline of the relict reef tracks and lithified sand ridges determine the effect of the geologic framework on longshore variability. It was concluded that the geological framework biases the influence of contemporary dynamics onto beach morphology in contrast with traditional beach state models.

CHARACTERIZING WAKE SIGNATURE AND DEVELOPING WAKE CLIMATOLOGY TO DETERMINE BEACH RESPONSE IN RICH PASSAGE, PUGET SOUND, WASHINGTON

In Rich Passage, Puget Sound, Washington episodic northerly wind events are observed to generate significant beach change in winter, where recovery of beach profiles in summer is in response to wave wash generated by commercial and recreational vessels operating at variable speeds. Extensive wave and wake monitoring has been conducted to characterize temporal and spatial variability of wave wash on shorelines in the study area. Time series of wave events have been extracted from wave measurements at multiple nearshore points based on GPS vessel position data, and visual observations of vessel traffic. A typical wake signature developed for each vessel class routinely transiting the passage, is characterized by temporal variations in the wave height, wave period, and shape of the wave energy spectrum. Individual wake events were summarized by wave height distributions for a specific vessel class to establish wake climates for the study area during given time intervals. Wake studies also included correlation of wave height to vessel speed and direction of transit. Comprehensive wake climates are essential to determining the overall hydrodynamic climatology for modeling of beach response.

REACTIVE OXYGEN EFFECTS ON DISSOLVED ORGANIC MATTER AND MICROBES

We have been examining the effects of photochemical processes on dissolved organic matter(DOM) and subsequent availability to microbial flora. Our approach is to use two well-characterized DOM sources, one with a predominantly terrestrial signature (Suwannee River DOM) and another with a predominantly microbial signature (Pony Lake DOM). Although these different end-members have very different compositions as revealed by high resolution mass spectrometry, they behave very similarly when exposed to solar irradiation. With both DOM sources, singlet oxygen production represented a large proportion of the photochemical oxygen demand when DOM concentrations were high—more than 50% at 40 mg C/L. Furthermore, when exposed to singlet oxygen, both of these DOM sources produced large quantities of peroxides. Peroxide production was similar in both of these sources despite differences in composition. When singlet oxygen-exposed DOM was subsequently presented to microbial flora, growth was inhibited for approximately two days followed by biomass production similar to a non-treated control. We are examining the possibility that singlet oxygen -generated peroxides may have been sufficient to inhibit microbial growth rates.

CARBONIC ANHYDRASE EXPRESSION IN ZOSTERA MARINA

Aquatic photosynthesis in seagrasses varies greatly from terrestrial photosynthesis mecha

nisms. From a variety of evolutionary adaptations and physiological responses to the aquatic environment. The physical chemistry of the water presents challenges in obtaining a supply of CO2 for photosynthesis that must be overcome. The rate of diffusion of CO2 in water is 1 x 104 times slower than it is in air, and at an alkaline pH (such as that of ocean water) HCO3- is the dominant dissolved inorganic carbon species. Therefore, the conversion of HCO3- to CO2 is a slow process. Since the pathway for inorganic carbon fixation involves an enzyme, ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), that can only utilize CO2 as a substrate, it is advantageous for a marine organism to develop an inorganic carbon concentrating mechanism (CCM) that usually involves carbonic anhydrase (CA). Photosynthetic efficiency and rates are thus limited by inorganic carbon. This research looks into the pathways of inorganic carbon acquisition in Zostera marina with emphasis on the role of carbonic anhydrase, and the response to projected increases in concentrations of dissolved aqueous carbon dioxide.

EFFECTS OF SEASONAL STRATIFICATION ON NUTRIENT RETENTION IN A COASTAL LAGOON WITH HARMFUL CYANOBACTERIAL BLOOMS

Excess nutrient supply is a common cause of eutrophication in coastal waters, where hydrodynamics strongly modulate the relationship between nutrient loading and productivity. This study addresses the physical processes that lead to nutrient retention, and subsequently harmful algal blooms, in a shallow, tidally choked, coastal lagoon. The project site, Rodeo Lagoon, is located in the Golden Gate National Recreation Area, California, and experiences intense blooms of cyanobacteria. Monthly transects of the lagoon show it is stratified by salt in winter, when freshwater inputs from the watershed and saltwater inputs from storm surge are both large. In addition to monthly water quality monitoring via transects and grab samples, the study includes two comprehensive, multi-week field observations of lagoon hydrodynamics contrasting turbulent mixing parameters under stratified winter conditions with well-mixed summer conditions. Wind is the dominant source of mixing, leading to the expectation of well-mixed conditions for this shallow site. However, strong density gradients can seasonally reduce vertical turbulent exchange of nutrients throughout the water column. The phasing of salt-based stratification means that annual losses of nutrients via flushing are diminished.

EFFECTS OF AG AND TIO, NANOPARTICLES ON THE SURVIVAL AND METABOLISM OF ZEBRAFISH (DANIO RERIO) EMBRYOS

Nanoparticles have numerous applications in industry and are defined as materials with one or more dimensions in the 1–100 nm size range. The release of manufactured nanoparticles into natural environments surrounding urbanized areas are likely to impact the health of organisms in aquatic ecosystems. To test potential impacts of silver (Ag) and titanium oxide (TiO2) nanoparticles, we selected zebra fish (Danio rerio) embryos as our model system. Embryos developed for 24 and 48 hours before exposure to Ag and TiO2. Lethal Dose 50 (LD50) for both 24 and 48 hour embryos exposed to Ag was 0.04 mg/ml
and the effective dose (ED) for both 24 and 48 hour embryos exposed to Ag was 0.03 mg/mL. Increases in oxygen consumption at and below the ED have been observed, and ongoing experiments to observe metabolic costs of biological responses to Ag and TiO₂ particle toxicity are underway. Results from this study illustrate the tolerances of early developmental stages in vertebrates to specific concentrations of Ag and TiO₂ nanoparticles. This research may elucidate mechanisms employed by aquatic organisms to combat possible nanoparticle contamination.

POPULATION CONNECTIVITY IN MARINE SYSTEMS: PROGRESS AND PROMISING DIRECTIONS

The study of population connectivity has evolved over the last decade to include a broad array of approaches to assess the scales and mechanisms over which successful larval dispersal operates within marine systems. Strong interest in this topic has been stimulated by a need to provide spatial management options to resource managers. The major challenges in this effort are to provide a quantitative understanding of the processes and scales controlling successful larval dispersal and how connectivity influences the dynamics of the affected populations. Resolving the mechanisms controlling larval dispersal will involve a coherent understanding of the relevant physical processes and how organisms mediate the physical outcome. Multiple scales will be important, and therefore understanding how the processes are coupled across scales is essential. Identifying patterns will need to involve efforts that focus on a variety of species with different life histories across various environments. In concert, the problem is multidisciplinary, but one requiring interdisciplinary research effort. This talk will provide an overview of these topics and issues with the aid of literature and on-going projects as examples.

Cowles, G. W., University of Massachusetts-Dartmouth, New Bedford, USA; gcwesg@umassd.edu

A FULLY IMPLICIT SOLVER FOR THE SHALLOW WATER EQUATIONS ON UNSTRUCTURED GRIDS USING A PRECONDITIONED DUAL-TIME-STEPPING APPROACH

With the recent rise in affordable computing power and common employment of parallelization techniques to expand practical problem scale, grid resolution in coastal ocean simulations has been reduced to O(10m) scale. This can be problematic for explicit time-marching schemes, which are constrained by the CFL condition and can require O(10^5) time steps to integrate one period of tidal forcing. Problem stiffness arising from the disparity between gravity and convective wave speed in these low Froude number flows as well as wide ranges in mesh scales in unstructured grid and AMR approaches contribute to the inefficiency of the explicit approach. In this work, a fully-implicit solver for the shallow water equations is described. By using dual-time-stepping, an unconditionally stable scheme can be achieved with any temporal accuracy. The method presented is matrix-free and requires the solution of a coupled set of equations to obtain the flow solution at each time step. The sub-iteration process is accelerated using multigrid and preconditioning techniques. Results for a realistic coastal application are provided. This method can be extended to solution of the hydrostatic primitive and Navier-Stokes equations.

BIO-PHYSICAL INTERPLAY BETWEEN VERTICAL GRADIENTS IN VELOCITY, PHYTOLANKTON, AND DISSOLVED ORGANIC MATTER

Planktonic thin layers typically display steep vertical gradients in particle concentration, usually in conjunction with vertical gradients in horizontal velocity (vertical shear). Less well-documented are the steep vertical gradients in dissolved constituents that occur within the same vertical profile, but not solely in association with the gradients in particles. We base our analysis on several datasets obtained over the past decade in three distinct coastal systems: Oregon Island, WA; Oregon continental shelf; and Monterey Bay, CA. Our high-resolution profiling system uses several optical instruments to characterize the particulate and dissolved fields. For particles, we measure in situ chlorophyll fluorescence, particulate absorption (ac-9), particulate attenuation (ac-9), and particulate backscattering (volume scattering function meter). For dissolved components, we measure in situ CDOM fluorescence from UV excitation. We have found that over 70% of observed particulate thin layers possessed coincident steep gradients in CDOM, but many steep gradients in CDOM were detected without coincident particulate thin layers. These CDOM gradients and layers provide an important biological/chemical signature for the discrimination of coastal water types.

ZOPLANKTON SPECIES COMPOSITION AND ABUNDANCE IN THE EASTERN BERING SEA IN SUMMER: RESULTS FROM A WATER COLUMN STABILITY ON ZOPLANKTON COMMUNITY STRUCTURE

Recent shifts in climate toward warmer conditions may threaten commercial fisheries by altering lower-trophic level productivity and trophic relationships on the southeastern Bering Sea shelf. We examined zooplankton community structure near the Pribilof Islands and on the middle shelf of the southeastern Bering Sea in summer of 1999 and 2004. Between 1999 and 2004, the summer zooplankton community of the middle shelf shifted from large to small species with significant declines in the biomass of large scyphozoans, large copepods, armors and euphausiids, and significant increases in small copepods and small hymeodruses. Stomach analysis of age-0 pollock from the middle shelf indicated a dietary shift from large to small copepods from 1999 to 2004. This shift in zooplankton community was accompanied by a threefold increase in water column stability in 2004 relative to 1999, primarily due to warmer water above the thermocline. These results suggest that if climate on the Bering Sea shelf continues to warm, the zooplankton community may shift from large to small taxa which could strongly impact apex predators and the economies they support.

COALESCENT AND BIOPHYSICAL MODELS OF LONG-DISTANCE DISPERSAL DYNAMICS IN NERITID SNAILS

Marine species in the Indo-West Pacific have ranges that can span thousands of kilometers, yet studies increasingly suggest that mean larval dispersal distances rarely exceed 200 km. Gene flow across these ranges must therefore rely on some extent on 1) leptokurtic long-distance dispersal and 2) larval dispersal among intermediate “stepping stone” populations, but it is difficult to distinguish between these processes. This study addresses this problem by integrating spatially explicit advection-diffusion models of larval dispersal with gene flow estimates from coalescent analyses. We estimated gene flow among South Pacific archipelagos in two species of marine snail and two species of freshwater snails that both have pelagic marine larvae but that differ in their adult habitat. Our preliminary conclusions are that stepping-stone dynamics are important to long-distance connectivity over short time-scales and in stable populations, but non-equilibrium processes such as rare long-distance dispersal events and metapopulation dynamics may be equally as important in promoting genetic connectivity across large distances. This study provides an empirical assessment of a biophysical model that will be useful in the design of marine reserve networks.

SURFACE FRESHENING OF THE TROPICAL PACIFIC WARM POOL SINCE THE 1950s.

An analysis of 1955-2003 sea surface temperature and salinity data collected in the tropical Pacific enables us to detect long-term trends in the tropical Pacific Ocean, with emphasis on the Warm Pool waters. The trend in the stratification of the surface layer is also studied. Since 1955, and more rapidly since the 1976-77 climate shift, the tropical central north tropical ocean, whose salinity has been significantly warming and freshening in the region. The freshening is more striking for the lower-salinity waters. One exception concerns the western Coral Sea and the central north tropical ocean, whose salinity has been increasing. Our study also indicates a significant low-frequency extension of the Fresh Pool located under the SPcz and in the eastern sub-tropical, interrupted by dual-time-scale variations. The observed salinity trends suggest an intensification of the hydrological cycle in the tropical Pacific, consistent with changes expected under global warming.

INTERACTIONS OF CHEMOSYNTHETIC BACTERIA WITH MERCURY AT DEEP-SEA HYDROTHERMAL VENTS

Microorganisms that inhabit deep-sea hydrothermal vents have likely evolved in the presence of elevated concentrations of mercury, which is complexed with sulfur in these environments. Hence, chemosynthetic microbes, which obtain energy from the oxidation of sulfur compounds, are likely exposed to its toxicity. To test this hypothesis we collected fluids from diffuse flow vents at 9°N on the East Pacific Rise (EPR). The concentration of total mercury (THg) in the samples ranged from 2.8 to 88.7 ng/L, while the abundance of mercury resistant thiobacilli oxidizing bacteria ranged from 0.2% to 24.6% of the total thiobacilli oxidizers. A correlation between mercury resistant bacteria and THg concentration suggested acclimation of these microbes to life in the presence of toxic mercury. Mercury speciation in the medium used to grow thiobacilli oxidizing bacteria showed the exclusive presence of negatively charged complexes of mercury thioulate, which were metallothioneine-like in nature. Ongoing work on pure cultures of mercury resistant bacteria and their resistance mechanisms will lead to an understanding of the role of these organisms in mercury biogeochemistry in geothermal environments.

SELECTIVE TIDAL STREAM TRANSPORT FOR PINK SHRIMP IN SOUTH FLORIDA
This coastal-estuarine species use selective tidal stream transport (STST) for horizontal movement. STST is thought to influence local migration, in which animals move up and down the water column during one tidal phase to promote transport in an "appropriate" direction, and remain or on near the bottom during the other phase to avoid being transported the "wrong" way. One remarkable aspect of STST is the reversal in direction of the migration at different life stages. Our research in South Florida suggests that pink shrimp postlarvae use a dark flood tide to move and last quarter moon to advance toward the western boundary of Florida Bay and into the bay's interior, and juveniles leave Florida Bay, moving in the opposite direction, by using the ebb tide on illuminated nights (full moon). An STST was detected in mysis and postlarvae migrating across the Southwest Florida shelf, suggesting earlier initiation of STST behavior in pink shrimp than other penaeids. The phase lag and attenuation of the tide accompanying their movement into Florida Bay may influence distribution of settlement-stage postlarvae on nursery grounds.

NEAR-SURFACE SHEAR-FLOW IN THE POLEWARD BRANCH OF THE TROPICAL PACIFIC MERIDIONAL-OVERTURNING CELL
Easterly trades blowing on the equator produce poleward Ekman divergent flow and upwelling. Since ADCPs cannot measure near-surface currents, measurements of the surface poleward branch of the meridional-overturing cell typically require extrapolation above ~20 m and thus depend upon assumptions of the near-surface shear. To test these assumptions, from May 2004 through February 2005, 5 current meters were placed at 5 meter intervals between 5 m and 25 m on a surface mooring near the 26°N, 148°W TAO mooring. The data show mean shear in the zonal flow due to thermal wind, and a slab-like poleward flow due to the competing effects of southward-thermal wind shear and poleward-Ekman spiral shear. Nighttime mixing and daytime restratification result in a diurnal jet and a corresponding diurnal cycle in the near-surface shear. On tropical instability wave timescales, the shear exhibits a complex structure due to variations in the orientation of the cold tongue front relative to the trade winds, and due to variations in the stratification and mixing over the course of the tropical instability wave.

RADON-222 AS A TRACER OF COASTAL GROUNDWATER DISCHARGE: EXAMINING CONTROLS ON SPATIAL VARIABILITY
Groundwater discharge has in recent years emerged as an important source of nutrients to the coastal ocean. Radon-222 is an excellent tracer of this discharge because it is strongly enriched in groundwater relative to surface water and is chemically non-reactive. One of the largest uncertainties in using radon as a quantitative tracer of discharge arises from the spatial variability in the radon-222 content of the groundwater. We carried out a study in West Falmouth Harbor (MA) to try to better understand the causes of this variability. A reasonably consistent two-fold increase in radon-222 activity was observed between surficial groundwater and groundwater from a depth of ~9 m in five different locations adjacent to the harbor. The surface deficit of radon-222 coincides with an increase in ‘excess air’ as indicated by the ratio of N2/Ar suggesting that both are driven by a common process. This interpretation will be checked using noble gas data, and the implications of this observation for the timing of gas equilibration in the aquifer and for the use of radon-222 as a tracer will be discussed.

SENSITIVITY OF MERIDIONAL-OVERTURNING RESPONSE TO SWITCHED-ON SOUTHERN OCEAN WIND
Southern Ocean wind variability may cause decadal global overturning variability. In a pre-ice age ocean model, the overturning anomaly due to switched-on wind and stress was 2-3 times stronger in the Pacific than in the Atlantic. Here, model experiments test the hypothesis that this is due to the Pacific being wider than the Atlantic. Idealized experiments are run with narrow and wide Pacific basins and with different North Pacific surface forcing scenarios. The Pacific overturning anomaly P is much bigger for a wider Pacific. In the first decade, P is only modestly sensitive to the density forcing. As it nears steady state, runs with stronger North Pacific density have much bigger P and somewhat smaller Atlantic overturning anomaly. These results indicate that the basic state has a profound effect on the anomalies. They also highlight the active role played by the Pacific, in contrast to the assumption that all the wind-driven outflow from the southern hemisphere (SH) flows into the North Atlantic. Generally, a strong signal develops within decades. Shallow water theory suggests that the timescale is shorter in the SH than in the Northern, and increases with basin width. The experiments show these features, but timescales differ within hemispheres and between basins. Curiously, in a single-basin experiment, the timescale is insensitive to basin width. In the two-basin experiments, timescales have a complicated dependence on North Pacific density.

ENGAGING UNDERGRADUATES WITH HUMAN IMPACTS
A survey of undergraduates entering an introductory oceanography course reveals that students feel a strong personal connection with the ocean, are concerned about human impacts, and are intrigued by exotic biology and cool technology. Any of these topics will help engage students in a formal oceanography course, but teaching about science of human impacts has effects that may reach far beyond the course itself. Students completing an oceanography course that includes the science of human impacts feel significantly more confident in their understanding of ocean issues, more responsible and more empowered to act for the good of the ocean. These attitudes are strongly correlated with improved attitudes about the nature and relevance of science, as well as with course grades and other measures of content knowledge. A separate survey of marine educators was used to validate the survey; the most significant difference between the educators (experts) and students (novices on pre-class surveys) is confidence in their understanding of ocean issues.

HYDROGRAPHIC CONSEQUENCES OF FLOW OVER TWO ADJACENT SEamounts WITH DIFFERING BATHYMETRY ARE REVEALED IN WATER COLUMN PLANKTON ECOLOGY
Seasonal studies encompassing both thermally stratified and deep mixed conditions demonstrated different types of seamount hydrodynamics in Lake Michigan. A persistent southward flowing current intercepts two mounts rising out of 150m: one steep-sloped to 36m and one shallow-sloped to 38m. During mixing periods, both impart stability to the overlying water, producing a progression of vertical isotherms that are several tenths of a degree warmer than surrounding basin water during winter. During stratification, leeside eddies and thermoline displacement are much greater for the shallower seamount. Seamount characteristics include full thermoline compression over the leading edge, well-sorted bottom composition, leading edge bottom composition, doming of deep cool isotherms over the plates, and apparent downwelling and sediment deposition on the lee side are readily demonstrated, albeit to different degrees, for both. In contrast to marine seamounts, both result in consistently depilated overlying plankton, possibly resulting from interaction with dense benthic filter-feeding nematode populations. Flow over these features may expose benthos to a far greater volume of water than a stagnant model would predict, making the MidLake Reef Complex a serious component of basin-scale ecology.

EFFECTS OF PREY AND ENVIRONMENTAL VARIATION ON SPATIAL DISTRIBUTION AND TEMPORAL VARIABILITY OF GROUNDFISH IN THE NORTHERN BERING SEA
Bottom water temperature increases are thought to be influencing northward fish range expansion and altering fish community structure in the Bering Sea north of St. Matthew Island as seasonal sea-ice becomes less prominent. During two icebreaker cruises on the USCGC Healy (7 May - 5 June 2006 and 16 May - 18 June 2007), groundfish were collected at 43 stations in 2006 (59 otter trawls), and 52 stations in 2007 (72 beam and 17 otter trawls). Arctic cod (Boreogadus saida), Bering flounder (Hippoglossoides robustus) and Snailfish (Liparidae) are the dominant fish in the northern Bering Sea. Patterns in species distribution and abundance (catch per unit area) are being analyzed in the context of prey items and environmental variables, such as bottom water temperature, salinity, and nutrient concentrations, along with sediment grain size and carbon content. Results indicate that groundfish may be competing for some of the same benthic food resources as are used by specialist benthic predators such as walrus, gray whale, bearded seals and spectacled eiders that feed on macrofauna in the rich Bering Sea sediments.

INTEGRATING REAL DATA IN K-12 ACTIVITIES: THE DEVELOPMENT OF OCEAN LITERATE STUDENTS USING SHRIMP: FLounder, AND MARSH LESSONS Ocean literacy concepts can be woven into K-12 activities ranging from animal biology to coastal processes. We present the activities that we have designed as part of a collaboration between a Savannah State University student and K-12 teachers in the community. Our activities have even been incorporated into pre-K classrooms. For example, one lesson focuses on flatfish shape and growth, as students act out the various life stages of a flounder. In another activity, we talk about how scientists sort their fish catches, which provides us with an opportunity for appreciation of fishery and fish abundance. Guess shrimp: provide a model for us to discuss the Ocean literacy concept of predator-prey dynamics; we explain how a small, commercially unimportant species has a great impact on the food web. Finally, we designed a series of K-12 activities based on marshes. The importance of sampling accuracy and precision are demonstrated through the use of student-constructed marsh models as well as field-based exercises. Given proper training, students can become reliable collectors of marsh data that can be useful to scientists.

FORECASTING WAVE ENERGY AND SALT MARSH ELEVATION CHANGES IN STUDIES OF ESTUARINE SHORELINES Efforts to forecast estuarine shoreline erosion rates demand precise measures of the wind wave regime. We utilized our Wave Energy Model (WEMo), which incorporates fetch, user-defined wind data, and bathymetry to calculate wave energy and asked whether this can forecast sediment accretion and loss rates of fringing Spartina alterniflora marshes in North Carolina. We created digital elevation models of the sites to track meso-scale elevation changes (+/- 2cm) and used surface elevation tables (SETs) and horizon markers to calculate fine-scale (mm/year) measures of sediment accretion. Fine scale measurements were made at the upper and lower edges of paired marshes from 7 sites between 2005 and 2007. Initial results indicated no relationship between fine-scale measures of wave energy and marsh elevation change, although at a coarser scale WEMo predicted a logarithmic decline of marsh frequency with wave energy. Shoreline features such as oyster reefs and breakwaters did significantly increase marsh elevation change, particularly at the lower marsh edge, where accretion exceeded elevation change. Acute events and landscape features may ultimately control the formation and distribution of fringing marshes in this region.

TIMING AND ATTRIBUTION OF OBSERVED NORTH ATLANTIC HEAT AND FRESHWATER CONTENT VARIABILITY Over the last fifty years, the subpolar basins and Nordic Seas exhibited a full cycle of changes in heat and freshwater content observed, to first-order, around the structure of the NAO/O ((O)) forcing. Although the freshening there between the 1960s and 1990s was long noted, it was be extra extraordinary; it was comparable in timing and amplitude to the natural variability of freshwater storage diagnosed from control runs of coupled climate models. The observed 50-year fluctuation of freshwater content can largely be accounted for as a combination of local storm track / precipitation anomalies, variability in moisture flux convergence onto the Arctic Ocean and its watersheds, and episodic accumulation and release of sea ice and freshwater from the Arctic governed by the regional atmospheric pressure patterns. Subpolar heat and freshwater content anomalies fluctuated in synchrony and were generally density-compensating. By contrast, the Nordic Seas heat and freshwater storage records diverged in the late 1980s resulting in reductions in density in the waters beneath the sill depths of the overflows. The vertical redistribution of temperature and freshwater anomalies, however, inhibited significant alterations of the density contrast that sustains the Atlantic MOC strength. Little, if any, sustained change in the AMOC is evident in the modern oceanic instrumental record.

SEASONAL TRANSPORT OF GRAVEL ON A MIXED SAND AND GRAVEL BEACH IN A LOW ENERGY, MESO-TO MACRO-TIDAL SETTING. In this work we present direct measurements of coarse sediment (gravel) transport from a beach in Rich Passage, Puget Sound, WA that is exposed to wind waves, tidal currents, and waveak. Few studies to date have quantified the relative role of different forcing mechanisms and the corresponding time scales of morphological response in such environments. Radio Frequency Identification (RFID) Passive Integrated Transponder (PIT) technology is implemented in two yearlong track studies of sediment particles, and complemented with beach profile surveys and meteorological and hydrodynamic measurements. The sampling of the gravel tracers provides sufficient resolution to reveal the dominant transport patterns over varying wave climates. Beach response to the wind wave climate is controlled by site specific exposure to prevailing winds. In the case examined, gravel transport by wind waves is dominated by the combination of vessel wakes and tidal currents.

THE RELATIVE IMPORTANCE OF LARVAL AND ADULT DISPERSAL IN THE ECONOMICALLY IMPORTANT GAG GROUPER MYCTEROPECA MICROLEPSIS: A GENETIC APPROACH The pelagic larvae of most marine organisms are carried by ocean currents for days to weeks at a time and serve as demographic links between geographically-separated patches of adults. Among some species, the adults also move tens to hundreds of kilometers in order to mate and spawn, and it is not immediately obvious whether larval or adult dispersal is primarily responsible for gene flow. The gag grouper (Mycteoperca microlepis) is an economically-important, slow growing, protogynous fish found throughout the Gulf of Mexico, northwestern Atlantic and Brazil. To separate the relative importance of gage dispersal at larval and adult stages, we propose to assess gene flow between Gulf and Atlantic populations. Our prediction is that migration between Gulf and Atlantic gage populations via larval dispersal could only occur in one direction (Gulf to Atlantic via the Gulf Stream), while migration by adults could occur in both directions. We have sampled 11 microsatellite loci within several hundreds of individuals of known age class in the Gulf and Atlantic, and will present an analysis of the strength and directional bias of gene flow.

SELENIUM ESSENTIAL, TOXIC, AND INCREASINGLY BEING MOBILIZED TO COASTAL AND OPEN OCEAN WATERS Selenium is a biologically essential element, but it is also toxic depending on its chemical form and concentration. Selenium is enriched in fossil fuels, particularly coal, and therefore introduced to surface waters directly and via the atmosphere. An excellent example of anthropogenic selenium inputs to coastal waters is the San Francisco Bay estuary where fluxes from oil refineries in the 1980-90s rivaled that from the major freshwater input, the Sacramento River. The deposition of selenium from the atmosphere to the surface waters of the North Atlantic has been documented, but we now have atmospheric and water column data for the western North Pacific that show Se from coal combustion in Asia is actually elevating surface water concentrations. Interestingly, silver is also enriched in these same waters, suggesting that it too is derived from coal combustion; Se may act as a coal combustion tracer. These results will be discussed in light of the new international GEOTRACES program that will examine the biogeochemistry of trace elements and their isotopes in the world's oceans.

RECONSTRUCTING UPPER OCEAN NITRATE CONCENTRATIONS VIA BARITE SE/S: DEVELOPMENT OF A NEW PROXY Bio-limiting nutrients such as nitrate affect C fluxes from surface waters, but paleo proxies need to be reconstructed their historical behaviors. In this respect, the accumulation rate of marine barite in sediments tracks C export, but not what’s driving it. However, other elements are incorporated into/barite that may track nutrients. Selenium as selegen precipitates with barite, but more significantly, depth profiles of selenium closely follow those of nitrate. Thus, Se/S in marine barite may at least semi-quantitatively record upper ocean nitrate concentrations. We are conducting calibrations using abiotic barite precipitation (varying selenate at constant sulfate), precipitations within decaying phytoplankton that simulate water column production, and determinations of Se/S in barites from sediments and core tops. The abiotic precipitations show an excellent correlation between barite and solution Se/S (r=0.88), light temperature dependence, and an enrichment of Se/S in barite relative to the solution of 15-30, which is similar to those seen in core tops analyzed to date. Se/S in barite formed in decaying phytoplankton behaves similarly. The discussion will include speculations on other uses for Se/S in marine barite.

NUMERICAL STUDY OF INTERNAL TIDE BREAKING PROCESSES Internal tides generated by the interaction of barotropic tides with topography represent almost half of the total internal wave energy. Internal tide breaking is therefore believed to play a crucial role in oceanic circulation. Tidal generation of solitons is one of the main processes involved in internal tide breaking. However, our knowledge of this mechanism is still incomplete. Previous results of Gerken (J.Mar.Res. 2001, Non Lin. Process. Geophys. 2003) obtained from a weakly non linear, non hydrostatic model, have shown for instance the dramatic influence of the pycnocline strength on solitons formation and propagation. Here, we use OOF5, a fully non hydrostatic numerical code developed by K. Winters to study propagation and breaking of internal tides in 2D idealized geometry, for different
stratification strength and latitudes. Therefore, we extend Gerken's results to the fully non linear, non hydrostatic case, while accounting for the influence of parametric subharmonic instability (PSI) by varying the latitude. Ultimately, we shall use these results as a basis for parameterizing internal tide energy transferred to solitobars and to high frequency waves through PSI as a function of bulk parameters: tide energy stratification, latitude.

DECADAL RESPONSE OF THE ATLANTIC MERIDIONAL OVERTURNING CIRCULATION TO LOCAL AND REMOTE FORCING
The MIT adjoint model in an 1 degree global configuration is used to study the variability of the Meridional OvERTurning Circulation (MOC) in the North Atlantic. The adjoint model allows the calculation of the sensitivity of the MOC to several model inputs, including initial conditions and atmospheric forcing, in a single model integration. These adjoint sensitivities are used to identify how anomalies along the western boundary and the interior, and thus the MOC, are sensitive to local and remote forcing. Our study suggests that the buoyancy forced variability of the mid-latitude MOC at a particular time is the sum of at least the last 40 years of winter-time buoyancy forcing over the subpolar gyre. This variability is characterized by a decadal oscillation, which is a robust feature of the model integrations. Positive heat loss anomalies, for example during NAO+ phases, are leading to an increased MOC for the next 10 out to a decreased MOC for the following 10 years and so on. The periods are nearly independent from latitude at which the jet function (i.e. the MOC) is defined. Whereas the decadal oscillation is a robust feature in our model runs, the sensitivity of the MOC to surface heat fluxes can also display a seasonal variation, but this is critically dependent on the formulation of the surface boundary conditions. We further discuss the utility and accuracy of adjoint models on decadal timescales.

EFFECTS OF PROTOZOA GRAZERS AND PERIODIC SUBSTRATE ADDITION ON GROUNDWATER MICROORGANISMS
Both substrate periodicity and the presence of protozoan grazers have been shown to affect bacterial community composition. In this study we analyzed groundwater microbial communities, collected from an aquifer at Waquoit Bay, MA. In laboratory incubations, communities were subjected to periodic addition of carbon substrate (acetate) and/or removal of grazers. Terminal restriction fragment length polymorphism procedures were used to describe the diversity within the resulting microbial communities. Periodic removal of grazers did not alter the diversity of the community when compared to communities subjected to a one time addition of acetate. However, community diversity was found to be different when samples were with and without grazers were collected. Interestingly, samples incubated without grazers had significantly higher numbers of heterotrophic cells and higher dissolved organic carbon concentrations. We conclude that the removal and subsequent absence of grazers leads to proliferation and diversification of microbial communities in a groundwater setting. The loss of a control mechanism, such as grazers, on microbial proliferation could have serious consequences for the use of groundwater resources in the future.

SAR OBSERVATIONS OF RESONANTLY GENERATED INTERNAL SOLITARY WAVES
SAR images revealed the two-dimensional propagation characteristics of short-period internal waves generated at Race Point Channel in Massachusetts Bay. The main characteristics of the two-layer flow are described based on the criticality of the Froude Number, calculated from available in situ measurements at Race Point Channel. The generation mechanism of the observed internal solitary waves is investigated. The solitary waves are generated during the ebb phase of the tide within the Channel. On some occasions, two trains of internal waves are generated presumably at the same location but at slightly different periods during the ebb tide. It is suggested that these two individual packets of waves result from flow passage through resonance. One packet is generated when the flow velocity enters the transcritical regime during the acceleration phase of the (ebb) tidal current, and another packet is generated during the deceleration phase. Both packets propagate upstream when the tide slackens, but with slightly different propagation directions.

SELECTIVITY AND GRAZING IMPACT OF TWO DOMINANT SPECIES IN THE CALIFORNIA CURRENT ECOSSYSTEM: EUHAPUS PACIFICA AND CALANUS PACIFICUS
Grazier addition experiments were carried out using field prey assemblages from coastal upwelling conditions to offshore mesotrophy during a CCE-LTER Process cruise in April 2007. Clearance rates of Euphausia pacifica revealed plastic preferences, following the relative availabilities of prey sizes and types determined by image analysis microscopy. In contrast, Calanus pacificus showed more of a fixed size preference. Both species preferred diatoms and autotrophs other than dinoflagellates. However, preference scaled with relative carbon contributions of the different groups, and clearance rates on heterotrophs increased with their increasing biomass. Behavior plasticity results in spatial differences in the potential grazing impacts on microplankton groups, which do not scale linearly with prey abundance. Additionally, the ability to exploit variable carbon resources in dynamic environments results in spatial differences in the carbon contributions of microplankton taxa, which could have potentially significant impacts on population success.

ONE CENTURY SEDIMENTARY RECORD OF MERCURY AND LEAD POLLUTION IN THE SAGUA ESTUARY (CUBA) DERIVED FROM 210PB AND 137CS CHRONOLOGY
Distribution of Hg and Pb were analyzed in a sediment core collected in the Sagua estuary, located in the north-centre of Cuba. This estuary receives the discharge of the Sagua River, one of the most polluted rivers discharging into the Cuban coastal environments. Depth profiles of metal concentrations were converted to time-profiles by using a 210Pb-derived vertical accretion rate, estimated 0.52 cm y-1 (0.17 cm y-2) for Hg and Pb respectively. The Hg increase is due to the incomplete treatment of industrial wastes from a chlor-alkali plant with mercury anode, present in the Sagua basin. Lead fluxes to sediments showed a gradual increase from the 20s to the present time, in good agreement with population increase in Sagua la Grande city. The transitory Pb flux reduction in the 90s is coincident with a period of Cuban economy contraction.

THE AUSTRALIAN INTEGRATED MARINE OBSERVING SYSTEM
The Integrated Marine Observing System (IMOS) is a set of equipment distributed in the ocean around Australia and puts data and information services to facilitate research and applications. Collectively the equipment will contribute to meeting the needs of marine research in Australia in both open oceans and coastal oceans. The value from this infrastructure investment lies in the coordinated deployment of a wide range of equipment aimed at deriving critical data sets. These, in turn, become the infrastructure for a wide range of research and educational roles at a variety of scales. The infrastructure also contributes to Australia’s role in international programs of ocean observing. IMOS was initiated in 2007 with an investment of $A55.2M by the Department of Education, Science and Technology under auspices of the National Cooperative Research Infrastructure System, and a nearly equal contribution in matching funds. The range of observations includes three open ocean projects (Argo-flots, Enhanced ships of Opportunity and a Southern Ocean Mooring), three coastal physical projects (moorings, glider floats and radar towers) and three coastal biological projects (passive acoustic listening stations, acoustic screens and instrumentation of the Great Barrier Reef).

FLOW-DRIVEN EXCHANGE OF SOLUTES AND PORE WATER AT THE SEDIMENT-WATER INTERFACE
Solute and pore-water exchange at the sediment-water interface affects nutrient availability and fate of contaminants in benthic environments. To better understand roles of sediment properties and mobility in these processes, we conducted flume experiments examining penetration of dye and salt tracers into a porous bed underlying channel flows with velocities up to nearly 1 m/s. The porous bed comprised 1.5-mm diameter glass beads and, in selected experiments, was covered with a 1-mm mesh to prevent sediment transport and development of bedforms, even when the flow speed was otherwise sufficient to mobilize individual particles in the bed. Visual measurements of the depth of dye penetration into an initially clear-bed water bed with time were made and validated with independent assessments of tracer exchange using in-bed lysimeters. We report that, for nominally flat, rippled and selected experiments, was covered with a 1-mm mesh to prevent sediment transport and development of bedforms, even when the flow speed was otherwise sufficient to mobilize individual particles in the bed. Visual measurements of the depth of dye penetration into an initially clear-bed water bed with time were made and validated with independent assessments of tracer exchange using in-bed lysimeters. We report that, for nominally flat, rippled and
PHOTOCHEMICAL PRODUCTION OF C1–C3 ALKYL NITRATES DURING GOMEC.

The photochemical production of low molecular weight alkyl nitrates (C1–C3) was observed in shipboard incubation experiments along the Gulf of Mexico East Coast Carbon Cruise (GOMEC), July 2007. This is the first time alkyl nitrate production experiments have been carried out in coastal waters using fresh samples. Seawater samples from the surface ocean at nine stations along the cruise track and spiked with varying levels of nitrite were analyzed. The concentration of alkyl nitrates increased with the addition of nitrite. The production rate of alkyl nitrates was clearly dependent upon the initial concentration of nitrite, most likely as the source for NO radicals for the reaction of ROO and NO to make alkyl nitrites. The magnitude of the production of alkyl nitrates varied between water samples and preliminary data analysis suggests that the ratios of alkyl nitrates changed significantly between water samples. This is different from previous observations in the open ocean. The implication is that the sources of organic peroxys radicals may change depending on the sample location, suggesting that it may be possible to observe alkyl nitrate formation to qualify organic matter.

ANOTHER WAY TO LOOK AT RECOVERY OF COASTAL SEDIMENTS FROM EXCESS CARBON LOADING

Boston Harbor has a long history of receiving domestic and industrial wastes, including municipal sewage. The Massachusetts Water Resource Authority (MWWA) has taken remedial actions to improve sediment and water quality of the harbor by improving sewage treatment and reducing anthropogenic inputs. Initial efforts began with the cessation of sludge discharge to the harbor in 1991. Long-term monitoring conducted by the MWWA has shown that sediment quality in the harbor has improved in response to these actions. Significant decreases in total organic carbon (TOC) and abundances of the sewage tracer, Clostridium perfringens were observed since the early 1990s. A significant downward trend was also observed in the intercept of the linear fit between TOC and percent fines over the monitoring period (p < 0.001), which reflects burn off of excess organic carbon after sewage sludge discharge was ended and decreases in the carbon load as the other interventions were completed and the sediments adjusted to the reduced carbon loading. Evaluation of the slope and intercept of the percent fines versus TOC relationship appears to provide another measure by which to assess system recovery.

REE SEAWATER CONCENTRATIONS IN THE BERING STRAIT AND THE CHUKCHI SEA

Nd isotope data from filtered samples show that Pacific water entering the Arctic through Bering Strait is significantly altered by processes on the shelf areas, gradually changing the isotopic signal of Pacific water to less radiogenic values. It is suggested that this shift is caused by interactions between sediments and exchange with re-suspended sedimentary particles. We present REE concentrations in unfiltered water samples from the Bering Strait and the Chukchi Sea. Vertical profiles were collected in the Bering Strait (50 m) and the Chukchi Abyssal Plain (1450 m). These data show the presence of suspended particles in Bering Strait, with more than 10 times higher Nd concentrations in some unfiltered samples compared to 0.22 micron filtered fractions. While total REE concentrations in the Bering Strait are similar high when compared to North Pacific seawater, dissolved Nd concentrations in Bering Strait remain at slightly enhanced levels. This indicates that the suspended fraction is largely inactive, supposedly minerogenic. However, the change in Nd-isotopic composition reveal that at least a fraction of the suspended matter is available for exchange with dissolved REE.

DECADAL TREND OF DISSOLVED OXYGEN IN THE WESTERN PACIFIC ACROSS IS6E

Japan Meteorological Agency has been conducting routine observation of hydrographic section in the top 2000m water column along 165°E between 30°N and 3°S once or twice a year since 1996. The changing parameters in the open ocean begin with dissolved oxygen (DO) analyzed by Winkler method. Data are now undergoing rigorous quality checking. Prelimnarily, we have analyzed the trend of DO on various isopycnal surfaces in the zone just to the south of Kuroshio Extension (28°N – 30°N) using the data set of WOCE P13 in 1993 as a benchmark. In general, trend of DO decrease and apparent oxygen utilization (AOU) increase were seen. They are mostly not statistically significant, but are significant in deeper layers; e.g., AOU is increasing at a rate of 3.5±1.1 μmol kg⁻¹ per decade at potential density 27.0 that does not outcrop in the North Pacific.
SATELLITE REMOTE SENSING OF THE BALTIC ECOSYSTEM AND ITS PRIMARY PRODUCTION

The Baltic Sea is of great importance to the countries surrounding it and its ecosystem is evolving as a result of human activities. This requires a regular monitoring of environmental processes in the Baltic which, together with in situ analysis at selected sites and times, can only be effective with the implementation of remote sensing technology. On the other hand the optical properties of the Baltic waters differ significantly from those of open seas, so the remote sensing of the characteristics of its ecosystem, in particular pigments and primary production (PP), has to be based on quite different algorithms, compared to those applied in the ocean waters. With this end in view, a comprehensive national project DESAMBEM - Development of satellite method of the Baltic ecosystem monitoring (PEZ KBZ-056/PO4/2001-2005) was executed in years 2002-2005. The mathematical models and algorithms for the remote sensing of the Baltic ecosystem and its primary production were developed and can be applied in the future. This work shows that the new algorithms have a strong potential in terms of monitoring Baltic ecosystems from space. Some analysis of PP data and validation of Baltic PP satellite algorithms are also provided.

ROLE OF GRAVITY CURRENTS ON SEAFLOOR MORPHOLOGY

Gravity currents containing large concentration of silt and clay can have major role on sea-floor morphology and the dispersion of sediment to the continental shelf and beyond. To investigate the impact of gravity current on the seafloor morphology, a generalized 2.5D morphodynamic model has been developed. The model assumes that the gravity-driven flow of suspended mud is supported by the wave-induced suspension of sediment in the turbid layer and is important to the shelf morphology and sediment dispersal beyond the continental shelf. The model uses depth-averaged equations for describing the conservations of suspended and bed load sediment, as well as the momentum and turbulent kinetic energy. These equations along with the Exner equation of bed sediment continuity are solved using a predictor-corrector scheme. The model studies the interaction of extreme river flow events with the seafloor, shelf processes as well as the along and cross shore currents. Based on a number of studies from the El River Shelf project (ONR, STRATAFORM), the present study includes an idealized representation of surf zone, shoreface and shelf processes to study the whole source-to-sink system of sediment sharing components. Different scenarios are used to emphasize the relative role of the interacting sediment transport flux gradients to characterize the nature of seafloor deposition.

OBSERVATIONS OF THE UPPER OCEAN BOUNDARY LAYER INFRONTS

The spatial structure and turbulent fluxes at strong density fronts were investigated using the high resolution of an acoustically-tracked, water-following Lagrangian float and a new towed body "Triaxus" that conducted rapid three-dimensional surveys around the float on a scale of 1-10 km. The float measured the turbulent intensity and fluxes in the boundary layer. Large eddy simulations of the boundary layer are used to help interpret these data. The presence of strong lateral gradients affects the boundary layer in several ways: The direction of the Ekman transport relative to these gradients can strengthen or weaken the front and enhance or suppress the mixed layer deepening. Several fronts have persistent regions of highly negative potential vorticity apparently sustained by wind forcing. The resulting instabilities can enhance the boundary layer turbulence, thereby providing a direct path from the geostrophic flow to turbulence and dissipation. They can also rapidly stratify the boundary layer when the wind weakens. Examples of these effects from fronts off Scotland and in the Kuroshio will be shown.

EXPERIMENTAL INTERNAL WAVES

We study the emission, propagation and reflection of internal waves. The use of a novel internal wave generator capable to produce large amplitude internal waves will be emphasized. Results on the reflection on various topographies will be given with and without rotation.

ON THE MECHANISMS AND TEMPORAL VARIABILITY OF HIGH-LATITUDE CHLOROPHYLL CONCENTRATIONS

Variability in global chlorophyll biomass (Z Chl) and marine net primary production (NPP) is a critical determinant of atmospheric composition and climate change. Recent oceanographic literature has developed the paradigm that stratification of the tropical and subtropical upper ocean exerts the primary physical influence on nutrient supply to
surface biota and consequently NPP. According to this view, variability in these regions dominates the global signal while observed changes in Σ C at high latitudes average the spatially and make no significant global contribution. To test this hypothesis we conduct a detailed study of the recent spatial and temporal variability in chlorophyll concentrations at high latitudes, examine its relation to changes at lower latitudes and explore linkages to local physical processes. We assess the primary physical forcing of variability in nutrient supply and NPP for cooler, seasonally stratified seas by relating Σ C to simple hydrography. We utilize satellite measurements of ocean colour and surface ocean properties as well as historical hydrographic records.

APPLICATIONS OF THE DIAGENETIC MODEL CANDI IN PENSACOLA BAY

We explored the robustness for a sediment diagenesis model. The model, CANDI (Carbon and Nutrient Dynamics In situ) has many variables which allows the model to be adjusted for different environments. Pensacola Bay overlying water (OW) concentrations for oxygen, nitrate, total phosphate, total ammonium, and total hydrogen sulfide were inputted into the model along with literature values of other OW nutrient concentrations for which no data were available. A median relative error close to twenty percent was obtained using nitrate sample data for the first three centimeters of Pensacola Bay. CANDI’s large repertoire of variables makes the model applicable to many environments the model is more complex as a result. Usually models compromise between simplicity and accuracy. However, CANDI sacrifices simplicity for generality not accuracy.

REMOTE SENSING OF A HARMFUL ALGAL BLOOM IN MONTEREY BAY, CALIFORNIA

The Coastal Ocean Applications and Science Team (COAST) was formed by NOAA to assess the need and utility of measuring coastal ocean color from a geostationary satellite. The first COAST experiment was conducted in Monterey Bay September 3-15, 2006. For the Monterey Bay experiment we used the Florida Environmental Research Institute’s (FERI) Spectroscopic Aerial Mapper with on-board Navigation (SAMSON). SAMSON collects a full hyperspectral dataset covering 256 bands in the VNIR (3.5 nm resolution over 380 to 970 nm range) at 72 frames per second. Monterey Bay was sampled at 5 m Ground Sample Distance (GSD) as frequently as every 30 minutes. At the time of the COAST experiment there was a Harmful Algal Bloom in the north-east corner of Monterey Bay. Extensive measurements of in-situ optics and biology were collected to characterize the bloom and its optical properties. The bloom had a distinct optical signature that was easily recognized in the remote sensing data. The dominant species in the bloom was Akashiwo sanguinea, a strong vertical migrator. The vertical migration was documented in the times series of SAMSON data.

GLOBEC SYNTHESIS AND MODEL EXAMINATION OF PROCESSES CONTROLLING COPEPOD POPULATIONS ON GEORGES BANK

An overview of US GLOBEC synthesis will precede discussion of research on 3D model applications. Biological and physical processes that influence the distributional patterns of copepod populations were examined using a “stage-with-mean-age” model, FVCOM, a nitrogen-phytoplankton-zooplankton-detritus (NPZD) model, and an integrated modeling system that was easily recognized in the remote sensing data. The dominant species in the bloom and its optical properties. The bloom had a distinct optical signature. CHARACTERIZATION OF NOVEL SPONGE-ASSOCIATED BACTERIA FROM THE GIANT BARREL SPONGE, XESTOSPONGIA MUTA

Xestospongia muta, the Giant Barrel Sponge, is a tropical marine sponge that is ubiquitous throughout the Caribbean. Molecular and culture based techniques have shown that this sponge is host to a very diverse microbial community. Several media types have been used to isolate bacteria from this sponge in an attempt to access the true bacterial diversity of cultivable bacteria present. Several novel bacteria have been cultured from this sponge and these isolates are likely to be the first representatives of new species or genera, based on initial 16s ribosomal RNA gene sequences. We are further characterizing these bacteria with methods that include full 16s ribosomal RNA gene sequencing, biochemical characterization, gram-staining, and motility assays. This work forms the basis for describing new bacterial species for these sponge-associated isolates.

ON THE GENERATION AND USE OF PROBABILISTIC WIND FIELDS FOR THE SIMULATION OF STORM SURGE AND INUNDATION

Hurricanes are the most costly, large-scale natural disasters impacting the U.S. Strong winds remote inundations originating over the shelf or damage may exist. For purposes of emergency planning and mitigation, numerical models are used to simulate the response of the coupled atmospheric-oceanic-estuary system. For hindcast, the atmospheric state can be fairly well determined; however, accurate forecasting (especially of intensity) is still lacking. One method to address the present forecasting inaccuracies is to use a probabilistically forced ensemble of synthetic wind and pressure fields. Using historical best track and forecast model guidance from the National Hurricane Center, empirically-derived probabilistic track and intensity errors are used to assemble an ensemble of synthetic wind and pressure fields. The resulting surge and inundation response for each ensemble member is then combined to produce aggregated forecast products (e.g. Maximum of Maximum or probability of exceedance). Using data from recent hurricanes, this paper will discuss the inundation response of selected coastal regions in Florida to an ensemble of synthetic storms and its impact for forecasting during the 2004 hurricane season.

EFFECTS OF WESTERN BOUNDARY CURRENT DYNAMICS ON THE INTERNAL WAVE FIELD OF THE SOUTHEAST FLORIDA SHELF

Shef shell internal wave fields are typically highly variable and dominated by wind and tidal forces. However, this is not necessarily true for outer shelf regions or very narrow shelves where remote physical processes originating over the slope or damage may exist. A strong influence on the internal wave climate. During the summers of 2003 and 2004 we conducted observational studies on the inner Southeastern Florida Shelf. This region experiences an energetic internal wave field and is close to the axis of the Florida Current. The data exhibit broad spectrum baroclinic energy, from f to f0, corresponding to baroclinic processes including the internal tide, cool-water internal bores, and high-frequency internal waves. Wavelet analyses of the coupled current with altimetry images of the Straits of Florida reveal the strong influence of Florida Current fluctuations on outer shelf flows. Diurnal-band instabilities in the Florida Current such as frontal eddies can modify the internal wave field on the shallow shelf and slope, at times, even more than tides. Finally, we present evidence for internal wave processes and associated processes including the internal tide, cool-water internal bores, and high-frequency internal waves. concentrations, with chlorophyll concentrations increasing with distance away from the bay. Zones of reduced oxygen tend to occur under surface layers of elevated chlorophyll.

Numerical and Theoretical Investigations of North Pacific Subtropical Mode Water and Its Role in Pacific Climate Variability

To better resolve the role of Subtropical Mode Water (STMW) in the exchange of information between the atmosphere and the ocean linked to climate variability, high-resolution MIT General Circulation Model (MITgcm) simulations are used to study the formation, evolution, and dispersal of STMW and thereby STMW's role in Pacific climate variability. During a 171-month time period (from Jan 1992 to Mar 2006), the seasonal variability is the dominant temporal pattern observed. From climatological model fields, STMW exhibits unique features in time and space. This can be seen more clearly by dividing the cycle into three distinct time periods: the formation, the isolation, and the dispersion periods. In addition to seasonality, there is also a distinct interannual signal observed in STMW. This variation pattern is connected closely to the climate shifts of North Pacific. Further investigation shows high correlation between the STMW variability and the Pacific Decadal Oscillation index. Implications of the role of STMW in decadal variability are explored as well as investigation into possible dynamics and mechanisms with the use of a Planetary Geostrophic Ocean Model.

Resolution of Bottom Boundary Layer Transports in a Model of Canyon Upwelling

The active transport of carbon out of the surface ocean by migrating fish that form the deep scattering layer is poorly known, but potentially large. Biomass measurements and CTD profiles from the CCE-P0704 cruise were combined with physiological and mortality rates from the literature using a computer model. The model results indicate an overall fish-mediated transport of 0.7-3.2 mg C m⁻² d⁻¹ in the California Current. The fish carbon flux is similar to estimates of the migratory zooplankton flux from other ecosystems and is 6-7% of the passive carbon flux measured concurrently with sediment traps. The measured fish biomass is biased low due to net avoidance. Correction of the bias based upon published capture efficiencies indicates that fish-mediated carbon flux is 45-50% of the passive flux measured with sediment traps at 100 m. We plan to measure capture efficiency bias on future CCE-LTER cruises by combining quantitative sonar data with mesopelagic trawl sampling.

Spatial Variation in Stable Carbon and Nitrogen Isotope Ratios in Primary Producers and Selected Consumers from Shallow Coastal Waters

Ratios of stable carbon and nitrogen isotopes represent a hallmark of contemporary in situ measurements. The distribution of carbon and nitrogen isotopes in seawater reflects the trophic status of the ecosystem and can reflect the impact of human activities. Rates of carbon and nitrogen cycling in coastal ecosystems are significantly higher than in the open ocean. The mixing of nitrate and ammonia from riverine inputs with the overlying oxygenated surface waters produces a unique isotopic signature that is used to track the carbon and nitrogen cycles in these systems. The study of carbon and nitrogen isotopes is essential for understanding the role of coastal ecosystems in the global carbon and nitrogen cycles.

Applications of Plankton Tracking and Identification for Underwater Device Ensembles

In order to develop in-situ methods for quantifying plankton movements, particle trajectories were extracted from video captured aboard the R/V Thomas G. Thompson, along a 1300-mile transect in the coastal northeastern Pacific in May 2007. Videos captured at sea were noisy from detritus and ship motion. Four algorithms to identify active swimming were compared, two algorithms estimate mean and std. flow vectors, one estimates average particle speed, and one estimates the mean directional distribution of all particles. Individual deviations from average water motion were used to identify active swimming. To develop a suite of algorithms effective across varied conditions, a diverse set of video footage was analyzed; footage had varying particle densities, water motion, and variations therein. Estimation of mean flow vectors identified active plankton with high precision for video footage with lower particle density and more water motion. For footage with higher particle densities and low water motion, performance decreased as density increased. Automatic methods of plankton trajectory identification could be used for developing a near real time system of monitoring biological activity and distinguishing from abiotic particle density.
predators into a realm normally devoid of these. Cross Seamount, located roughly 185 miles south of the Bering Sea, has sea ice that is 33 meters thick and has a diameter of approximately 8km. Using a dual warp modified Cobbd trawl with an open square mouth of approximately 140m², trawls were conducted both directly over and away from the summit of Cross Seamount to target the deep scattering layer during the day and the shallow scattering layer at night. All organisms collected were identified down to the lowest taxonomic level possible. Results from this study indicate that there is a significant decrease in abundance of organisms and absence of certain deeper migrating taxa directly over the summit as opposed to away. Reasons for the significant decrease in abundance could be due to increased predation directly over the summit or from active variation avoidance.

STABLE ISOTOPIC COMPOSITION OF DISSOLVED SILICON IN THE EASTERN ATLANTIC OCEAN

Diatoms are important primary producers in nutrient-replete environments such as upwelling zones and the Southern Ocean, where they may account for up to 75% of annual primary production and represent a significant carbon export from the surface ocean. As diatoms fractionate Si isotopes during formation of their siliceous frustules, the Si isotopic composition of diatomaceous opal and surface seawater reflects the degree of silicic acid utilisation. However, the use of Si isotopes as a paleoceanographic proxy is hampered by incomplete understanding of the dynamics of Si in the ocean, and a more thorough investigation of the modern ocean, especially nutrient-depleted waters, is thus vital. We present the stable isotope composition of Si dissolved in surface and deep waters of the eastern Atlantic Ocean. These samples, including highly depleted surface zones in which Si concentrations lie below 2µM, were collected on cruise ANT XXIII/1 and measured using high-resolution MC-ICPMS (Nu Plasma 1700).

FRESHWATER FLUXES IN FRAM STRAIT FROM A 9-YEAR LONG MOORING RECORD

Excessive amounts of freshwater added to the northern North Atlantic from the Arctic through Fram Strait can moderate the dense water formation and associated ocean density contrasts driving the northern part of the Meridional Overturning Circulation (MOC). Here, we present results from a 9-year long mooring record in western Fram Strait at 79°50' North which provides a platform to monitor the liquid freshwater flux from the Arctic into the Nordic seas continuously. The observed annual and interannual variability as well as long term changes of the water mass properties and volume transport in East Greenland Current are presented. The annual mean freshwater flux relative to a salinity of 34.9 is observed to be relatively constant despite a slight increase in the total annual mean southward volume transport in the Fram Strait over recent years. Relative to the 9-year mean the summer months of 2005 and 2006 indicate increased freshening of the outflowing upwell over deep water mass at the mooring sites in the East Greenland Current and on the East Greenland Shelf.

MODELING THE ICE-OCEAN ECOSYSTEM IN LANDFAST ICE ON THE CHUKCHI SHELF AND WITHIN THE FLUCTUATING ICE MARGIN OF THE BERING SEA

In recent years, modeling of both pelagic and sea ice regimes has revealed new insights into life at the dynamic interface between sea ice and water. Central to these modeling studies are field investigations, which are for the most part scarce in the Arctic. However, two sites on the Alaskan shelves have yielded and continue to produce biophysical multi-year time series observations that are crucial to the modeling work. This presentation will provide an overview of numerical modeling studies conducted through collaborations in recent years for the landfast ice ecosystem in the Chukchi Sea and the ice-ocean ecosystem in the fluctuating ice margin of the Bering Sea. Using the one-dimensional model, physical controls on biota are assessed, and hypotheses, such as seeding of the phytoplankton bloom by ice algae, investigated. Work in progress, including the addition of a sea ice microalgal loop, will also be presented. This new component of the model will help to investigate the partitioning of sea ice primary production between the pelagic, benthic and sea ice microbial realms under climate change.

LONG LIVE LIMPETS: SUSTAINING A COLLABORATIVE SCIENCE EDUCATION PROGRAM

The LiMPETS program is a collaborative effort among California’s National Marine Sanctuaries, the Farallones Marine Sanctuary Association (FMSA), the Marine Science Institution at the University of California at Santa Barbara, and the University of California at Santa Cruz. The LiMPETS network was created in 2002 when the National Marine Sanctuaries streamlined and united two independently conceived student monitoring programs, the Seymour Center’s Student Intertidal Monitoring Program (SIMP) and FMSA’s Sand Crab Monitoring Program. Protocols for monitoring rocky intertidal and sandy beach ecosystems were developed with the expertise of Dr. John Pearse, Dr. Jennifer Saltzman, and others. Since 2002, partnerships, funding, and leadership within the program have both helped and hindered the growth and success of LiMPETS. Lack of funds and support for the program has stymied its growth. However, our diverse partnerships and the integrity of the program itself, are the program’s greatest strengths. We will share past and present challenges and successes of this unique science education program and will unveil our new website and strategic plan for growth and sustainability of the LiMPETS program.

SEANET: COLLABORATIONS IN OCEAN SCIENCE EDUCATION IN ALASKA

A unique collaboration among ocean research organizations in Alaska has created an informal network of communicators, educators and scientists soon to be formalized as SEANET - Scientists and Educators of Alaska Network, part of a proposed Center for Ocean Sciences Education Excellence (COSEE): Alaska—People, Oceans and Climate Change. By sharing a senior outreach manager, the Alaska SeaLife Center (research and informal education), North Pacific Research Board (research) and Alaska Ocean Observing System (coastal and ocean monitoring) collaborate in communicating about their marine research programs to audiences in Alaska, the nation and the world. Together, the organizations sponsored the first Communicating Ocean Science (COS) Workshop during the annual Alaska Marine Science Symposium, which drew more than 400 ocean scientists to present the results of their research in Alaska’s seas. At the COS workshop, scientists, educators and communicators shared best practices in local, regional and national programs for communicating ocean science, and in 2008, will focus on networking scientists and educators.

CREATING INTERACTIVE DATA TOOLS & CASE STUDIES TO SUPPORT FUTURE USE OF SATELLITE-DERIVED SALINITY DATA

Despite the long history of ocean exploration, salinity has never been measured in 25% of Earth’s oceans. After its May 2010 launch, the NASA Aquarius instrument will measure global sea surface salinity (SSS) and produce monthly maps with 0.2 psu accuracy. How do we engage today’s learners to utilize these future data sets? By providing resources that demonstrate how improved understanding of salinity patterns - with ties to climate and the water cycle - can benefit society as a whole. Our “hands on” activities include lessons about the water cycle - can benefit society as a whole. Our “hands on” activities include lessons about
velocity field is examined in comparison with the frontal hydrography. Hydrography of the front is examined between cruises from the Scripps data. A strong near-bottom high salinity tongue is frequently present in the first and last cruises coming from the outer shelf waters. The front is most easily seen in the second cruise when temperatures dropped and a storm was present. The water column was vertically mixed, as opposed to the first and last cruises in which vertical stratification was present.

AN EVENT BASED APPROACH FOR OCEAN OBSERVING DATA: A CASE STUDY ON STRATIFICATION PROCESSES IN THE GULF OF MAINE

Rapidly expanding oceanographic data collection is creating a need for approaches to highlight and visualize important events within observational data streams. We have developed an objective method to find and extract oceanographic events from the Gulf of Maine Observing System (GoMOOS) time series data and have built an events database. The events are explicit change units detected across multiple variables, depths, geographic locations, and temporal granularities. An event viewer allows visualization and investigation of event-event relationships in different spatio-temporal settings. This presentation will illustrate the event approach using stratification events within the Gulf of Maine detected at intra-seasonal (~2-30 day) to interannual scales. We compare seasonal events (e.g. the transition from mixed to stratified conditions) and intra-seasonal events (e.g. multi-day periods of continuously increasing stratification) for each of the six years in the data record across buoy locations, depths, and years. The results enrich our understanding of oceanographic and temporal variation in timing and drivers of stratification. This approach holds promise beyond oceanographic data analysis for a broad range of sensor network data streams.

DeHaan, C. J., Naval Oceanographic Office, Stennis Space Center, USA, christopher.dehaan@nvo.navy.mil

SPECTRAL COMPARISONS BETWEEN A HIGH RESOLUTION MODEL AND IN SITU DATA IN FREQUENCY AND WAVE NUMBER

We will use spectral analyses of a high resolution (3km) regional Navy Coastal Ocean Model (NCOM) and a large number of temperature-salinity profiles collected in the western Pacific, to make comparisons between the model and the data. The dominant frequencies and wave numbers in both the model and the in situ data will be determined and compared. Particular emphasis will be placed on the internal tide band and its importance in the upwelling region, which will be used to validate which frequencies and wave numbers the model is reproducing well, and which it is not. It has been determined that the internal tides have a large day to day impact on the model's forecast capability. The period under study gives us a unique opportunity to evaluate internal tides as there were no major weather events or changes in the large scale ocean features to confuse the analysis.

BIO-OPTICAL VARIABILITY OF SOUTH AND EAST AUSTRALIAN COASTAL WATERS AND IMPLICATIONS FOR THE PARAMETERISATION OF COMPLEX WATERS ALGORITHMS

There is a significant demand for MERIS- and MODIS-derived, valid and accurate, estimates of chlorophyll, TSS and CDOM (as well as Kd or primary productivity) for the optically complex waters of the Australian East Coast, including the Great Barrier Reef. State-of-the-art remote sensing of coastal water bodies involves forward modeling that accurately reproduces the water leaving radiance or reflectance. An inversion process (such as a look up table approach or an optimisation inversion) is then applied to create remote sensing based maps of a water column variable from the remote sensing spectral information. Often it is assumed that one average set of Specific Inherent Optical Properties is adequate for the inversion. In many coastal environments, the interaction of river outflow plumes and tidal inflow of often clear ocean water cannot be described accurately by a fixed bio-optical region. Thus adequate knowledge of the variability of optical properties that exist within one remote sensing image over optically shallow to optically deep waters is crucial for creating remote sensing based maps of these aquatic ecosystems. The spatial and temporal variability of Apparent Optical Properties, Inherent Optical Properties and Specific Inherent Optical Properties from the Australian East Coast, including the Great Barrier Reef will be presented and strategies to deal with this variability in a remote sensing image will be discussed.

OPTICAL PROPERTIES OF TERRESTRIAL CDOM: RELATION TO LIGNIN

In a previous study, we proposed that the optical properties of humic substances (HS) and terrestrial chromophoric dissolved organic matter (CDOM) originate from the molecular charge transfer interactions between hydroxy-aromatic donors and quinoids acceptors formed by the partial oxidation of lignin precursors. Previous work by Hernes and Benner (2003) showed that lignin phenol content co-varies with CDOM absorption on the Mississippi River with this idea. To further test whether degraded lignin is the predominant source of terrestrial CDOM, we investigated the spatial and seasonal variation across the Middle Atlantic Bight of (a) terrestrial CDOM optical properties (absorbance and fluorescence); (b) lignin phenol content; (c) ultra-high resolution mass spectrometry of C18 extracted organic matter. Preliminary data show that (i) C18 phenol content correlates with the terrestrial CDOM emission maxima for an extracted lignin matches that of CDOM; HS, and C18 extracted organic matter (C18-OM); (ii) ultra-high resolution mass spectra of HS and C18-OM are consistent with that of degraded lignin.

Benthic predators, such as blue crabs (Callinectes sapidus), use dispersed chemicals to locate prey, such as bile salts, Mercenaria mercenaria. Most previous studies of this predator-prey interaction have concentrated on the predator behavior rather than the source characteristics controlled by the bivalve prey. Nevertheless, recent studies have shown that the source characteristics and ambient flow conditions greatly influence the structure of the chemical plume and therefore the information available. Source characteristics that may be altered by bivalve behavioral response to ambient flow conditions influence the bivalve prey movement and therefore the information available. Source characteristics that may be altered by bivalve behavioral response to ambient flow conditions include the excurrent flux, flow unsteadiness, and siphon behavior. We hypothesize that
certain combinations of source characteristics and ambient conditions may create a pre- 
refrigeration, and importing digital signal information downstream. In the minimal signal 
anomalous jet. This study, a Particle Image Velocimetry (PIV) system was used to quanti- 
the current velocity of the benthic bivalve clam Mercenaria mercenaria under varying ambi-

monitoring sea surface salinity in the global ocean from ships of opportunity

Sea surface salinity (SSS) observations are needed to improve our understanding of the 
earth’s water cycle and climate variability. SSS has proven to be valuable for improving 
estimates of evaporation minus precipitation budget, describing and understanding cli-
timate variability at seasonal to decadal time scales, testing physical processes, and 
numerical model performances, improving mixed layer representation by assimilation 
techniques used in operational oceanography, quantifying the role of salinity on sea level 
change, and improving El Nino prediction lead time. The importance of SSS in the cli-
mate system has motivated the development by European and US/Argentina space agencies 
of dedicated satellite missions (SMOS and Aquarius) to enhance global observations. 
This presentation focuses on the French SSS Observation Service (http://www.legos.obs-
mip.fr/observations/sss/), its strength and potential developments. This service aims at 
collecting, validating, archiving and distributing in situ SSS measurements derived from 
Voluntary Observing Ship programs, both for climate research and operational oceanogra-
phy. Details will be given about instruments and software, management of real time 
data transmission, validation processes for real time and delayed mode data, with a special 
focus on derived products, climatic indices and recent scientific results.

MECHANISMS OF VARIABILITY IN A CONVECTIVE BASIN

The oceanic poleward heat transport and the meridional overturning circulation are strongly affected by what happens in convective basins, where dense water is formed. Interannual variability in the formation and export of dense water is mostly due to changes in the two main drivers: local buoyancy fluxes and the remotely-forced circulation. Their relative contribution is investigated by using an idealized model for a convective basin. This model consists of two isopycnic layers. Dense water formation is induced by buoyancy loss in the interior, which is at rest. Newly formed dense water is transmitted to the surrounding boundary current through parameterized eddy fluxes. The inflow conditions in the bound-
ary current, i.e. the thickness of dense water and the barotropic velocity, represent the influence of the remotely-forced circulation. When applied to the Labrador Sea, the model suggests that variability in the formation of Labrador Sea Water simply integrates the atmo-
spheric buoyancy forcing on decadal timescales, whereas variability in the export of dense water as Labrador Sea Water is directly related to the subpolar gyre variability.

FACTORS INFLUENCING NITROGEN-CHLOROPHYLL RELATIONSHIPS FOR TEN ESTUARIES ON THE U.S. ATLANTIC AND GULF OF MEXICO COASTS

Regression relationships between summer concentrations of total (inorganic + organic) nitrogen and phytoplankton chlorophyll a in surface water have been developed for nine estuaries on the U.S. Atlantic coast and one adjacent to the Gulf of Mexico. These systems are estuarine embayments and six are river-dominated estuaries. All systems show substantial year-to-year variability in relationships between total nitrogen (TN) and chlorophyll a. Freshwater inflow and temperature appear to influence year-to-year vari-
ability in response. Comparisons among estuaries are made using data averaged over sev-
eral summers. Such relationships between TN and chlorophyll a concentrations for river-dominated estuaries are weaker and more system-specific than for estuarine embayments. However, when data for river-dominated systems are analyzed within zones having narrow ranges of water clarity, relationships for most systems strengthen and become more similar. Important factors influencing time-
averaged response of chlorophyll a to TN in these ten systems are estuary type (embay-
ment vs. river-dominated), and the magnitude and spatial distribution of water clarity.

THE POWER SPECTRUM AND VERTICAL STRUCTURE OF THERMOCLINE OXYGEN VARIABILITY

The observed variability of dissolved O2, now documented in every ocean basin, appears to be especially strong at decadal time scales and at the base of the ventilated thermocline. We propose novel hypotheses for these two recurrent features, illustrating them with an idealized model of the oxygen cycle forced by random physical and biological fluctua-
tions. The response of O2 to those fluctuations is strongly damped at time scales shorter than that of thermocline ventilation, producing a red spectrum even without any distinct decadal climate forcing. The O2 spectrum may be further modulated by the coupling between physical and biological sources of O2 variability. The vertical structure of O2 vari-
ance is influenced by the basin-scale isopycnal O2 gradient in the mean state, because it de-
termines the magnitude of O2 anomalies produced by circulation variability. Both hypo-
theses find support in observations and in GCM experiments. Our results suggest that along with long-term climate change, stochastic processes may be an important influence on the variability of biogeochemical tracers in the ocean interior.

WIND FORCING AND PHYSICAL, NITRATE AND FLUORESCENCE VARIABILITY IN THE SURFACE BOUNDARY LAYER OVER THE NORTHERN CALIFORNIA SHELF

The northern California shelf exhibits an archetypal spring and summer upwelling/re-
xtration cycle whose physical, nutrient, and fluorescence variability is well described. Variability in other seasons is not described as well. We review and contrast the spring and summer variability to that in fall and winter using data from the NSF Coastal Ocean Processes (CoOP) Wind Evaporation and Shell Transport (WEST) program. Data include meteorological and physical oceanographic parameters from a dense buoy array over the shelf and nitrate and chlorophyll fluorescence over the mid-shelf near Bodega Bay, CA. During spring and summer upwelling, the surface boundary layer can extend to 30 m or more. The cold, nitrate rich upwelled water is clear with low fluorescence. Relaxation events are accompanied by surface warming, a shallower surface boundary, and increased surface fluorescence peaks. Surface nitrate levels rapidly decrease to zero. In late summer, relax-
ation events lengthen and fluorescence often increases. Some of the highest fluorescence levels occur during fall. In winter and early spring, relatively low fluorescence and surface nitrate co-exist, however the nitrate is seldom drawn down to zero.

STABLE CARBON ISOTOPES OF LIPIDS IN CORAL AND ZOOXANTHELLAE TISSUES AND THEIR SUGGESTED CONTRIBUTION TO THE VARIATION OF RESPIRATORY CARBON DIOXIDE

The concentration of lipids and their stable carbon isotopic composition has been mea-
sured in the organic tissues of corals and their associated zooxanthellae from Montastrea faveolata. These samples were collected monthly from the Florida reef tract between 1995 and 1996 at a number of different reefs. The δ 13C values of lipids were found to be significantly lower than bulk tissue values for both coral and zooxanthellae. The δ 13C values of the lipids from coral tissue range from -20.32 to -14.06%, and the lipids of the zoa-
xanthellae range from -22.9 to -11.98%. The lipids were most depleted in δ 13C values in the fall, and most enriched in the spring. Results of this study suggest that the seasonal trends seen in respiratory CO2 of scleractinian corals previously noted may be linked to variation in the amount of lipids composing the coral’s respiratory material. The origin of the seasonal variations in the isotopic composition of the lipids may be related to carbon limitation or variation in the seasonal cycle of δ 18O in the coral reef environment.

SENSITIVITY OF OCEAN CIRCULATION AND TRACER DISTRIBUTIONS TO SMALL CHANGES IN SURFACE HEAT AND FRESHWATER FLUXES

Sediment cores retrieved from the ocean floor reveal significant changes in the distribu-
tion of many chemical tracers in the ocean on timescales of hundreds to thousands of years. Changes in the distribution of tracers over time have been used to infer changes in the characteristics of the large-scale ocean circulation. In this study, we vary the surface heat and freshwater fluxes in a three-dimensional coarse-resolution ocean general circula-
tion model (OGCM) to show that the distribution of chemical tracers in the ocean can undergo significant changes with very little change in the values of some key ocean circu-
lation components. For example, we show that variations in radiocarbon age in the North Atlantic on the order of that observed on glacial-interglacial timescales can be achieved with little change in either the strength of the meridional overturning circulation or in the northward heat and freshwater transports by the ocean. Our results indicate that large changes in tracer distributions may not necessarily imply large changes in the large-scale ocean circulation or heat transport.

THOUGHTS ON THE MESOSCALE, MIXING AND TOPOGRAPHY

Dissipation of energy from mesoscale, or `balanced’, flow is an important unresolved prob-
lem in oceanography. Recent observations of elevated mixing over complex topography suggests interactions between the mesoscale and topography results in transfers from
balanced flows to unbalanced flows. Analytical and numerical examinations of the mechanics of such interactions are described.

VENUS: TWO YEARS OF EXPERIENCE AND RESULTS FROM A CABLED OBSERVATORY

The Victoria Experimental Network Under the Sea (VENUS) is a cabled ocean observatory, with arrays near southern Vancouver Island, in both Saanich Inlet and the Strait of Georgia. The first array was deployed in February 2006 with an observatory node at 100m depth in Saanich Inlet. The second array, with nodes at 300 and 1750m was deployed in the Strait of Georgia in the fall of 2007. The fibre optic cabled observatory allows for unprecedented power and bandwidth to and from instruments connected to the observatory nodes. Data is retrieved and available over the web in near real-time. Preliminary instruments include standard oceanographic devices such as CTDs and ADCPs, as well as inverted echo-sounders, broadband hydrophones, dissolved gas sensors, settling traps, and a user controllable pan and tilt digital camera. Advanced systems under development include a dedicated sediment and delta dynamics laboratory. The data archive and instrument access are provided through the VENUS web site (http://www.venus.uvic.ca/), where galleries can be searched and data products requested. An overview of the observatory infrastructure, some preliminary scientific results, and how new users can access the facility will be presented.

NORTH PACIFIC CYCLES EXPLAIN OCEAN CLIMATE AND ECOSYSTEM CHANGE IN THE CALIFORNIA CURRENT

Decadal fluctuations of salinity and key biological variables in the Northeast Pacific over the past 50 years have been well documented and are thought to be related to climate change. Dramatic fluctuations in salinity, nutrients, chlorophyll, zooplankton biomass, fish stocks and seabirds, however, are often poorly correlated with the most widely used index of large scale climate variability in the region, the Pacific Decadal Oscillation (PDO). Here we define a new index of climate change, the North Pacific Gyres Oscillation (NPGO) and show that it is significantly correlated with previously unexplained fluctuations of salinity, nutrients and chlorophyll. Fluctuations in the NPGO are driven by regional and basin-scale variations in wind-driven upwelling and horizontal advection - the fundamental processes controlling salinity and nutrient concentrations. Nutrient fluctuations drive concurrent changes in zooplankton population concentrations, and may force similar variability in higher trophic levels. The NPGO thus provides a strong indicator of fluctuations in the mechanisms driving planktonic ecosystem dynamics. Observations and global warming simulations show the NPGO amplitude to be increasing over the last 50 years; we expect the dynamics underlying the NPGO to play increasingly dominant roles in forcing decadal changes in marine ecosystems.

BENTHIC TURBULENCE INDUCED BY NONLINEAR INTERNAL WAVES OF DEPRESSION

Results are presented from parallel spectral multidomain 3-D Direct Numerical Simulations (DNS) of the time-dependent boundary layer generated in the footprint of a fully Nonlinear Internal Wave (NILW) of depression. A frame of reference propagating at the wave phase speed is employed with wave Reynolds numbers reaching as high as $10^5$. The global instability of the separated wave-induced boundary layer produces benthic erotions characterized by the ejection of vortices high into the water column. The effect of developing transverse instabilities on the spanwise coherence of shed vortices is investigated. The energetics of the benthic boundary layer are quantified in terms of near-bed kinetic energy and dissipation rates and the structure of the bottom shear stress field. Depth-time plots of vorticity produced by virtual sensors spanning the lower 10% of the water column are compared with corresponding diagrams obtained from the CMO96 field experiment. A strong qualitative similarity is observed, suggesting that the mechanisms observed in the DNS are operative in the field. Finally, possible improvements are discussed for existing ADV-based parameterizations of along propagation-path NILW energy losses through bottom interactions.

MULTIDECADAL VARIATIONS IN BIODIVERSITY OF FISHES IN AN IMPACTED Ecosystem of Santos, Brazil, is one of the most affected by anthropogenic actions of South America, but it has an important role as rearing and residence grounds for the fish community. This study has evaluated multidecadal variations in its fish community structure. The ichthyofauna yielded 95 species and 29 families (only one elasmobranch). The fish community structure presents high abundance, biodiversity and richness, and is similar to that from 20 years ago. Some differences rose, suggesting that Santos Bay is an impacted area yet: only Sciaenidae amounted 73% of catch in numbers, and three species to more than 80%; there was a decrease of abundance and size of large predators, and of the relative importance of some species; the most abundant species is still the same but its importance is higher than before. After 20 years of improvement of environmental quality, questions as how to deal with this findings in an underdevelopment country with little past information; or the supposed benefits of the environmental protection actions; or the degree of resilience of the community and the way how to measure it, come up.

THE LINK BETWEEN BLUEFIN TUNA AND OCEAN ENVIRONMENTAL CONDITIONS

The bluefin tuna is considered one of the most economically valuable species of tuna in the North Atlantic. The high demand for bluefin tuna in the international markets has put this stock under heavy fishing pressure in recent years. Given the economical importance of the bluefin tuna fishery and the concerns regarding the depleted status of this stock, it is of utmost importance that we understand how environmental conditions affect the behavior and mortality of this species. This knowledge will aid fishery managers balance pressure on this stock from the fishing industry and the environment. In order to support this effort, we are linking information on oceanographic environmental conditions derived from satellite observations, such as sea surface and subsurface temperatures, surface wind, and water color to bluefin tuna catch and effort data. The combination of these data sets will make it possible to associate patterns in the distribution of bluefin tuna and fishing effort to oceanographic conditions and features. Quantifying these relationships and understanding the mechanisms that drive them has enhanced our ability to sustainably manage this species.

A NOVEL MECHANISM FOR MARINE PHOSPHORUS SEQUESTRATION VIA BURIAL AND TRANSFORMATION OF DIATOM-DERIVED PHOSPHOPHATE IN SEDIMENTS

Excess nutrient phosphorus is removed from wastewater by inducing sludge bacteria to synthesize polyphosphate. Here, we describe a similar, natural mechanism by which dissolved phosphate in marine surface waters is sequestered by polyphosphate-forming diatoms and transported to sediments as these polyphosphate-laden organisms senesce and sink. Cultured marine algae grown under phosphate replete conditions have previously been shown to store significant phosphorus as inorganic polyphosphate. But our findings represent the first instance in which natural communities of common marine diatoms have been shown to synthesize polyphosphate under sub-micromolar dissolved phosphate concentrations. Further, our results suggest that polyphosphate may nucleate the authigenic formation of calcium phosphate minerals in marine sediments. Thus, the transport of polyphosphate from its planktonic origin in surface waters to the underlying sediment, followed by subsequent mineral transformation provides a critical "biological pump" mechanism for the long-term sequestration of water column derived phosphorus in marine sediments. Importantly, this phosphorus removal mechanism may explain the puzzlingly dispersed distribution of fine-grained apatites observed in marine sediments worldwide.

HYPOXIA, A PARADOX OF EUTROPHICATION

The vast majority of our current marine hypoxic zones (about 200 documented cases) have developed over the last 50 years in response to anthropogenic forcing, through increased nutrient loadings and subsequent eutrophication. Until the 1950s, reports of mass mortality caused by lack of oxygen were limited to small systems with histories of oxygen stress. In the 1960s, the number of systems with reports of hypoxia-related problems started to increase, and in the 1970s and 1980s there was an explosive growth in systems with reports of hypoxia. By the 1990s most estuarine and marine systems in close proximity to population centers had reports of hypoxia or anoxia. There is encouraging news, since the 2000s, with some large systems such as the Black Sea and Boston Harbor responding positively to decreased anthropogenic stressors. While development of dissolved oxygen is the most widespread deleterious consequence of eutrophication, hypoxic area can be reduced or eliminated through management of nutrient or organic inputs. The rate and trajectory of recovery from hypoxia are functions of a system's resilience, and will be the focus of this presentation.

A HISTORICAL RECORD OF PARTICULATE ORGANIC CARBON EXPORTED FROM THE OB RIVER, SIBERIA

Permafrost soils and peat bogs in northern watersheds store vast amounts of organic carbon (OC) for many millennia, and these reservoirs are believed to be susceptible to destabilization by climate change. We characterized the properties of particulate OC exported from the Ob River, Siberia, and deposited in a deltaic lake to assess whether this large Arctic river exports significant amounts of permafrost-derived particulate OC and to determine how these properties have changed over time. Bulk elemental (C and N) stable carbon, carbono, lignin phenol and nuclear magnetic resonance (NMR) analyses reveal dramatic differences in the quality of the OC deposited in this lake over the last century, with OC ages ranging between 300 and 40 years. These results likely result from mixing of old, plant-derived OC that has been stored in the watershed for millennia with younger, algal-derived OC. Compound-specific radiocarbon analyses of higher plant wax biomarkers extracted from these sediments confirm that plant-derived OC within this sediment is significantly pre-aged.

LIVING IN A BACTERIAL WORLD: NEW PERSPECTIVES FOR TEACHING OLD CONCEPTS

Bacteria are in us, on us and all around us, but humans are not the only organisms to maintain constant associations with microbes. There is much to be discovered about the interactions between coral animals and the microbial community, and researchers at the Smithsonian Marine Station at Fort Pierce (SMSFP) are looking for answers by investigating the early life stages of two Caribbean corals, Porites astreoides and Acropora palmata. Coral microbiology offers an exceptional framework for teaching fundamental scientific concepts, but because this research is still in its infancy, it is rarely accessible for discussion in the classroom. SMSFP researchers and educators collaborated to develop an interactive teacher workshop based on that framework. The workshop “Coral Reefs: Bacterial Worlds” presents new perspectives on teaching the concept of symbiosis, draws on examples of marine animal-bacterial symbioses to discuss the evolution of complex life, and introduces microscopy, DNA extraction, and PCR and DNA sequencing, which are used at SMSFP to investigate microbiology and symbiosis in the marine environment. Here I present current coral-bacterial research and highlight key messages of the teacher workshop.

USING TRACERS FOR QUANTIFYING TRANSPORT PROCESSES IN LARGE-SCALE CONSTRUCTED WETLANDS

Chemical tracers (rhodamine-WT and LiCl) were injected into large-scale (147-928 ha) surface flow wetlands designed to remove phosphorus (P) from agricultural drainage waters in south Florida, USA. Analysis of the tracer response curves provided quantified parameters (effective hydraulic residence time, dispersion coefficient, residence time distribution, and tanks-in-series number) that provided a means of comparing hydraulic performance among wetlands. Internal monitoring of tracer and P concentrations yielded two-dimensional time series plots that identified which areas within a wetland were receiving most of the flow, and whether P removal was impaired because of hydraulic constraints. Because of the uneven wetland bottom topography and distribution of aquatic vegetation, preferential flow paths developed within most of the wetlands. This resulted in short circuiting in some parts of the wetland, while other areas were rendered as

REGIONAL COUPLED BIOGEOCHEMICAL-CIRCULATION MODELS TO EXPLORE TO WHAT EXTENT THE TROPICAL OCEAN MINIMUM ZONES ARE CONTROLLED BY THE PROCESSES SETTING THE SURFACE NUTRIENT LEVELS. OUR MODEL RESULTS SUGGEST ONLY A WEAK RELATION BETWEEN STOCKS OF SURFACE NUTRIENTS AND RATES OF OXYGEN CONSUMPTION. THIS HINTS AT A LIMITED ROLE OF IRON IN CONTROLLING OXYGEN MINIMUM ZONES.

The official data center for the International CLIVAR/CO2 Repeat Hydrography Program is the CLIVAR and Carbon Hydrographic Data Office (CCHDO) at the UCSD Scripps Institution of Oceanography. At the CCHDO, the CTDO, hydrographic, ocean carbon, and tracer data are collected, verified, corrected for content and format errors, assembled with relevant documentation, and carefully prepared for public dissemination and long-term archive. Shipboard data from US cruises for this program are available five weeks after return from sea. Availability of data from other nations depends upon individual data release and data sharing policies. Ocean carbon data are quality controlled by the Carbon Boundary Data Information Analysis Center (CBIAC) at Oak Ridge National Laboratory, and merged into the bottle data files at the CCHDO. Data are available from the CCHDO at http://cchdo.ucsd.edu and from CBIAC at http://cbicornl.oceans/oceans/RepeatSections/Repeat_map.html.

The CCHDO brings data sets together to a common content and readability standard and collects and preserves data documentation. All data sets are available in multiple formats, in addition to custom formats by arrangement. The CCHDO/WHPO also provides its public holdings, including documentation, to NODC/WDC-A for archiving and further distribution.

A HIGH RESOLUTION COUPLED SEA-ICE/OCEAN MODEL FOR THE ANTARCTIC PENINSULA REGION

A high-resolution (4 km) regional ocean circulation model that includes a dynamic sea-ice model and thermodynamically active ice shelves has been developed for the Antarctic Peninsula area. The dynamic sea-ice model (Budgell, 2005) is based on ice thermodynamics that include two ice layers, a snow layer, and a molecular sub layer at the ice/ocean interface. The ice-shelf thermodynamics are based on a three equation viscous sublayer model. Atmospheric forcing comes from several sources including the operationally used Antarctic Mesoscale Prediction System. We are in the process of running simulations covering the period of the SO GLOBEC field season (2001-2003) in order to examine the model fidelity with respect to hydrography (traditional and seal based), drifter, mooring and satellite measurements. The focus of the comparisons is to assess the model's suitability as a platform for studying the environmental effects on the region's biology, including ocean exchange and shelf retention.

DECREASES IN SUMMER PACK ICE EXTENT RESULT IN ANNUAL AND SEASONAL PREY SHIFTS AND LOWER BREEDING SUCCESS IN AN ARCTIC SEABIRD

We examined temporal variation in the availability and composition of fish in an area of the eastern Bering Sea experiencing major changes by cryogenic change by measuring annual and seasonal variation in the prey and nestling growth of the Black Guillemot (Cepphus grylle), an arctic seabird. In 2006 pack ice remained within 40 km of the breeding colony during the nestling period (late July to early September) and guillemots provisioned their young almost exclusively on Arctic Cod (Boreogadus saida), an ice-associated fish that is the guillemot's preferred prey. In 2007 prey choice and nestling growth were similar to 2006 until mid-August when ice rapidly retreated to >200 km from the colony. Chick growth was limited mainly on Arctic Cod (Boreogadus saida), an ice-associated fish that is the guillemot's preferred prey. In 2007 prey choice and nestling growth were similar to 2006 until mid-August when ice rapidly retreated to >200 km from the colony. Chick growth was limited mainly on Arctic Cod (Boreogadus saida), an ice-associated fish that is the guillemot's preferred prey. Using a high-resolution ocean circulation model forced by NCEP reanalysis fluxes, interannual variability of the Guinean Dome (GD) is studied from a western boundary of the Atlantic Meridional Mode (AMM). This is possible because the present model simulates SST anomalies associated with the AMM and GD well. The GD develops off Dakar seasonally from late spring to late fall owing to wind-induced upwelling; its seasonal evolution is associated with the ITCZ movement as discussed by Yamagata and Iizuka (1995). We find that interannual temperature variations of GD in boreal fall are significantly correlated with the AMM. When GD is unusually strong (weak) in fall, ITCZ is located anomalously northward/southward from late spring to early summer. This northward (southward) migration is due to a WES feedback mechanism in spring over positive (negative) SST anomalies. Whether this SST preconditioning in the GD region is associated with a previous opposite event or not needs more investigation. We conclude, however, that both positive and negative phases of AMM that develop in spring are linked closely to interannual variations of GD through the ITCZ migration.

ASSESSMENT OF SHORT-TERM TEMPORAL VARIABILITY IN THE COMMUNITY STRUCTURE OF TINTINNIDS, PLANKTONIC CILIATES OF THE MICROZOOPLANKTON

There are few data on the temporal variability of biodiversity metrics with regard to marine plankton. We sampled an open water site in the N.W. Mediterranean Sea subject to little advection. On 20 dates over a 4-week period in autumn 2004, large volume samples (10 l) were obtained from 6 depths between the surface and 90 m at the Dyfamed Station midway between the French coast and Corsica. Quantitative estimates of the tintinnid community varied considerably compared to qualitative descriptors. Average water column concentrations of tintinnids ranged from 10 - 501 l-1 and varied with chlorophyll concentrations. Numbers of tintinnid species varied between 24 and 33, from day to day and values of the Shannon H' index ranged from 2 to 2.7. However, identity of the dominant species (the most abundant species, collectively representing ≥ 50% of total individual abundance) was constant. Species rank-abundance curves for all dates were nearly identical and mostly closely resembled log-series distributions rather than log-normal or geometric distributions. This work was supported by the French program LIFE-CYBER and the European Network of Excellence MARBEF.

SEDIMENT PROFILES OF LESS COMMONLY DETERMINED ELEMENTS OBTAINED RAPIDLY BY LASER ABLATION-ICP-MS

Numerous studies have documented profound anthropogenic influences on trace element profiles in nearshore marine sediments from estuaries. However, the vast majority of these studies focus on a small number of relatively high-abundance of trace elements, (e.g. Ni, Cu, Zn, Cd and Pb). A high-throughput analytical method that greatly extends this list would be Laser Ablation - Inductively Coupled Plasma - Mass Spectrometry is a promising technique with unique advantages: time and labor expended on sample preparation are eliminated and results are obtained quickly. Laser Ablation-ICP-MS provides a high throughput analytical tool with significant potential for the study of marine sediments. We report the analysis of 10 l of sediments using LA-ICP-MS. We have demonstrated that select elements exhibit featureless profiles: S, Ca, Ti, V, Mn, Ge, Nb. In some cases, we have been able to identify specific origins of these profiles that may be due to anthropogenic influences, i.e. enrichment after 1920 followed by decline after ca.1980, possibly reflecting increased regulatory efforts: Co, Cu, Zn, Cd, Sn, Se, Tl, Pb and Bi. As expected the redox-sensitive elements: Mn, Re and U have similar profiles to one another and W's profile indicates that it is also a potential redox-indicator. The remaining elements exhibit featureless profiles: S, Ta, Ti, V, Mn, Ge, Nb.

ALTERNATE MECHANISMS CONTROLLING THE FORMATION, MAINTENANCE AND DISSIPATION OF THIN LAYERS IN WESTERN MUNTEY BAY IN 2005 AND 2006

Thin layer models have suggested that interactions between biological, chemical, physical and optical structures and processes can control the formation, maintenance of thin phytoplankton and zooplankton layers. As part of an ONR LOCM experiment, we deployed an array of autonomous profilers to quantify temporal and spatial changes in fine-scale physical, bio-optical and chemical structure and then used near-real-time data from the array to guide ship-based collection of plankton samples from inside and outside thin layers. In 2005, the dinoflagellate Akashiwo sanguinea formed thin layers each night at the depth of the nutricline then migrated up into the upper water column during the daytime where it could get sufficient light for photosynthesis. In 2006 several other dinoflagellates and a photosynthetic ciliate formed intense thin optical layers and oxygen maxima during day in near surface waters, but did not form thin optical layers at depth during the...
night even after surface nutrients were briefly depleted. These results emphasize the need to combine adaptive sampling with 3-D time series data when trying to understand the alternative mechanisms controlling thin layer dynamics.

It has been shown that the vorticity in the deep-water island wake is primarily generated by the stress in the boundary layer (Dong, et al., 2007). In the shallow-water island wake, the mechanism for vorticity generation differs from the deep-water wake significantly. The Regional Oceanic Model System (ROMS) is applied to study. The PV budget is calculated to analyze the generation and evolution of the PV anomalies in the wake. The PV analysis shows the frontal and diabatic processes are dominant in the PV generation and the redistribution of the PV anomalies are due to the advection process.

J., CSIRO, Hobart, Austria, ian.barton@csiro.au; THE GHRST-PP AND THE MULTI-PRODUCT ENSEMBLE (GMPE) OF SST ANALYSES

Accurate global SST is required for climate monitoring and by ocean and atmospheric forecasting systems on a daily basis to constrain systems at boundaries. The Global Ocean Data Assimilation Experiment (GODAE) High Resolution SST Pilot Project (GHRST-PP) has initiated a new activity, called the GHRST-PP Multi-Product Ensemble (GMPE) that uses ensemble techniques to investigate SST analysis differences using both analyses and observational products. As a UK contribution to the GMPE, the Met Office has implemented an SST ensemble system in collaboration with other operational agencies that allows centres to assess the relative performance of their SST product against a ‘consensus’ standard product. Each day a GMPE median average SST map from a number of input analysis products after their differing analysis grids have been homogenised by area averaging onto a standard 0.5° lat/lon grid. Operational SST maps from a number of input analysis products after their differing analysis grids have been homogenised by area averaging onto a standard 0.5° lat/lon grid. Operational SST and Sea ice analysis inputs include: OSMIA Met Office (UK), Reynolds’ (NCDCS, USA), NAVOCEANO K10 10km, NRI GHRST-PP 10km analysis, JMA 25km MGDSST, Japan, MERSEA 10km, France, BRMC Global, Australia, and 10km products from RSS USA. The GMPE ensemble is updated each day and output data sets are available together with a variety of diagnostic and anomaly plots on a daily basis (T0-24) at http://www.ghrst-pp.org/Todays-global-SST.html. This presentation reviews the GHRST-PP GMPE and provides a summary overview of differences between the input SST analysis data sets.

J., University of Central Florida, Orlando, USA, lwalter@pegasus.cc.ucf.edu; RECOVERY OF SALTMARSH FLORA AND FAUNA AT RESTORED MOSQUITO IMPOUNDMENTS IN MOSQUITO LAGOON (VOLUSIA COUNTY, FL)

In the 1960s, portions of saltmarsh habitat in Mosquito Lagoon, FL were impounded for mosquito management. The dike and adjacent ditch decreased the area of saltmarsh and changed the marsh’s hydrological characteristics. These changes facilitated invasion by exotic and native non-halophytic vegetation and decreased freshwater-estuary connectivity. Opening culverts and breaching dikes in the 1990s restored connectivity, followed by complete removal of dikes in the late-1990s. Vegetation monitoring began in 2005 and was expanded in 2007 to include the diversity and abundance of fiddler crabs, shorebirds, and vegetation at five restored impoundments in different stages of recovery and two reference sites. Soil characteristics, organic matter content, and elevation were measured to explain differences between restored sites and neighboring reference marshes. GIS-based estimates of area returned to marsh elevation were also made. Natural recruitment of native flora and fauna was observed at all restored sites. In addition, the abundance of exotic flora was reduced following impoundment restoration. These results are providing insight on the effectiveness of this restoration method, recovery rate estimates, and future saltmarsh restoration project planning.

H., Florida Geological Survey, Tallahassee, FL, USA; NORTHERN GULF OF MEXICO HOLOCENE SEA-LEVEL HISTORY AND ITS IMPACT ON BARRIER GROWTH

A detailed composite sea-level record for the late Quaternary of the northern Gulf of Mexico (NGOM) reveals the major sea-level events for the period since the Last Glacial Maximum (LGM), including a complete Holocene history. Following the LGM, sea level rose in pulses, apparently in response to global climate events. Millennium-scale cycles have persisted throughout the post-LGM, with amplitude diminishing with time. The northern Gulf of Mexico sea-level record correlates well with similar histories reported from the north and tropical Atlantic. During the mid- to late Holocene, the NGOM sea-level history depicts a rapid rise to near-current levels by about 6000 years ago. Since then, sea level has undergone swings of +/- 2 meters. This fine-scale sea-level behavior during the latter half of the Holocene has had a significant effect on the initiation and evolution of coastal landforms on Gulf of Mexico shorelines.

Donovan, C. D., Turner Designs, Inc., Sunnyvale, USA, cd Donovan@turnerd esigns.com; Younan, L., Turner Designs, Inc., Sunnyvale, USA, lyounan@turnerd esigns.com; TWO NEW SENSORS AVAILABLE FOR AQUATIC OPTICAL CHARACTERIZATION AND VARIABLE FLUORESCENCE

Turner Designs has developed two new optical sensors the C6 Multi-Sensor Platform and the PhytoFlash Submersible Active Fluorometer. The C6 Multi-Sensor Platform was designed for extended or short-term deployments with a mechanical wiper that eliminates bio-fouling. The instrument can be configured with up to six optical sensors ranging from ultra-violet to the infrared spectrum. Depth and temperature sensors are also included. A variety of optical sensors can be configured differentiating chlorophyll a pigments in algae, fresh water and marine cyanobacteria pigments, turbidity, CDOM, as well as custom optics for specific pigments. Performance data including the optical characterization of a freshwater lake will be presented. The PhytoFlash Submersible Active Fluorometer is an in situ variable fluorescence system that has been developed to allow for real-time measurement of the primary variable fluorescence variables: Fv, Fo and Fm. Practical applications include the detection of the onset of algal blooms, indication of nutrient status of planktonic algae as well as the measurement of algal community change. Performance data will be presented.

d'Orgenville, M. University of Toronto, Department of Physics, Toronto, Canada, morgl@ atompix.physics.utoronto.ca; Peller, W. E., University of Toronto, Department of Physics, Toronto, Canada, marc.dorgenville@utoronto.ca; THE RELATION OF THE PACIFIC AND ATLANTIC BASINS ON DECADAL AND MULTIDEcadAL TIMESCALES

The relation between the Pacific Decadal Oscillation (PDO) and the Atlantic Multidecadal Oscillation (AMO) is investigated based on analyses of Sea Surface Temperature (SST) observations over the past century. It is shown that the AMO either leads the PDO by 13 years or lags the PDO by 17 years. The AMO and PDO might therefore be viewed as part of the same oscillation cycle with a period of approximately 60 years. It is further argued on the basis of the same observations that the PDO may be viewed as involving an ocean basin scale mode of adjustment with decadal time scale that is superimposed on a multidecadal modulation. The validity of this interpretation of the PDO based on the analysis of observations is further investigated through the investigation of coupled global climate model simulations performed using the NCAR CCSM 3.0 model. In simulations that reach steady state the PDO is observed to have a multidecadal modulation related to the North Atlantic variability. The simulation performed using the NCAR CCSM 3.0 model. In simulations that reach steady state the PDO is observed to have a multidecadal modulation related to the North Atlantic variability.
The Southern Ocean's Subantarctic and Antarctic Intermediate water masses dominate the oceanic uptake of anthropogenic CO₂. The model means show a decrease in the annual mean subduction and entrainment rates resulting from warming and freshening at the ocean's surface in the South-East Indian and Pacific Oceans. A corresponding cooling and freshening is found on density surfaces within the ocean interior in these two water masses (upper 1500 m) and compare well with observations. There is a decrease in the loss of the net surface buoyancy flux at model and intermediate water densities (25.8 to 27.4 kg m⁻³) which is dominated by surface water heat and the flux driven by Ekman transport, and through increases in the vertical stratification below the mixed layer. Our multi-model analysis shows a decrease in the renewal rates of Southern Ocean water masses and hence affecting the uptake of anthropogenic CO₂.

LONGITUDINAL PROFILES OF CDOM, TEMPERATURE, AND CONDUCTIVITY AS A MEANS TO LOCALIZE GROUNDWATER INPUTS IN THE SAN JOAQUIN RIVER, CA.

Dissolved organic matter (DOM) and nitrate (NO₃) in the San Joaquin River (SJR) are water quality constituents of concern because they may stimulate algal growth, and because of impacts on drinking water treatment. Past research utilizing isotopes of nitrogen and oxygen (15N and 18O) suggest that nitrate in local groundwater sources to the River may be derived from numerous confined animal feeding operations proximal to the River. But the areas where significant transfer occurs remain obscure. To localize potential groundwater inputs and investigate riverine DOM dynamics, a lagrangian boat survey was completed during low flow conditions along a 100 km reach of the SJR. A boat instrumented with GPS and a sensor probe was used to obtain continuous longitudinal profiles of depth, temperature, specific conductivity, pH, dissolved oxygen and optical properties of DOM throughout the entire river reach. The resulting longitudinal profiles displayed spatial and temporal variations in temperature, specific conductivity, dissolved oxygen and DOM dynamics which can be related to potential groundwater discharge areas as well as various surface water inflows.

CHANGES IN THE SUBDUCTION OF SOUTHERN OCEAN WATER MASSES IN TEN IPCC MODELS

The Southern Ocean's Subantarctic Mode and Antarctic Intermediate water masses dominate the oceanic uptake of anthropogenic CO₂ and store heat, freshwater and dissolved gases. We analyse the ocean's response to changes in surface forcing using two different methods and across ten models from the IPCC Fourth Assessment Report. We compare the 1950s 20th century mean climate and the 2090s A2 scenario, where CO₂ concentration reaches 860 ppm by the year 2100. Subduction rates are diagnosed and analysed on density surfaces (which evolve with time) and on surfaces that are fixed in time, defined by the position of density surfaces in the 1950s. The model means show a decrease in the annual mean subduction and entrainment rates resulting from warming and freshening at the ocean's surface in the South-East Indian and Pacific Oceans. A corresponding cooling and freshening is found on density surfaces within the ocean interior in these two water masses (upper 1500 m) and compare well with observations. There is a decrease in the loss of the net surface buoyancy flux at model and intermediate water densities (25.8 to 27.4 kg m⁻³) which is dominated by surface water heat and the flux driven by Ekman transport, and through increases in the vertical stratification below the mixed layer. Our multi-model analysis shows a decrease in the renewal rates of Southern Ocean water masses and hence affecting the uptake of anthropogenic CO₂.

MEETING ABSTRACTS

ASLO/AGU/TOS/ERF
and spatial variability of the warming and examine the relative importance of the air sea heat flux versus heat advection by the Atlantic Water inflows in forcing these observed changes. The biological responses to the warming are also highlighted. Changes include: earlier phytoplankton blooms; elevated zooplankton biomass levels; shifts in fish distributions and spawning sites; higher recruitment levels; and differing benthos communities. Of particular note is the northward extension of several species of fish resulting in a potential of Miami, Miami, Florida, usa, sevins@rsmas.miami.edu; Sanchez, M., Florida International University, Miami, USA, maestro42@fiu.edu; Bellmund, S., National Park Service, Homestead, USA, Sarah.Bellmund@nps.gov

NITROGEN CYCLING IN BISCAYNE BAY, FL

Biscayne Bay, Florida is a tropical coastal lagoon situated adjacent to a large urban population with many natural and anthropogenic nitrogen sources, including atmospheric input, N fixation, nutrient regeneration/recycling, landfill soil leaching, runoffs, septic tank leakage, and treatment wastewater effluent. To understand the relative importance of input sources of N, the stable isotope systematics (δ13C, δ15N, and δ18O) were measured in macroalgae, seagrasses, and seawater samples from Biscayne Bay and the Miami Central wastewatertail bove two years. Mean 615N and 613C for algal tissue in Biscayne Bay were +5.2 (+0.0%e) and +14.5 (+0.42%) and +6.9 (+0.1%) and +19.5 (+0.2%) for the wastewatertail algae. Within the Bay, nearshore algal samples were enriched by up to ~7% compared to offshore algae. High 813C values within the Bay imply regenerated seagrasses are the dominant DIC (dissolved inorganic carbon) source. Bay seawater and Miami Central wastewatertail had DIN (dissolved inorganic nitrogen) δ15N values of ~+4.5 (+0.0%) and ~7.5 (+0.7%), respectively. Combining 615N and 618O values from nitrate, an isotopically traceable precipitation component is distinguishable in the Bay; lower wastewatertail values imply a rathification nutrient origin. This study will con-tinue to examine temporal and spatial C, N O isotope variations at greater resolution.

THE IMPORTANCE OF CARRION TO ABYSSAL FISHES: STOMACH CONTENT AND STABLE ISOTOPE EVIDENCE

Photographic investigations document deep-sea fishes scavenging on the carcasses of surface living animals but the fishes also prey on deep-sea fauna. Few studies have attempted to deter-mine the relative importance of each trophic pathway. Recent documentation of inter-decadal changes in macrourid densities in the abyssal Pacific, possibly related to changing food supplies, has generated interest for investigating this trophic pathway. We conducted stomach content and stable isotopic analyses of two abyssal macrourids, potential carrion sources, and potential benthic prey, collected concur-rently at 4100m off California (station M). Stomach content analysis revealed squid, fishes, and carrion (hake, jack mackerel) as the most important prey for Coryphaenoides armatus. C. yaque-niae's diet included more small crustaceans and polychaetes. The nitrogen and carbon isotopic values of potential carrion were comparable to the most isotopically depleted benthic animals examined, deposit feeding echinoderms. The highest isotopic enrichments were observed in benthic shrimps and large predaeous polychaetes. Macrourids had intermediate values sug-gestin that while they forage on benthic prey, carrion is a major component of their diet. The implications of these findings to the abyssal food web will be discussed.

OFF-SHELF EXPORT FROM THE GULF OF LIONS CONTINENTAL SHELF: ROLES OF LACAZE-DUTHERS AND CAP DE CREUS CANYONS IN THE GULF OF LIONS SEDIMENT DISPERAL SYSTEM

The relationship between sediment supply, margin geometry, proximity to the source and wave/current processes controls the fate of sediment and the effectiveness of subma-rine canyons as active conduits for sediment from the continental shelf to the deep-sea. Sediment is transported to the southwest Gulf of Lions shelf in a step-wise process pri-marily from the Rhine River, along a mid-shelf mud deposit. Coarsened shelf deposits on the southwest terminus reflect increased energy caused by narrowing shelf topography. Here a central mud deposit is absent and the outer-shelf is bypassed. Export off-shelf in winter 2004-2005, was mainly by cold-water density currents but evidence exists for inter-nal wave resuspension, hemipelagic settling and sediment gravity flows. Seabed stratigra-phy in the canyons reflects localized zones of both ephemeral deposition and long-term accumulation. The canyon heads show evidence of sediment bypassing. In lower-canyon depths (>400 m water depth), sedimentation in distinct locations reflects both hemipelagic settling and sediment gravity flows. Local geology and flow interactions play a critical role in redistribution and off-shelf export of sediment in the Gulf of Lions.

ECOLOGICAL EFFECTS OF MERCURY DEPOSITION IN THE ADIRONDACK REGION OF NEW YORK; CRITICAL ISSUES FOR RECOVERY

We synthesize multidisciplinary research on atmosphere-forest Hg dynamics and effects on ecosystems in the Adirondack region of New York, including issues regulating recov-ery following emission controls. The Adirondacks have exhibited marked changes in net atmospheric deposition since about 1900 including decreases since the 1970s. Litterfall is the dominant input pathway of Hg (~17 µg/m2·yr) to the Adirondacks, throughfall is nearly balanced by soil erosion and the major loss is soil accumulation (~15 µg/m2·yr). Limited drainage losses ofionic Hg are converted to methyl Hg largely in wetlands, particularly during the summer growing season, supplying downstream surface waters. A recent survey of 25 Adirondack lakes shows the water columns have largely exhibited decreases in total and methyl Hg concentrations changes while the Hg content of yellow perch have been mixed. These changes appear linked to changes in the DOC concentra-tions. Critical issues for the recovery of Adirondack ecosystems are the effects of changes in atmospheric Hg, SO42- and NO3- deposition, changes in DOC and its influence of Hg bioavailability, and the legacy of Hg accumulated in soils.

SWITCH IN CARBONATE-SILICICLASTIC SEDIMENT DISPERAL AND ACCUMULATION DURING THE LAST GLACIAL SEA LEVEL CYCLE, GULF OF PAPUA SHELF EDGE AND ADJACENT BASINS

During the last 130ky, sediment composition/fux, shed to the Gulf of Papua (Gol) shelf edges and adjacent troughs, have changed dramatically through time. Highstand intervals, such as MIS 5e/Holocene MIS 1, are characterized by high bank-derived argonite fuxes; offshore slopes and basin floors become carbonate-rich. During the early regression when sea level had fallen down to ~40-70 m, netic carbonate production on atolls and barrier reefs shut down, whereas siliciclastic fuxes dramatically increased across all of Ashmore Trough. The distal and central parts of Ashmore slope became sediment starved, whereas its more proximal northern slope continued to receive high siliciclastic fuxes throughout the late regression and lowstand, when the GoP coastline had migrated to the modern shelf edge. A large volume of sandy/muddy siliciclastic sediment, bypassing this part of Ashmore, accumulated as numerous turbidites in the adjacent Pandora Trough. The initial sea level rise during early deglaciation created favorable conditions for the establish-ment/growth of coral reefs alongside the modern shelf edge on top of the former lowstand siliciclastic coastal deposits. The timing of a calci-turbidite accumulation and the first appearance of bank-derived argonite in the fine carbonate fraction in the basins coincide to a time interval when sea level had risen to ~50-40 m, marking the re-flooding of the modern atoll tops which remained exposed for most of the glacial cycle.

ENSOS IN THE TROPICAL PACIFIC CORALS FROM STABLE ISOTOPE AND RADIOCARBON MEASUREMENTS

We present isotope measurements of monthly and annual coral bands from sites in the tropical and subtropical Pacific Ocean, including the Galapagos Islands. The purpose of this study is to understand the changes in circulation and climate that have occurred in the past few hundred years within the context of ENSO and the Interdecadal Pacific Oscillation. Measurements of δ14C and δ18O in monthly and annual coral samples re-volve periods of high ENSO variance, particularly during the Little Ice Age (late 1600s), and periods of low ENSO variance including the early 1800s. Possible mechanisms that could account for the observed variability of the isotope records, including teleconnections to mid and high latitudes, will be discussed.
KELVIN WAVE ENERGY IN THE INDONESIAN ARCHIPELAGO

Kelvin waves generated by winds over the equatorial Indian Ocean propagate eastward along the equator, bifurcating to the north and south upon reaching Indonesia. Sumatra, Java and the Nusa Tenggara island arc act as a branchy waveguide, directing the waves eastward along the coast and allowing some energy to pass into the Indonesian seas. The continued energy penetration, however, means that the energy is partitioned between the passages of the Indonesian archipelago are poorly understood due to a historical lack of data that adequately distinguish the space and time scales of the different forcing mechanisms. Here, we present a filtering program to de-trend the Kelvin waves generated by winds over the equatorial Indian Ocean. For the purposes of this study, the energy associated with the Kelvin waves is isolated using a wavelet analysis and a wavelet thresholding technique. The energy within the Kelvin waves is transferred to the SEDEX model and the physical and biological responses of the ecosystem are simulated. The SEDEX model is used to simulate the physical and biological responses of the ecosystem. The model results are compared favorably with field observations from the SEDEX model. The model results are compared favorably with field observations from the SEDEX model. The model results are compared favorably with field observations from the SEDEX model.
generating baroclinic topographic waves by a tropical cyclone impacting a low-latitude continental shelf

Numerical model experiments have been performed to analyze the low-latitude baroclinic continental shelf response to a tropical cyclone. The theory of coastally trapped waves suggests that, provided appropriate slope, latitude, stratification and wind stress, bottom-intensified topographic Rossby waves can be generated by the storm. Based on a scale analysis the Nicaragua shelf is chosen to study propagating topographic waves excited by a storm, and a model domain is configured with simplified but similar geometry. The model is forced with wind stress representative of a hurricane translating slowly over the region at 6 km h⁻¹. Scale analysis leads to the assumption that baroclinic Kelvin wave modes have minimal effect on the low-frequency wave motions along the slope, and coastal-trapped waves are the primary topographic Rossby waves. Analysis of the simulated motions suggests that the shallow part of the continental slope is under the influence of barotropic topographic wave motions and at the deeper part of the slope baroclinic topographic Rossby waves dominate the low-frequency motions. Numerical solutions are in a good agreement with theoretical scale analysis. Another model experiment forced with a faster translating hurricane demonstrates that fast moving tropical cyclones do not excite energetic baroclinic topographic Rossby waves. Instead, robust inertial oscillations are identified over the slope.

MULTIDIMENSIONAL PATHWAYS OF GROUNDWATER ADVECTION AND ASSOCIATED NUTRIENT FLUXES IN SALT MARSH ESTUARIES

We explore two different pathways of nutrient delivery via groundwater discharge in two contrasting New England salt marsh estuaries: in the first, freshwater is delivered primarily by overland flow; in the second freshwater input is dominated by groundwater discharge. We used geochemical tracers, radon- and radium isotopes, to determine large-scale fresh groundwater recharge. We also quantified tidally induced pore water circulation through the marsh bank sediments. A multi-tracer mass balance model was used to evaluate pore water residence time, which in turn was used to estimate carbon remineralization rates derived from pore water nitrogen increases over time. We also examined the role of the spring-neap tidal cycle in pore water exchange dynamics.

SURFACE WATER PH MEASUREMENTS AND CARBONATE CHEMISTRY IN THE NORTH ATLANTIC OCEAN (ICELAND BASIN)

A semi-autonomous potentiometric pH system has been deployed between the UK (Glasgow) and Iceland (Reykjavik) during July and August 2007 aboard the RRS Discovery. During this cruise, biophysical interactions in the Iceland Basin were investigated during a post-bloom period on an eddy scale surface. High resolution pH measurements were undertaken in seawater sampled continuously from the ship's underway supply (~5m depth). This potentiometric method consists in a flow-cell approach using a highly reproducible free-diffusion liquid junction. Accuracy and precision of 0.01 pH unit can be achieved and high resolution data obtained if care is taken with electrode handling and Tris buffer preparation. The pH measurements showed small scale spatial and temporal variations, and correlation of pH and fluorescence data was observed, which indicated biological control on the carbonate system. Results of pH measurements were compared with discrete measurements of Dissolved Inorganic Carbon and Total Alkalinity in order to get a good understanding of the carbonate system in this area.

INTRASEASONAL VARIABILITY OF INDIAN OCEAN SEA SURFACE TEMPERATURE DURING BOREAL SUMMER. MADDEN-JULIAN OSCILLATION VERSUS SUB-MONTHLY FORCING AND PROCESSES

Air-sea interactions in the Indian Ocean during boreal summer are investigated with a series of experiments using the HYbrid Coordinate Ocean Model (HYCOM). QuickSCAT...
winds and satellite observed OLR are used to identify the wind and convection patterns associated with 10-30 day atmospheric intraseasonal oscillations (ISOs). We assess the validity of the model SST output via comparisons with TRMM SST, and find that HYCOM does a good job of correctly simulating the ocean's response to both submonthly and MJO events. Representational regions in the Arabian Sea, the Bay of Bengal, and the warm pool that are simulated particularly well are chosen for further study. We find that wind plays a much larger role in altering SSTs than either shortwave fluxes or precipitation. Wind speed is slightly more dominant than wind stress in many cases, which is different than wintertime events, during which the two are comparable. We then evaluate how wind speed (via entrainment and turbulent heat fluxes) and wind stress (via upwelling and horizontal advection) modify SSTs.

COUPLING BETWEEN THE C, N, P, FE, SI, CA AND LITHOGENIC CYCLES IN A GLOBAL OCEAN BIOGEOCHEMICAL AND ECOLOGICAL MODEL

We present comparisons of a broad suite of observational constraints from satellites to sediments with a multiple element (C, N, P, Si, Ca) biogeochemical model of small, large and diazotrophic phytoplankton and cycling of organic matter. The model includes such processes as gas exchange, atmospheric deposition, river inputs, ligand-based iron scavenging, N2 fixation, water column denitrification and sediment processes of lithogenic and iron retention. The CACO2 model calculates denitrification. Phytoplankton physiology is based on colimitation by light, nitrogen, phosphorus and iron with flexible N, P, Fe, chlorophyll, Ca and Si stoichiometry. Loss of phytoplankton to the microbial loop and to mesozooplankton is parameterized through a size-based relationship. This model is embedded in a 1-degree; global ice-ocean general circulation model (MOM4) forced by atmospheric reanalysis for quantifying the relationship between food web structure, biogeochemical cycles and atmospheric CO2 signature. Our analysis focuses on controls on the decoupling between the various elemental cycles represented in the model and on the dynamical roles played by variability linked to the annual cycle, El Nino, and other modes.

THE ECOLOGY OF ARCTIC LAGOONS IN A CHANGING CLIMATE: ARE TERRESTRIAL INPUTS OF ORGANIC MATTER IMPORTANT?

The nearshore shelf of the Beaufort Sea receives massive freshwater discharge from the Mackenzie River and along with numerous smaller rivers and streams elsewhere along the coast, produce an environment that is decidedly euxinic in character, especially in late spring and summer. Because of its low in situ productivity, allochthonous inputs of organic carbon are important to the functioning of this arctic euxinic system. Coastal erosion and river discharge add significant amounts of suspended sediment from upland regions into coastal lagoons. The depletion in the 13C content of invertebrate and vertebrate consumers, which drops about 4-5 ppt eastward along the eastern Alaskan Beaufort Sea coast, may reflect the assimilation of this terrestrial organic matter into local food webs. On the eastern Alaska-Beaufort Sea coast, we describe the ecological structure of these coastal lagoons for the first time. The possible role of terrestrially derived carbon to arctic euxinic food webs is especially important in view of the current warming trend in the arctic environment and the role of advective processes that transport carbon along the nearshore shelf.

ECOLOGICAL IMPACTS OF THE 2005 RED TIDE ON ARTIFICIAL REEF STRUCTURES

A harmful algal bloom (red tide) and associated anoxic/anoxic event in 2005 resulted in localised to chitin deposited around cell wall girdle bands during the interval when one tial phase and silicate starvation. These cells were also stained with a fluorescently labeled lectin under nitrate limitation; one was upregulated under both silicate and iron limitation. Expression of chitin synthase genes were also monitored in batch cultures during exponen
tial phase and silicate starvation. These cells were also stained with a fluorescently labeled chitin-binding lectin and the resulting fluorescence signal was measured quantitatively with flow-cytometry. Staining of stained, silicate-limited cells indicated that the lectin localized to chitin deposited around cell wall girdle bands during the interval when one chitin synthase gene was upregulated. Elongated, silicate limited cells formed aggregates during the period that nitrogen-rich chitin was enriched at their girdle bands, which may have implications for the nutrient composition of sinking biomass at the end of a bloom.

MEASUREMENT OF COPEPOD PREDATION ON NAUPLII USING QPCR OF THE CYTOCHROME OXIDASE I GENE

Copepod adults may be important predators on copepod nauplii in the ocean. Field (verti
cal distribution) and lab (swimming behavior, escape responses) observations suggest that there are species-specific differences in predation susceptibility. We present a method here to directly measure in situ predation rates by older stage copepods upon copepod nauplii using species-specific primers for the mtCOI gene and real-time quantitative PCR. The general approach is to determine the mtCOI gene copy number of an individual prey organism and the copy number of the same gene in the stomachs of predatory copepods collected in the field. From knowledge of DNA disappearance rates in the stomachs, inges
tion rates can be calculated. mtCOI copy number have been determined for stages N1 to N2 of Acartia tonsa. Using species-specific primers, mtCOI genes of A. tonsa N2 fed to adult Centropages typicus was detectable for up to 3 hr. Exponential rates of decline of prey mtCOI genes were similar to those measured for gut pigments. This method could be modified to examine feeding ecology in a range of predator-prey systems.

PROFILING ALTIMETRY COMPARED WITH SWATH ALTIMETRY IN THE CONTEXT OF TERRESTRIAL HYDROLOGY DATA ASSIMILATION

Accurate characterization of the hydrologic cycle at local, regional, and global scales is an essential aspect of many crucial science and societal questions. Current methods for characterizing surface water and river discharge are inadequate in many parts of the world because of poor spatial and temporal distributions. A spaceborne synthetic aperture radar swath altimeter, WATER HM's KaAtR instrument, has been proposed for measuring such river discharge variables. Is it possible to use a Kalman filter to determine discharge by solely a profiling altimeter (PA) without the aid of in-situ observations? The swath altimeter (SA) provides a measurement of surface elevation across a swath tangential to the flow path, while the PA provides only a single elevation measurement along the flow path. In this paper, the PA and SA measurements are inter-compared in the context of a data assimilation system for river discharge estimation. The DA scheme utilizes the LISFLOOD- FP model to obtain a priori estimate of discharge and floodplain inundation and ingests altimeter measurements generated by the Jet Propulsion Laboratory Instrument Simulator. Observing System Simulation Experiments are performed to examine the relative performance of the PA and SA measurements in the context of the DA scheme for discharge estimation.

CHITIN AS A COMPONENT OF THE DIATOM CELL WALL

Chitin is the most abundant polymer in the ocean and is synthesized by the enzyme chitin synthase. Analysis of diatom chitin synthase genes suggests that more genera of diatoms may synthesize chitin than previously thought. To discover potential roles of chitin, chitin synthase gene expression was measured in Thalasiosira pseudonana cultures grown under silicate, iron, or nitrate limitation. All chitin synthase genes were down regulated under nitrate limitation; one was upregulated under both silicate and iron limitation. Expression of chitin synthase genes was also monitored in batch cultures during exponen
tial phase and silicate starvation. These cells were also stained with a fluorescently labeled chitin-binding lectin and the resulting fluorescence signal was measured quantitatively with flow-cytometry. Staining of stained, silicate-limited cells indicated that the lectin localized to chitin deposited around cell wall girdle bands during the interval when one chitin synthase gene was upregulated. Elongated, silicate limited cells formed aggregates during the period that nitrogen-rich chitin was enriched at their girdle bands, which may have implications for the nutrient composition of sinking biomass at the end of a bloom.
data are a high signal-to-noise measure of large-scale temperature with excellent temporal resolution. Although only a few realizations of the seasonal cycle are available, inter- and intra-annual variabilities have signal amplitudes comparable to the seasonal cycle. The sea-
sonal cycle of temperature is mostly accounted for by local air-sea heat exchange. The time
scales for some of the changes in temperature are short, sometimes of order weeks. Not all
available acoustic paths are suitable for assessing the seasonal cycle, however. Near Hawaii, the
acoustic sampling does not extend to the near-surface waters, so seasonal variations there are not
measured. To better understand the nature of the signals, the temperature changes observed
by the acoustics will be compared to temperature changes modeled by a co-temporal, high-resolution ocean model (POP: Parallel Ocean Program).

USING RESOURCE COMPETITION THEORY TO UNDERSTAND THE DISTRIBUTION OF MARINE PHYTOPLANKTON

Resource competition theory has been used by ecologists to predict outcomes of competi-
tion between phytoplankton, and their distribution in the environment (Tilman, 1977).
Here we use this theoretical framework to gain insights into the solutions of a global three
dimensional physical-biogeochemical-ecosystem numerical model. This model is initialized with many phytoplankton types, whose growth traits are drawn randomly from observed ranges. The resulting spatially varying ecosystem structure is therefore self organizing rather than imposed. In particular, the model successfully characterizes the observed dis-
tribution of the picocyanobacteria Prochlorococcus, which dominate the phytoplankton community in regions of much smaller density. We use the theoretical framework, modified to include the effects of light, temperature and grazing on phytoplankton abundances, to investigate the physical and ecological factors that underpin the modeled biogeography. We find that Prochlorococcus dominates regions where the physical environ-
ment is fairly stable, and at least one of their required nutrients are drawn down to low levels that are consistent with the theoretical predictions. In these stable regions the chemical re-
composition is regulated by the characteristics of the ecosystem structure.

THERMOCLINE AND SUBTHERMOCLINE CURRENTS FROM THE CENTRAL TO WESTERN EQUATORIAL PACIFIC: A SNAPSHOT VIEW FROM THE EUC-FE CAMPAIGN

Shipboard ADCP observations were obtained in August/September 2006 across the equa-
toral Pacific from 140ºW to 145ºE, providing a quasi-synoptic view of the circulation. Centered in the thermocline, the Equatorial Undercurrent (EUC) straddles the equator above the westward Equatorial Intermediate Currents. Filtering out large vertical scales using a baroclinic mode decomposition reveals the signature of the Equatorial Deep Jets (EDJ): zonal currents within 1.5° of the equator from 400 m depth to the bottom of the measurements, reversing with 300-400-m vertical wavelength. The EDJ's are zonally
consistent over the central 40º of the survey, but not over the entire zonal extent. At the
western boundary, two currents contribute high-salinity south Pacific waters to the EUC:
the northwestward New Ireland Coastal Undercurrent is split by topography, with its
western boundary, two currents contribute high-salinity south Pacific waters to the EUC.

ASSESSING THE ROLE OF ENVIRONMENTAL STRESSORS AND GENETIC COMPOSITION ON TOXIN PRODUCTION IN LAKE ERIE CYANOBACTERIAL HAB POPULATIONS

Blooms of the cyanobacterial HAB Microcystis have recently resurged in some regions of the
Great Lakes and, due to the use of these water bodies for water drinking and recreation, there is a significant need to understand the factors contributing to bloom toxicity. Microcystis bloom toxicity is regulated by both environmental factors and genetic com-
position. The response of the natural Microcystis community to some key environmental stressors (nutrients, light, grazers) was assessed by measuring changes in growth rates and concentration of the microcystin in laboratory experiments. Additionally, a quantitative PCR assay was used to quantify changes in the number of toxic colonies using the mcyB gene, which is involved in the synthesis of the toxin microcystin. The genetic composition of the Microcystis community in western Lake Erie was also assessed over the course of a bloom season using both the highly variable phyocyanin intergenic spacer

region (PC-IGS) and mcyB. Sequence analysis showed that there is shift in community composition over time and that strain composition plays a role in Microcystis bloom toxicity in this region.

A REGIONAL WAVE MODELING SYSTEM IN THE ADRIATIC SEA

A wave prediction system using the SWAN (Simulating Waves Nearshore) model was run
covering the Adriatic Sea and the Gulf of Manfredonia supporting the field experiment, “Dynamics of the Adriatic in Real-Time 2006” (DART06) which provided a unique oppor-
tunity for examining the characteristics of ocean surface waves and model performance in such a regional environment. The regional SWAN model was run in real-time from October 2005 to November 2006 using winds from forecasts provided by the ALADIN meteorological model run by the Croatian Meteorological and Hydrological Service. Comparisons of the daily forecasts of significant wave height to in situ and altimeter measurements showed that SWAN performed fairly well with a generally small negative bias. Afterwards, SWAN was run in hindcast mode to include wave-current interaction by using surface currents as input from NCOM (NAV Coastal Ocean Model) run at the Navy Research Laboratory. The results of including wave-current interaction showed significantly improved wave model performance. Several cases will be illustrated to show wave model performance issues in this particular environment.

SUB-INERTIAL MID-SHELF ACROSS-SHELF OFFSHORE FLOWS IN THE SURFACE LAYER OF THE CENTRAL MID-ATLANTIC RIGHT

An examination of sub-inertial across-shelf, offshore flows over the mid-shelf of the cen-
tral Mid-Atlantic (MAB) was conducted using surface velocity measurements from a long
range HF radar system. Observations from Aug 2002 to Jan 2004 were used to subjectively identify several episodic flow patterns over an area approximately 240km by 115km off the New Jersey coast. The predominant structure was a shelf-wide flow that primarily occurred during months in which the water column is usually well-mixed (Oct-April). The other episodic flow patterns typically had a smaller single scale region of intensified across-shelf flow. An EOF analysis of the across-shelf flow was performed in an attempt to determine the robustness of the observed spatial features and to study the physi-
cally forcing to these modes. EOF mode 1 dominated the variance and appeared similar in structure to the mature state of the shelf-wide episodic events. In terms of forcing, cur-
rent vector/wind stress correlations over the study region revealed significant seasonally
dependent spatial variability with across-shelf flow during the mixed period appearing to be more closely associated with across-shelf wind stress. (25-60 at zero lag). On a larger scale, this research is important because the MAB circulation interacts with the Gulf Stream, a current critical in transporting heat to higher latitudes and in global circulation.

MERCURY RISK TO BIRDS IN THE SAN FRANCISCO BAY ESTUARY

The San Francisco Estuary is a site of hemiherpic importance for waterbirds, and also has a legacy of mercury contamination. We examined space use in four common waterbird species and assessed mercury concentrations in adults, chicks, eggs, and their prey, and quantified the effects of mercury on reproduction. We found that mercury was highest in Forster’s terns and assessed mercury concentrations in adults, chicks, eggs, and their prey, and quantified the effects of mercury on reproduction. We found that mercury was highest
in Forster’s terns, followed by stints, Caspian terns, and avocets. Overall, we estimated
that risk to reproductive impairment was 22%, 22%, 10%, and 1% in Forster's terns, stints,
Caspian terns, and avocets. Moreover, 58% and 46% of breeding Forster's terns and their
eggs respectively, were at high risk to mercury impairment. Failed to hatch and abandoned
eggs had more mercury than randomly collected eggs for Forster's terns but not stints or
avocets. Further, we found that hatching success declined with increasing egg mercury in Forster's terns but not stints or avocets. We also found that dead stilt (but not avocet)
chicks had higher down mercury concentrations than randomly sampled living chicks.
Our results indicate that waterbird exposure to mercury is high enough to be a cause of
concern, and that reproduction may be impaired.

ASLO/AGU/TOS/ERF 2008 Ocean Sciences Meeting
The 2005 Caribbean coral bleaching event was the most extensive and devastating on record for this basin. NOAA Coral Reef Watch satellite data provided warnings that allowed researchers to document the extent and intensity of the event. The greatest bleaching and mortality were seen along the Antillean Arc where the thermal stress exceeded any seen in the Caribbean during the past 21 years of satellite data. Gridded in situ records showed that average temperatures were the warmest in over 100 years. Coral bleaching exceeded 90% at many sites, and extended across most of the wider-Caribbean region; mortality exceeded 40% at many sites. Collaboration among researchers from 22 countries provided the best documentation of a basin-scale bleaching event to date. This event showed one of the key problems that climate change poses to coral reefs: warming oceans can kill corals in even the best-managed or most remote coral reefs. Steps need to be taken to increase the resilience of coral reefs to survive bleaching, ocean acidification, and other climate change threats.

THE EFFECTS OF LANDUSE AND SOIL CHARACTERISTICS ON NUTRIENT LOADING USING THE SOIL & WATER ASSESSMENT TOOL (SWAT): A COMPARATIVE STUDY

Managing an ecosystem is a complex task due to the diversity of information required for holistic planning and policy implementation to ensure the health of an ecosystem. Watershed and environmental managers are tasked with decision-making and policy implementation with limited resources. A model integration tool, including Geographic Information Systems (GIS) that facilitates spatially explicit representation of the intricacies of the interactions between groundwater, surface water, soil, land cover and the climate to the streamflow and nutrient loading can be an invaluable tool for environmental managers. The Soil and Water Assessment Tool (SWAT) is a GIS-integrated model that can determine hydrologic budget of a watershed as well as nutrient loading into an ecosystem. This study uses SWAT to model physical processes for two nearby drainage basins in west central Florida and compares the resulting hydrology and water quality data to landuse and soil characteristics to determine if these components are major factors in the variability between the watersheds/nutrient loading.

IN SITU STUDY OF NUTRIENTS AND PH USING THE SPECTROPHOTOMETRIC ELEMENTAL ANALYSIS SYSTEM II (SEAS II): CASE STUDIES FROM RIVERINE AND OPEN OCEAN DEPLOYMENTS

Development of chemical sensors capable of high-resolution and high-frequency data sampling enables researchers to examine detailed vertical and diurnal variations of chemical species. The Spectrophotometric Elemental Analysis System II (SEAS II) offers a versatile robust instrument for measurement of chemical species under a variety of aquatic conditions. Nutrient and pH measurements from the Hillsborough River, Tampa Bay, Gulf of Mexico, and Atlantic Ocean demonstrate the ability of SEAS II to analyze in a broad range of aquatic environments. In addition, optical cells are easily reconfigurable allowing the user to determine analytes from low nanomolar to mid-micromolar concentrations. The instrument records and internally stores real-time measurement data and can transmit these data via cabled connections to a variety of receivers including a shipboard hydrowire system and wireless Ethernet adapter. We present data from Hillsborough River and Atlantic Ocean deployments to illustrate how the versatility of SEAS II make it a potential candidate for use in ocean observing systems.

USE OF MITOCHELONIAL CYTOCHROME B AS A TOOL FOR RE-EVALUATION OF THE NORTHERN GULF OF MEXICO SPECIES OF THE ZAUSODIES COMPLEX

Identification of species solely by their morphological characters can give misleading results because some species may not have differentiated morphologically. DNA sequence analyses can differentiate individuals that are genetically similar from those that are not. It thus provides another means of erecting species’ boundaries. When DNA-sequence-analysis results and morphological results agree, workers can view the morphologically based taxonomy with much more confidence and accept the utility of the morphological characters that were used to discern species boundaries. Our objective is to re-evaluate the morphologically defined species boundaries of the northern Gulf of Mexico species of the Zausodies complex (Copopea: Harpacticoidea: Harpacticoidae) with DNA-sequence data from the mitochondrial cytochrome b gene. Harpacticoids were identified morphologically. DNA was extracted from the posterior portion of individuals; the anterior portion was kept as a voucher. A portion of the target gene was PCR amplified and sequenced, and haplotype trees were generated by neighbor-joining analysis of the aligned sequence data. Preliminary results indicate that the morphological and DNA-sequence data are in agreement.

SEASONAL AND SUBINERTIAL VARIATIONS IN THE SOYA WARM CURRENT REVEALED BY HF RADARS, COASTAL TIDE GAUGES, AND A BOTTOM-MOUNTED ADCP

The Soya Warm Current (SWC) is a coastal boundary current, which flows along the coast of Hokkaido in the Sea of Okhotsk. Seasonal and subinertial variations in the SWC are investigated using data obtained by high-frequency ocean radars, coastal tide gauges, and a bottom-mounted acoustic Doppler current profiler. The velocity of the SWC reaches its maximum, approximately 1 m/s, in the summer, and becomes weaker in the winter. The almost same seasonal cycle was repeated in the period from August 2003 to March 2007. The SWC also exhibits subinertial variations with a period from 10-15 days. The surface transport by the SWC shows a significant correlation with the sea level difference between the Japan Sea and Okhotsk Sea for both of the seasonal and subinertial variations, indicating that the SWC is driven by the sea level difference between the two seas. The subinertial variations in the SWC are significantly correlated with the meridional wind component over the region. Continental shelf waves triggered by the wind are considered to be a possible generation mechanism for the subinertial variations.

LETHALITY OF PAH’S TO MARINE PHYTOPLANKTON

Polycyclic Aromatic Hydrocarbons (PAHs) are ubiquitous environmental contaminants derived from biogenic or anthropogenic sources from incomplete combustion of fossil fuel. PAHs reach and impact aquatic environments after ongoing atmospheric transport and subsequent deposition, or through direct spillage of petroleum and its refined products. Even if PAHs are considered toxic but not biocumulative for high organisms, for phytoplankton they are, and may reach higher levels in the cells, being a key vector to transfer to other organisms. Lethality of PAHs has been quantified for a variety of aquatic organisms as copepods, sandworms or macroalgae, but not for phytoplankton. The goal of this study was to quantify the lethality of two different PAHs (Pyrene and Phenanthrene) to marine phytoplankton by analyzing the effect of different concentrations of PAHs, ranging from 1 to 1000 µg/L, on the growth and cell death a variety of phytoplankton species growing in cultures and compared with the lethality observed in natural communities. The resulting cell death-PAHs relationships observed will be used to define the thresholds and points of non return of PAHs to marine phytoplankton.

MODEL AND IN SITU STUDIES OF LARVAL DISPERSAL AND CONNECTIVITY IN GLACIER BAY, ALASKA

Larval dispersal may be driven by multiple physical oceanographic processes; however, in Glacier Bay, a high latitude (fjord in Alaska, temporal variation in late-stage larval abundance of Dungeness crabs, Cancer magister) suggests that transport of larvae into the fjord is tidally-driven. In this interdisciplinary study we compared spatial distributions of larvae with results from a 2-D tidal circulation model (ADCIRC) for Glacier Bay. The model is forced with tides, meteorological conditions and freshwater inputs. We observed that late-stage larval abundance is highest near the mouth and declines with distance up the bay. The model suggests that these larvae could enter Glacier Bay from the west and be transported to their observed locations on the flood tide. The model also suggests that larvae in Glacier Bay are not connected to larvae found to the east of the bay as a result of a circulation barrier. We hypothesize that these larvae are immigrating into Glacier Bay after developing outside, akin to the observation in CA, OR, and WA that larvae migrate offshore to the continental shelf and return to nearshore areas as megalopae.

INFLUENCE OF ENVIRONMENTAL VARIABLES ON THE MICROBIAL COMMUNITY OF ARCTIC LAND FAST SEA ICE

Changes in sea ice community structure affect carbon and nutrient cycling in polar seas, but the response in microbial species composition to key environmental variables still remains largely descriptive. Using ice cores recovered from 3 locations near Point Barrow, AK in May 2006, we documented the diversity and composition of eukaryotic sea ice microorganisms in relation to vertical depth within the cores, light availability (mainly as variable snow cover) and nutrient concentrations. We used DGGE (denaturing gradient gel electrophoresis) of a PCR (polymerase chain reaction) amplified section of the 16S rDNA gene in combination with epifluorescence microscopy to compare the community struc-
ture of the major eukaryotic microbial phylotypes in the ice. We find that there are clear differences in the community structure from the top of the ice to the bottom of the ice at all sites, as expected, but more importantly, between sites with (30 cm) and without (0 cm) snow. This underscores the importance of snowfall and snow distribution for sea ice microbial community structure on scales of only meters, and the potential impact of climate change on sea ice ecosystems.

APPLICATION OF MICROARRAY TECHNOLOGY TO INVESTIGATE CORAL RESPONSE TO STRESS AT DIFFERENT SCALES ON SOUTH FLORIDA REEFS

Coral communities are increasingly impacted by a variety of natural and anthropogenic stressors acting on local or global scales. Based on the type of stressor and scale of impact, corals exhibit different responses. A better understanding is needed regarding how corals respond to the cumulative effects of stressors acting on different scales. Through the application of microarray technology, gene expression profiles can be used to diagnose which stressors are impacting coral populations in the field. Changes in gene expression are key elements of the stress response, occur before physiological damage is evident, and can be directly related to the causative agent of stress. In this study, a focused coral gene microarray was used to detect gene expression patterns of coral in South Florida associated with changing environmental conditions. This is the first study to use a focused Cnidarian microarray to detect stress in field coral populations related to seasonal events, such as precipitation as well as point source stress, such as xenobiotics. In addition, a clear correlation between the expression of symbiont genes with the expression of host stress response genes was evident. Through the application of microarray technology and gene expression profiling, varying degrees of stress impacting different sites across times were compared in natural coral populations.

AN AUTOMATED VISUAL EVENT DETECTION SYSTEM FOR OBSERVATORY VIDEO

The permanent presence of underwater cameras on oceanic observatories, such as the Victoria Experimental Undersea Network Under the Sea (VENUS) and Eye-In-The-Sea (EITS) on Monterey Accelerated Research System (MARS), will generate valuable data that can move forward the boundaries of understanding the underwater world. However, sightings of underwater animal activities are rare, resulting in the recording of many hours of video with relatively few events of interest. The burden of video management and analysis often requires reducing the amount of video recorded and later analyzed. Sometimes enough human resources do not exist to analyze the video; the strains on human attention needed to analyze video demand an automated way to assist in video analysis. Towards this end, an Automated Visual Event Detection System (AVED) is in development at the Monterey Bay Aquarium Research Institute (MBARI) to address the problem of analyzing terabytes of video. Here we describe the overall design of the system to process video data and enable science users to analyze the results. We present our results analyzing video from the VENUS observatory and test data from EITS deployments.

OBSERVATIONS AND MODELS OF MOMENTUM, HEAT AND MASS EXCHANGE FROM CLIMODE

The NSF sponsored CLIMode MDMo Water Dynamic Experiment (CLIMODE) is designed to investigate the formation, evolution, storage, and dispersal of Eighteen Degree Water (EDW), the subtropical mode water of the North Atlantic. One of the overall objectives of CLIMODE is to improve our estimates EDW formation through air-sea exchange. To conduct these investigations, the air-sea interaction team relied on research vessels, a highly instrumented surface drifter and a drifting Air Sea Interaction Spar (ASIS) during the CLIMODE field programs. All of these platforms measured the momentum, buoyancy, sensible heat, and mass fluxes using the direct covariance method after motion correction. Of particular interest were the extreme conditions encountered during cold air outbreaks. The combination of high winds and large air-sea temperature and humidity difference drove combined latent and sensible heat fluxes that exceeded 1200 W/m² during these events. Additional extreme wind events drove surface stresses that routinely exceeded 10.0 N/m². These enormous fluxes and air-sea gradients are used to reduce the uncertainty in the drag coefficient, Stanton number and Dalton number at wind speeds greater than 15 m/s.

NEAR-RESONANT FORCING OF THE COASTAL OCEAN BY SEA BREEZE/LAND BREEZE NEAR THE CRITICAL LATITUDE IN THE GEORGIA BIGHT

Recent analysis indicates that non-tidal diurnal currents approach 30cm/s on the shelf of the Georgia Bight, with appreciable diurnal variance persisting from April through October. These diurnal motions appear to be inertial oscillations (IOs) and near-inertial internal waves, forced by diurnal winds associated with sea breeze/land breeze (SBLB), resonant with the inertial frequency at 30°N. Near the critical latitude, diurnal/inertial currents can exceed 25cm/s more than 120km offshore and are surface-intensified, with IOs in the lower layer 180° out of phase with those in the upper layer. Observational wind and current data from 1999-2006 are analyzed from a moored array in the Georgia Bight, between 29-32°N, where linear theory predicts significant changes in SBLB structure, and SBLB may be modified by the presence of the Gulf Stream. The spatial structure, variability, and phase of diurnal/inertial currents are described and compared to that of diurnal wind forcing as both the atmospheric forcing and ocean response pass through the critical latitude for diurnal/inertial resonance. The vertical structure and phase-locking of the currents to the diel cycle may have significant implications for cross-shelf larval transport.

AIRCRAFT TEMPERATURE MEASUREMENTS IN THE SNOHOMISH ESTUARY DURING COHSTREX

During the COHSTREX experiment in July 2006, the Snohomish estuary in Washington State was surveyed with an airborne infrared imager in order to map the river’s surface temperature, Tskin. The along-river maps of Tskin contain the signature of several estuarine processes. Tidal movements of the estuary front was captured by repeated surveys over the tidal cycle. A near-surface warm layer developed diurnally, with enhanced warming in cloud-free, light-wind conditions. In addition to these river-scale changes in Tskin, the maps also capture the small-scale variability of coherent structures shed from bottom bedforms, wakes from in-river obstacles like pilings, and wakes from small motorboats. These turbulent overturns bring deeper water to the surface, and thus their infrared signature has the potential to give information on the water’s vertical stratification. The relation between Tskin disturbances and vertical stratification will be evaluated here based on comparison to the in-situ moored data of COHSTREX.

MODELING WAVE- AND TIDE- DRIVEN CURRENTS WITH DELFT3D FOR AUVFEST 2007

In June 2007, the Delft3D modeling suite was used to determine wave and circulation conditions during AUVFest at Panama City Beach, Florida. The model for AUVFest was designed to encompass two areas in which a variety of technologies, including autonomous underwater vehicles (AUVs), operated. Bathymetry for the Delft3D model was created by combining low resolution bathymetry with bathymetry collected by AUVs in the areas of interest. The modeling exercise coupled the flow and wave components of the Delft3D suite, and acquired boundary conditions for the components from PCTides and SWAN model runs for the entire AUVFest area of Panama City Beach. An acoustic doppler current profiler (ADCP) was deployed in an area of interest but relatively deep water; preliminary comparisons showed that the model underpredicted velocities at the ADCP location because Delft3D computed only wave-driven currents. We will alter the modeling approach in the flow component by specifying dominant tidal harmonics along the boundaries, thus including tidal currents in the computation. We will compare the results to the ADCP data and examine the differences of the two modeling approaches.

PROSPECTS FOR TIDAL STUDIES WITH HIGH-RESOLUTION ALTIMETRY

Atmospheric data from the TOPEX/Poseidon and Jason-1 missions have allowed tidal elevations in the open ocean to be mapped to high accuracy—even minor constituents such as M4 (mixed tides of ocean amplitude measured in cm) can now be reliably determined with the long timeseries available. However, many tidal phenomena remain poorly constrained by the coarse sampling of a traditional nadir altimeter. For example, internal tides are clearly seen in the altimeter data radiating away from generation sites over rough topography in the deep ocean. However, wavelengths are ~100 km or less, and thus poorly sampled by a nadir altimeter. Model simulations show that maps of internal tide energy flux constructed from T/P data significantly underestimate actual fluxes. Increasing the sampling density (e.g., by using tandem mission data) increases the mapped fluxes. However, accurate mapping, which may shed light on tidal mixing and energy dissipation in the deep ocean, would require almost complete spatial coverage. Challenges
also arise with the surface tides in shallow coastal seas, where spatial wavelengths are much shorter than typical meter track spacings, and frequency spectra are often more complex due to the presence of non-linear constituents. Future technologies that provide nearly continuous coverage and extend close to the actual coast would greatly improve our ability to map tidal elevations and currents, in these areas of great societal importance.

**DAILY VARIABILITY IN ENVIRONMENTAL CONDITIONS AND PHYTOPLANKTON COMPOSITION DURING TWO BLOOM EVENTS IN THE LAFAYETTE RIVER, VIRGINIA.**

The Lafayette River is a eutrophic urban tidal tributary prone to seasonal harmful algal blooms, with cell densities recorded during this study on average twice that of other Virginia tributaries. Over a 34-day sampling period, two distinct bloom events occurred involving Cryptomonas spp. and the mixotrophic dinoflagellate Gymnodinium instriatum. Chlorophyll a, nutrient levels, physical and chemical parameters were measured daily in addition to phytoplankton enumeration. Sixty-five species of phytoplankton from 8 major taxonomic groups were identified during the two bloom events. Mean total phytoplankton cell densities ranged from 5.8x10^3 to 7.8x10^4 cells l^-1. Picoplankton densities varied from 3.7x10^6 to 1.3x10^7 cells l^-1. During the bloom periods, Cryptomonas spp. and Gymnodinium instriatum constituted as much as 96.1% and 89.8% of the cells respectively, contributing to a negative correlation between diversity and productivity (r=-0.71, p=0.0005). Precipitation, elevated nitrogen concentrations, and decreased salinity were associated with both blooms. Picoplankton abundance was also elevated during the bloom periods. The short length of both blooms (~5 days) emphasizes the usefulness of daily monitoring studies in understanding the effects of environmental conditions and ecological interactions on phytoplankton populations.

**ORGANIC CARBON CYCLING OVER THE NORTHWEST ATLANTIC MARGIN: IMPORTANCE OF LATERAL TRANSPORT.**

The fate of the diverse sources of organic carbon (OC) supplied to and produced over continental margins remains a subject of debate, but there is growing evidence that a significant fraction may be transported to the interoceanic basins. Establishing the fluxes and mechanisms involved in margin-to-deep-ocean carbon transport therefore represents an important challenge. The Northwest Atlantic margin is characterized by the existence of strong and persistent detached and bottom nepheloid layers that may serve as conduits for export of OC to the interior ocean. As part of a project to understand dynamics of particulate OC (POC) in this region, suspended and sinking POC was collected using submersible pumps and bottom-tethered time-series sediment traps deployed over the continental slope adjacent to a physical oceanographic mooring array. Geochronical data (including isotopic and lipid biomarker compositions) as well as flux measurements provide strong evidence for significant lateral transport of POC. When evaluated in the context of hydrographic observations, this information provides constraints on the provenance and transport pathways of POC over the continental margin.

**VARIATIONS IN SPRING SST AND FORAGE FISH DISTRIBUTIONS IN THE SOUTHEASTERN BERING SEA; BASIS SURVEY RESULTS FOR 2002-2007.**

The eastern Bering Sea (EBS) shelf is a highly productive high latitude system that provides critical habitat for important pelagic fish stocks. Shelf-wide surveys were conducted during late summer / early fall 2002-2007 in the eastern Bering Sea, as part of a multiyear international research program, Bering-Aleutian Salmon International Survey (BASIS), to study the effects of ocean conditions and lower trophic level variations on forage fish abundance and distribution. The EBS underwent large-scale warming during 2002-2003, followed by cooler spring shelf surface temperatures and a more southerly ice extent in 2006 and 2007. This shift substantially altered juvenile salmon and other forage fish (e.g. age-0 pollock, herring, and age-0 pacific cod) abundance and distribution in the southeastern Bering Sea and may affect the overall ecology of this region.

**THE NORDIC SEAS AS A PACEMAKER IN THE OCEAN CONVEYOR**

The dense overflows from the Nordic Seas are the main source of North Atlantic deep water and thus complete the overturning of the Atlantic Meridional Overturning Circulation (AMOC). We assess the influence of key regions and processes within the Nordic Seas on the state of the overflows using three independent sources of data: a unique set of hydrographic observations from 1950 to 2005, a dedicated tracer release experiment, and output from a regional ocean model. The commonly presumed causality between convective mixing in the Greenland Sea and changes in the overflows is neither evident in the observations nor in the model. There is on the other hand significant co-variability between the properties of the cyclonic loop of Atlantic-derived waters through the Nordic Seas and the overflows feeding the Atlantic conveyor. The found co-variabilities - or lack thereof - is a benchmark for the variability that should be reproduced in models that address AMOC and decadal predictability.

**SEDIMENT TRANSPORT PROCESSES AT THE MOUTH OF COLUMBIA RIVER.**

Tides, density differences due to river inflow, and an extremely severe wave climate are the driving forces for flow at the mouth of the Columbia River (MCR), USA. Interaction between irregular bathymetry and jetties aborting both sides of the inlet result in a complex sediment transport field near the entrance. A process-based numerical model (Delt3D Online Morphology) was applied to obtain insight into the relative importance of different forcing mechanisms for sediment transport. Validation of model results with field measurements over the period August-September 2005 shows that the model reproduces the dominant flow features, and salinity and wave fields near the entrance reasonably well. Comparison of results for different forcing scenarios indicates that residual sediment transport is the result of a near balance between tidal and non-tidal flows. Density stratification affects the system from a depth where it interacts with an incoming tide at the mouth during low wave conditions. Finally, sediment transport and morphologic change of the ebb tidal delta is largely driven by storm waves.

**GLOBAL OBSERVATIONS OF INERTIAL WAVES FROM LAGRANGIAN DRIFTERS.**

Since January 2004 surface drifters from the Surface Velocity Program are tracked by multiple satellites and this allows for the resolution of ocean surface currents variability at higher frequencies than previously available, especially towards higher latitudes. From this dataset, this study describes the characteristics of Lagrangian frequency velocity spectra as a function of latitude, on basin scales. As an example, inertial and semidiurnal tidal peaks are clearly resolved. A robust global feature is the general confinement of anticyclonic spectral energy at a given frequency between the equator and the latitude at which this frequency equals the local inertial frequency. It is hypothesized that this manifestation of inertial waves which have been forced by the wind stress at the surface and have propagated freely according to beta-dispersion.

**HIGH LATITUDE SULFUR CYCLING IN LOS ALAMOS ICE-OCEAN MODELS.**

As a central component of several marine systems models, the biogeochemical Parallel Ocean Program (POP) has recently been augmented with a dynamic global sulfur cycle. Although most results are encouraging, high latitude processes remain deficient; polar improvements necessarily constitute a next generation emphasis. Based on a blend of available regional simulators, eponitic algae and their high DMS production have been implemented within the Los Alamos sea ice model (CICE), which runs interactively with POP and produces Pan-Arctic results in agreement with sparse data. Pelagic ecosystems within POP have been adjusted to reflect dominant high latitude phytoplankton classes including Phaeocystis. The new species are treated as segregated explicit variables competing with diatoms and microbes. Progress will be reported for (1) Arctic simulations conducted in a decoupled cryobiological CICE, (2) the northern polar domain of the POP ocean model, and (3) basin scale, interactive ice-ocean computations. Sensitivity tests include incorporation of biotic absorption of solar radiation within the skeletal layer using multiple scattering radiative transfer. In addition to the Arctic work, preliminary results will be presented for the Southern Ocean.

THE IMPORTANCE OF PH, PARTICULATE CARBON, AND PHOTOSYNTHESIS IN CONTROLLING WATER-COLUMN RESPIRATION RATES IN THE AMAZON BASIN

although water-column respiration has been hypothesized to be the main source of outgassing CO₂ from Amazonian rivers, we lack an understanding of the variability in the observed rates. This study examined the variability of respiration rates in rivers and streams throughout the Amazon Basin and the organic source material of respired CO₂. Respiration rates ranged from 0.03 to 1.77 µmol L⁻¹·h⁻¹ of O₂ consumed and were most positively correlated with fine particulate organic carbon (r²=0.708). Respiration was also positively correlated with pH (r²=0.58). Sites with a pH < 7 (low pH) had a higher ratio of respiration to photosynthesis (2.3 ± 0.3) than sites with a pH > 7 (high pH) (1.1 ± 0.2). The isotopic signature of respired CO₂ suggests that autochthonous carbon is fueling respiration at high pH sites, whereas C₃ and C₄ vegetation are respired at low pH sites, with C₄ vegetation playing a larger role during the high-water period. Depth-integrating respiration rates reveal that respiration accounts for 21-37% of the evading CO₂ in large rivers, indicating that other processes are also important producers of CO₂.

ORGANIC MATTER IN CARBONATE BIOMINERALS: A BULK AND MOLECULAR ISOTOPE APPROACH TO ECOLOGICAL MONITORING AND RECONSTRUCTION

Filter-feeding bivalves are increasingly used as integrators for monitoring water-quality trends in estuaries. Stable isotopic analysis is a powerful technique that may be employed for this purpose. As bivalves feed near the base of the trophic pyramid, the carbon and nitrogen isotopic compositions of the tissues of these organisms are reflective of estuarine primary production, and thus provide data relevant to water-quality monitoring. Organic matter incorporated into the shells of these organisms during calcification draws on the same biochemistry as the body tissues and therefore preserves similar signals. Consequently, organic matter in bivalve shells represents an archive of data for historical reconstructions of water quality prior to the onset of monitoring efforts. Here, data will be presented showing the incorporation of dietary signals into the tissue and shell organic matter of the American Oyster (Crassostrea virginica) along a salinity transect in Rookery Bay, FL. Isotopic characterization of organic matter will be shown for both bulk samples and specific amino acids. The advantages of compound-specific amino acid analysis in this context will be discussed.

HIGH SPATIAL RESOLUTION MAPPING OF WATER QUALITY AND BATHYMETRY WITH A PERSON-DEPLOYABLE, LOW COST AUTONOMOUS UNDERWATER VEHICLE

YSI and OceanServer Technology partnered to develop the first autonomous underwater vehicle specifically designed for water quality mapping. Several of the features that make this person-deployable vehicle unique include the intuitive mission planning software, 12 hour run times with remote IF communication, and the complete on-board water qual-

ity sensor suite that samples at a frequency of 1Hz. The result is detailed maps of water

column. Therefore, Russell Reservoir may be a sink for iron, manganese, and phosphorus in the Savannah River System. Sediment samples were taken from the fore-
bays of Hartwell, Russell, and Thurmond Reservoirs and at an upstream location within Russell Reservoir. Russell had significantly more iron at the oxygenation system than at upstream locations within Russell or in Hartwell. Hartwell had significantly more iron than Thurmond. Phosphorous showed a similar distribution. Manganese was greater in the Russell forebay than at an upstream location or Hartwell. However, Thurmond had significantly more manganese than Hartwell or Russell.

IRON SEQUESTRATION IN LAKE SEDIMENTS FROM ARTIFICIAL HYPONIMETRIC OXYGENATION: RICHARD B. RUSSELL RESERVOIR

Upstream to downstream, Hartwell, Richard B. Russell, and J. Strom Thurmond are warm, monomictic reservoirs of the Savannah River. In summer, they undergo thermal and chemical stratification with hypoxic/anoxic hypolimnia. To improve the water quality of releases from Russell Dam during stratification, the U.S. Army Corps of Engineers is implementing a hypolimnetic oxygenation system in the forebay of Russell Reservoir. This system may facilitate oxidation and flocculation of iron and possibly manganese. Phosphorus can adsorb to the flocculates, and their sedimentation effectively removes them from the water column. Therefore, Russell Reservoir may be a sink for iron, manganese, and phosphorus in the Savannah River System. Sediment samples were taken from the fore-
bays of Hartwell, Russell, and Thurmond Reservoirs and at an upstream location within Russell Reservoir. Russell had significantly more iron at the oxygenation system than at upstream locations within Russell or in Hartwell. Hartwell had significantly more iron than Thurmond. Phosphorous showed a similar distribution. Manganese was greater in the Russell forebay than at an upstream location or Hartwell. However, Thurmond had significantly more manganese than Hartwell or Russell.

THE ANNUAL CYCLE OF IRON IN THE UPWELLING DRIVEN CENTRAL CALIFORNIA REGION

A seven years time series reveals an annual cycle of surface water iron in Monterey Bay, California that is dominated by the injection of high concentrations at the onset of upwelling each spring. A companion study at the upwelling center clearly indicates a sedi-

mentary source for the iron. River discharge during winter storms results in the deposition of a sediment "fluff" layer along the shelf at the upwelling center. Initial rapid shoaling of isotherms at the onset of upwelling brings water from the "fluff" layer to the surface. Iron concentrations then rapidly decrease although upwelling intensifies and iron nitrogenate concentrations occur ~ 2 months later. Decoupling of the iron and nitrate supply suggests the potential for iron limitation. However, iron limitation was apparent only one of the seven years, following two consecutive years of low river flow. Generally, complete drawdown of nitrate occurs by late summer, which cannot be supported by dissolved iron concentrations alone. Summer chlorophyll concentrations are highly correlated to dissol-

vable (unfiltered) iron concentrations emphasizing the importance of particulate iron in meeting this ecosystem's iron requirements.

OXYGEN CONCENTRATION VARIABILITY: A TRACER OF DIURNAL TO DEcadal-SCALE MARINE BIOLOGICAL AND PHYSICAL PROCESSES

The distribution of oxygen concentration in the ocean is determined by a combination of biological processes and ocean ventilation. The utility of oxygen as a tracer of biological processes and ocean environmental change has come to light in recent years because of repeated ship-board measurements on hydrographic sections and at ocean time-series stations. Seasonal changes in the eustrophic zone suggest that net community produc-

tion in the open ocean is less variable than suggested by satellite or model predictions. Decadal-scale changes in the thermocline indicate trends in ocean ventilation and circula-

tion. Because the reliability of oxygen sensors is improving and there has been an explo-

sion of platforms for making measurements remotely, it is now possible to realize a global coverage of oxygen change on seasonal and decadal scales. The temporal and spatial detail of oxygen change observed using sensors on Moorings, Argo floats, Sea Gliders and vol-

unteer observation ships demonstrate the utility of this approach. I address some issues of sensor accuracy and drift that must improve to resolve processes that create oxygen concentration changes smaller than a few percent.

SCIENCE (M)COMMUNICATION IN A POLICY WORLD – WHY BETTER?

Science has a clear role to play in informing natural resource policy by providing understanding and knowledge of natural (and other) processes to policy makers. However, scientists and policy makers alike are often frustrated by the apparent lack of consideration – or misuse – of science in the policy making process. Is it worth a scientist’s time to try to communicate their science directly to policy makers? Why not leave this task to the “experts”? Cultural differences between policy makers and scientists make this prospect daunting, but also suggest that participation by scientists is powerful.

MONITORING RIVERS AND LAKES WITH A KA-BAND INTERFEROMETRIC RADAR ALTIMETER

Profiling nadir-pointing radar altimeters are not capable of providing adequate space-time sampling of global surface water, independently of their intrinsic accuracy. To overcome this limitation, we present an instrument concept, the Ka-band Radar Interferometer (KaRIN), which is able to provide the appropriate space-time sampling with a height and slope accuracy suitable to resolve topographic signatures of land hydrology applications. The KaRIN instrument builds on the interferometric SAR concept demonstrated by the NASA Shuttle Radar Topography Mission (SRTM) and the Wide-Swath Ocean Altimeter concept. Two major modifications are made to these systems to achieve the desired performance. The spatial sampling requirement implies full synthetic aperture processing. Besides, achieving the desired height and slope accuracy with a realizable spaceborne instrument requires using a Ka-band radar at near nadir incidence. The sampling of river discharge requires an approximately weekly revisit time, an ability to image water bodies with a spatial resolution of 100m, a height accuracy better than 10cm and a slope accuracy of 10 microrad. To validate the science performance of the system we have implemented a Virtual Mission simulation and evaluated the measurement performances over a variety of water scenes. Simulations and related results will be presented. They demonstrate the ability of such a system to meet continental waters observation requirements.

THE INFLUENCE OF VARIABILITY IN PREY COMPOSITION AND DISTRIBUTION ON ADELIE PENGUINS (PYGOSCIS CLADAE) FORAGING ENERGETICS AND CHICK GROWTH: A MODELING STUDY

Individual-based models (IBMs) are developed to explore the implications of variability in prey available to Adélie penguins (Pygoscelis adeliae) on adult foraging energetics, chick growth and recruitment. The model is parameterized to reflect conditions of the western Antarctic Peninsula and the study is designed to consider environmental variability relevant to that region. The modeling environment consists of a central-place foraging model that interacts with an idealized prey-field comprised of prey-patches and is linked through the approach on two domains (a 1/30 degree model of the northwest European shelf, and a 1/12 degree model of the Atlantic Ocean) using 531 orbit cycles of T/P-Jason and 114 cycles of Topex tandem mission data. Solutions are validated using harmonic constants from a set of 77 shallow water tide gauges, demonstrating dramatic improvement in solution accuracy for NLC M4, M54, and M4N.

“PHOTOREMINERALIZATION” OF PARTICULATE ORGANIC CARBON

“Photoremineralization” of carbon accompanies previously reported “photodissolution” of particulate organic carbon (POC) from resuspended estuarine and deltatic bottom sediments. Irradiations of suspensions of bottom sediments from Atchafalaya Bay, LA were conducted in a solar simulator. Dissolved oxygen, POC, dissolved organic carbon (DOC), and dissolved inorganic carbon (DIC) were measured before and after every irradiation. Dissolved oxygen levels remained constant in dark controls but decreased in irradiated suspensions in proportion to POC loss, with one mole O consumed for every 2-3 moles POC “photodissolved”. Photodissolution of POC was recovered as a combination of DOC and

This article summarizes the findings of several field investigations into a coastal mixing zone
aquifer in the northeastern Yucatan Peninsula by cave-diving scientists. Divers equipped with
data-logging multi-parameter probes completed a series of salinity profiles along transects
that began offshore and ranged to 14km inland. These profiles were designed to provide a high
resolution 3-D map of the mixing zone morphology. The salinity profiles revealed mix
patterns similar to those found in traditional estuaries and described in classic papers on
estuarine classification and function (Hansen and Rattray, 1966; Pritchard, 1967). The effect
of physical mixing is the flux of significant volumes of seawater across the principal interface
and into the mixed zone. The water balance of the mixing zone is poorly quantified except at
a limited number of locations. However, preliminary results suggest that the mixing process
produces an inward flow of water from the Caribbean Sea inland to the mixing zone. In contrast to
submarine groundwaters discharge, this effect moves seawater from offshore to the terres
trial aquifer. This effect is referred to as seaweed induction.

A TIDAL CREED CONDITION INDEX BASED ON ECOLOGICAL VARIABLES
SAMPLED WITH RAPID SURVEY METHODS
The southwest Florida coast is a homogeneous ecological landscape characterized by nu
merous, usually short tidal creeks located in natural to urban settings. Watershed managers
seek rapid-survey methods to accurately describe the ecological condition of tidal creeks in
order to document their status and trends. A 3-year project produced a creek index based on
oyster, other mollusk, other invertebrate, fish, and nuisance algae variables measured in 16
tidal creeks in Sarasota County FL. Data were compared by transformations to unit-less
values and values were combined as geometric means. The index sorted creeks into a large
group in intermediate condition and smaller groups that were better and worse, but all
creek scores were less than 50% of possible maxima. Pearson correlations of index scores to
benthic inflow community data (used as an independent reference standard) were sig
significant (p<0.05) for faunal density and highly significant (p<0.01) for species richness.
The index was not significantly correlated with abiotic measures of creek or watershed condi

Carbon and nitrogen flows within the food web of a subtidal sandy sediment were studied using a dual stable isotope approach. First, 13C and 15N natural abundance of consumers and potential benthic and pelagic resources suggested a tripartite trophic network: the 13C isotopic signatures of some benthic fauna were similar to those of benthic diatoms (~16‰), other fauna or taxa were ~14‰- depleted, similar to benthic cyanobacteria (~20‰) and suspended particulate matter (~21‰); and, another group showed intermediate δ15C values, suggesting a mixed diet. Second, the microphytobenthos of sediment cores was labeled through a pulse-chase experiment with 14C bicarbonate and 15N nitrate. The fate of the labeled microphytobenthos was followed in the different heterotrophic consumers. Transfer of 13C and 15N to consumers was fast. Heterotrophic bacteria contributed most to the total heterotrophic incorporation of 14C, followed by meiofauna and macrofauna, consistent with the heterotrophic biomass distribution. Significant labeling of meiofauna allowed us distinguishing between utilization of MPB and phytoplankton-derived carbon. This dual approach provided complementary information on the role of MPB in structuring benthic communities in sandy sediments.

The model was used to study the impact of WAD, stratification, winds and river inflows, and the role of MPB in structuring benthic communities in sandy sediments.

collected surface water temperature, salinity, PCO₂, pCO₂, and air PCO₂ data every 3 hours almost continuously since December 2005 in Känoe Bay, Hawaii. All measured values showed significant variability over a range of time scales. Surface water pCO₂ ranged from 230 to 590 Pamt but was generally higher than atmospheric due to net calcification. A linear TA/salinity relationship was derived from discrete surface water samples collected near the mooring. Using this relationship and the mooring data, we evaluate the full carbon system with particular attention to factors influencing calcification rates. Surface water saturation state with respect to aragonite, for example, varied from 1.2 to 3.5 with low values occurring during storm fresh water input. We will discuss the variability in the carbon system and its potential influence on the local corals.

13C AND 15N IN POM IN RELATION TO MUCILAGE FORMATION IN THE NORTHERN ADRIATIC SEA

C and N stable isotope ratios and composition of particulate organic matter (POM) were studied weekly in spring and summer 2003 and 2004, and the latter affected by mucilage appearance, in the Gulf of Trieste (northern Adriatic Sea) to track the temporal variations and differences between the two years. The 13C and 15N composition of POM was not directly linked to phytoplankton biomass dynamics. The delta13C-POC values varied with temperature. In 2004, delta13C-POC variations followed the delta15N-POC values as well as the delta13C-DIC values which were probably dependent on photosynthetic use of 12C. Variations of delta15N-POC values were the consequence of phytoplankton N sources. Lower delta15N-POC (<3 ‰) and higher delta13C-POC (~20 ‰) values observed in July 2003 were probably due to contribution of N2 fixation. The significant correlation between delta15N-POC values and nitrate concentrations in 2004 implied intense nitrate assimilation in the ‘New primary production’ successively producing high molecular weight polysaccharide macrogel with a mean delta13C and delta15N values of -19 ‰ and 5 ‰, respectively. A low fractionation factor, -1 ‰, was found probably as a consequence of microbial biodenitrification and specific growth conditions. The 13C composition of POM revealed higher contribution of allochthonous organic matter in 2004 due to higher riverine inflow.

FRESH WATER IN THE NORTHERN EAST GREENLAND CURRENT FROM 1982 THROUGH 2005

We describe the distribution and variability of the Pacific fresh water and total fresh water in the East Greenland shelf and slope in the region west of the Polar Front from Fram Strait to 72øN. These waters make up a considerable part of the Polar Water leaving the North Pacific to the east. We determine the total fresh water and Pacific fresh water fractions using the phosphi- rate and nitrate concentrations together with salinity. During 1993 and 2002, alkalinity values were also determined allowing estimates of river water and sea ice melt water fractions as well. Pacific fresh water and river water accounted for almost all of the fresh water in this region in 2002, when data where taken early in spring, while a considerable amount of sea ice melt water was present in 1993, when measurements were done later in the season. In 2004 and 2005 there were almost no traces of Pacific fresh water in the East Greenland Current.

VERTICAL DISTRIBUTION AND POPULATION STRUCTURE OF COPEPODS ALONG THE NORTHERN MID-ATLANTIC RIDGE

The Mid-Atlantic Ridge (MAR) is the largest topographic feature in the North Atlantic Ocean. Despite generally limited surface production, there is evidence that the mid-ocean ridges are ecologically important for higher trophic levels relative to the surrounding open ocean. The complicated topography of the MAR influences local and regional circulation patterns which in turn are likely to affect the distribution of the zooplankton fauna. In this paper we explore the vertical distribution and population structure of selected copepod species on the northern MAR, with the goal of better understanding the nature of the interactions between zooplankton and a mid-ocean ridge system. Zooplankton were sampled on the ridge between Iceland and the Azores (~60-41 N) on the MAR-ECO-expedition in June 2004. Depth stratified sampling revealed information on vertical distributions from surface down to 2500 m. The Subpolar Front (SPF) is the major biogeographic boundary in the studied area. Several species were observed to change their vertical distributions along the transect, becoming deeper on the southern stations. Factors influencing vertical distributions are evaluated and relationships between zooplankton, water masses, and ridge topography are discussed.

THE EFFECT OF BENTHIC MACROALGAE ON JUVENILE CRAB PREDATION AND SURVIVAL IN THE YORK RIVER ESTUARY

Nutrient loading is causing an ecological shift in the Chesapeake region, leading to the loss of traditional habitats, like seagrass, in favor of a new less studied habitat, macroalgae. This change can have important consequences for the blue crab Callinectes sapidus, a major resource in this region. Mesocosm studies show that the benthic macroalgae Gracilaria can reduce predation mortality on juvenile blue crabs. This follow up field study tested the ability of macroalgae to effect survival rates of juvenile crab between 11-33mm carapace width in the York River a subestuary of the Chesapeake Bay. This experiment is ongoing, but preliminary results show algal presence and amount having an impact on crab sur- vival which varies with the size of the juvenile crab.

EFFECTS OF WIND-WAVE-CURRENT INTERACTION ON OCEAN AND SURFACE GRAVITY WAVE RESPONSE TO HURRICANES

In existing ocean models, momentum fluxes through the air-sea interface are parameterized by the bulk formulae, neglecting their dependence on the sea state. While surface gravity wave models usually ignore the affect of ocean currents. In this study, the wind/ wave/current interaction mechanisms and their effect on ocean and surface wave field response are investigated through a set of numerical experiments using a fully coupled wind-wave-current model. The Princeton Ocean Model (POM) was used to simulate the ocean response and the wave fields are simulated using the WAVESWATCH III model for all experiments. The results show that the spatial variation of the hurricane-induced surface waves plays an important role in reducing momentum fluxes into currents in the rear-right quadrant of the hurricane. During wave/current interaction, the momentum flux is mainly affected by the reduction of wind speed relative to currents while the wave field is mostly affected by refraction due to the current shear. Results of three case studies in Ivan (2004) suggest that an improved drag parameterization and the wave current interaction improve the wave forecasts.

A DUAL-WEIGHTED POD APPROACH FOR 4D-VAR ADAPTIVE MESH OCEAN MODELLING

Proper Orthogonal Decomposition (POD) is an efficient way to reduce the dimension size of both the dynamic model and control space in 4D-Var data assimilation by identifying the few most energetic modes in a sequence of snapshots from a time-dependent system. Our motivation is to develop a novel POD reduced 4D-Var data assimilation technique for a 3D mesh adaptive finite element model (Imperial College Ocean Model). An effective dual-weighted (goal-based) approach is employed to estimate error and optimise the reduced bases, thus improving the quality of reduced order models, whilst the same goal- based function can be used to guide mesh adaptivity and inversion. The reduced order adjoint model developed here is used to optimise the initial conditions in a gyre case. The new POD model has been validated by comparing 4D-Var simulation results from adaptive and static meshes. Furthermore, error estimation (including the error in POD reduced modelling and the interpolation error in adapting the mesh) is carried out allowing us to assess the quality of reduced order adaptive mesh models.

BEDLOAD SEDIMENT TRANSPORT IN THE SWASH ZONE OF LABORATORY BEACHES

High flow velocities and substantial sediment transport can occur in the swash zone resulting in large morphological changes. However, swash flows are complex owing to
asymmetry, turbulence and infiltration processes making it difficult to understand and quantify sediment mobility and transport patterns. Nearly all studies of instantaneous swash-zone sediment transport have focused on the suspended load component even though time-averaged measurements have shown the bedload component can be a dominant mechanism. Our work involves testing newly fabricated resistivity concentration probes to resolve the time-dependent sediment concentration profile in the bedload layer of the swash zone. We present new instrumentation and assessment of test designs that have been made to determine the optimal design which ensures consistent plausible results. Preliminary bedload data from the swash zone of a laboratory beach will be discussed.

APPLICATION AND EVALUATION OF A DATA-ASSIMILATIVE COASTAL OCEAN FORECASTING SYSTEM

The application and evaluation of a data-assimilative coastal ocean forecast system based on the Regional Ocean Modeling System (ROMS) will be presented. The focus will be on applications of the system to the Monterey Bay region and the Southern California Bight. Both ROMS configurations use atmospheric forcing produced by regional atmospheric models and are integrated using a 3-dimensional variational data assimilation algorithm (3DVAR). For the Monterey Bay region, emphasis of development is found between independent measurements of temperature and salinity and the co-located ROMS-analyzed values. An assessment of the forecast skill and predictability will also be presented. Concerning this, preliminary results obtained for the Monterey Bay during August 2006 show a significant increase in forecast skill when surface current data gathered by coastal High-Frequency radars are assimilated. This increase makes the forecasts more skillful than persistence forecasts. Analysis of the forecasts for the Southern California Bight will be presented at the meeting.

INSPIRED BY CURIOSITY, INSPIRED BY USE: A PARADIGM FOR OCEAN SCIENCE AND ENGINEERING RESEARCH

Funding sources for ocean science and engineering research in the United States have been shifted periodically since the 1930s. The post-Cold War funding situation has caused the academic sector to examine options for new sources of funding and the quid pro quo of accepting such funding. The balance between major program activities (e.g. ORION) and individual grants within NSF is vigorously debated within the ocean science community. New partnerships between government agencies (e.g. NOAA) and the academic community are being forged. Private philanthropy is considered as an increasingly important source of funding for ocean science research and education by various private and public academic organizations. I submit that the "Pasture's Quadrant" paradigm of the late Professor Donald Stokes is one useful framework for organizing the interactions within ocean science and engineering research and applications of the research and for organizing productive discussions with present and potential sources of funding, including private philanthropy.

A STATISTICAL INVERSE MODEL IN THE SOUTHEASTERN PACIFIC OCEAN

It has been suggested in older and recent literature (e.g. Shaffer et al., 2004) that a broad deep eastern boundary flow is linking the equatorial Pacific Ocean to the Southern Ocean. The depth range of this flow corresponds to the Pacific Deep Water (2500m) where it is suggested by the distribution of perminal 3He originating from the East Pacific Rise. In this study, we propose to use a large set of data along with inverse techniques to estimate the stationary advection and diffusion of water properties and tracer concentrations (potential vorticity, potential temperature, salinity, dissolved oxygen and silica concentra-

to the area of interest. The various data are combined into an inverse model first developed by McKeague et al. (2005), Herbig et al. (2006). The model uses a advection-diffusion-model and Markov Chain Monte-Carlo techniques to estimate velocities along and across surfaces of neutral density as well as isopycnal diffusivities. It is composed of 9 layers between the 27.4 and 28 neutral densities. The circulation in the upper layers of the model compare well with direct independent estimates of velocities from oceanic float trajectory and profiler data. The model is being tested with extreme data in the deeper layers in regards to the 3He distribution along the Eastern boundary and its mixing with the Antarctic Circumpolar Current.

OBSERVATIONS OF THE TURBULENT DISSIPATION RATE IN THE SURFZONE

Surfzone turbulence, generated at the surface by breaking surface gravity waves and near the bottom from the vertical shear of ocean currents, vertical mixing, sediment, tracers, and biota. However, the vertical structure of surfzone turbulence and the relative contributions of these two sources is not well understood. Turbulence is often quantified using the turbulent dissipation rate (dissipation). During the HR06 experiment at Huntington Beach CA, a cross-shore transect of seven ADVs were deployed that were sampled rapidly (8 Hz) in order estimate the dissipation rate. The changing tide levels provide a range of depths at each instrument and the waves and currents varied over the month-long experiment. Dissipation is much larger within the surfzone than seaward of it, and increases with increased incident wave height indicating that breaking-waves are a strong the turbulent source. However, at times strong alongshore currents also contribute significantly to the observed dissipation. Various dissipation scales will be examined to determine the relative importance of each source under various wave, tide, and current conditions. Supported by ONR, NSF, CA Coastal Conservancy, and NOAA.

ROGUE WAVES IN OCEANIC TURBULENCE

A stochastic model of wave groups is presented to explain the occurrence of exceptionally large ocean waves, usually referred to as rogue waves. The model leads to the description of the non-Gaussian statistics of oceanic turbulence (Zakharov 1990) and to a new asymptotic distribution of crest heights over large waves in a form that generalizes the Tayfun model (Tayfun 1986). The new model explains the unusually large crests observed in experiments of random wave trains. However, comparisons with realistic oceanic measurements gathered in the North Sea during an intense storm indicate that the general-ized Tayfun model do not appear to improve upon the Tayfun distribution.

PERMANENT EL NINO IN THE EARLY PILOCENE: EVIDENCE, MECHANISMS, AND THE POLEWARD HEAT TRANSPORT PARADOX

Proxy temperature records show that in the early Pliocene, approximately 3 to 5 million years ago, the tropics were characterized by permanent El Nino-like conditions. The equa-torial Pacific was as warm as in the west as it is in the west today. Concurrently, major coast-al upwelling regions were up to 10°C warmer. This climate state persisted even though the external factors that control climate were essentially the same as at present and the Earth was experiencing greenhouse conditions similar to today’s, with the concentration of CO2 in the atmosphere comparable to present day values. State-of-the-art climate models fail to reproduce this permanent El Nino even when forced by large oceanic atmospheric CO2. Is there a problem with the data, or with the models? Here, we discuss mechanisms for permanent El Nino conditions, likely causes of why the models fail to replicate them, and potential implications for modeling climate change in the tropics. In particular, we conclude that the current generation of climate GCMs may lack an additional mechanism of poleward heat transport essential for maintaining a permanent El Nino.

EVIDENCE FOR UPEWELLING OF CORROSIVE ‘OCEAN ACIDIFIED’ WATER ONTO THE CONTINENTAL SHELF

During a cruise in May-June 2007 onboard the RV Wecoma, we observed ‘ocean acidified’ water that is corrosive to calcifying organisms upwelling onto the continental shelf of western North America from Queen Charlotte Sound, Canada to San Gregorio Baja California Sur, Mexico. The ocean uptake of anthropogenic CO2 has shoaled the aragonite saturation horizon so that seasonal upwelling exposes significant portions of the shelf to waters that are undersaturated with respect to aragonite. The corrosive waters reached mid-shelf depths of ~40-120 m along most transect lines, and reached all the way to the surface on two transects off northern California. In the region of the strongest upwelling, the isoleines of Ω = 1.0, DIC = 2190 and pH = 7.75 closely followed the 2.6°C potential density surface. This density surface shoaled from a depth of ~175 m in the offshore wa-ters and breached the surface over the shelf near the 100 m bottom contour, ~40 km from the coast. These results indicate that the upwelling process caused the entire water column
Hydrographic, water quality, and nutrient data from the Louisiana shelf are analyzed to produce quantitative criteria for defining process-oriented zones within the hypoxic sediments is mainly from the Yangtze River watershed including upstream input. Lead to 39.213 for Pb208/Pb204. The study shows that Pb in the Yangtze River intertidal zone of U238, U235 and Th232 and the isotope ratios are different from source to source.

Therefore, the ratios of these Pb isotopes can be used to find the origin of Pb. In this study, a total of 59 surface sediment samples (<5 cm) were obtained from the Yangtze River estuary intertidal zone. We will address the interannual variability of the hypoxic area and the effects of reduced and increased nutrient loadings and organic carbon inputs from the rivers and estuaries on the hypoxic area. We focus in particular on the recurring summer hypoxia of the eastern shell. Model results reproduce the basic features of the hypoxic zone. These include seasonality, size, location, duration, and vertical structure of the regions depleted of dissolved oxygen. The model also indicates that nutrient loading is an important factor in controlling the creation of reducible material, however, physical forcing processes, such as wind forcing, freshwater stratification, and current shear, control the spatial and temporal scales of variability of near-bottom dissolved oxygen concentrations.

Mixing of the West Spitsbergen Current: Summertime Observations The West Spitsbergen Current (WSC) is the major source of heat and salt for the Arctic Basin. It carries warm and salty Atlantic Water northwards through the Fram Strait. Along the path, WSC cools and freshens rapidly. To study the processes involved in the mixing of WSC, profiles of high-resolution CTD and dissipation rate of TKE were collected in the upper 500 m, in August 2005 and 2007. Sections across WSC cover 750 km along-path distance from Bear Island to the north of Svalbard, crossing the Yermak Plateau. Consistent throughout all sections is enhanced dissipation over the sloping bottom boundary (Moum et al., 2004) is proposed to account for the enhanced mixing. The downwelling favorable northward flowing WSC results in cross-slope transport of relatively cold and fresh coastal water at the bottom which is statically unstable and convects vertically leading to vigorous mixing. Significantly enhanced turbulent fluxes are inferred at the slope suggesting that the boundary layer mixing can be an important mechanism in summertime cooling and freshening of WSC.

Fernandes, A. M., Earth Resources Technology, Inc. at NOAA/NOS Center for Operational Oceanographic Products and Services, Silver Spring, USA, alexandre.fernandes@noaa.gov

Paterson, C. L., NOAA/NOS Center for Operational Oceanographic Products and Services, Silver Spring, USA, christopher.paterson@noaa.gov

Tidal currents in lower Cook Inlet, Alaska, are investigated using direct velocity measurements from a boat-mounted Acoustic Doppler Current Profiler (ADCP). A series of channel transects were performed in the summer of 2005 at Anchor Point as part of NOAA’s
Kachemak Bay Research Reserve activities. Observations of the tranverse vertical velocity structure in this area are limited and have been mostly obtained from scattered ADCP deployments. In this study, the transect data are used to map the spatial structure and to estimate the volume transport of the tidal currents. Results from previous 40-day ADCP deployments on the same line as the boat track are used to identify major harmonic constituents. These results, obtained using NOAA's standard harmonic analysis routines, indicate a strong dominance of semidiurnal tides with maximum tidal current velocities of about 100 cm/s.

VERTICAL PROJECTION OF VELOCITY, DENSITY AND TEMPERATURE USING VELOCITY-BASED FEATURE MODEL AND A LINEARIZED EQUATION OF STATE

One of the challenges in observational oceanography has been to infer the subsurface velocity field from surface observations. We use velocity-based feature modeling technique (VBFM) to describe and characterize a vertical section of observed horizontal velocities, and then create a realistic 2-D velocity field for a region. By separating the observed velocity section into two non-dimensional functions, one for the shear profile, and other for the horizontal structure, it is possible to represent the original velocity section using only the surface velocity for value. Assuming geostrophy and using the thermal wind relation, one can then estimate the density field. The associated temperature field is determined by using a linearized equation of state with a constant salinity value. As a first example of this methodology, we present some results for the Brazil Current - Intermediate Western Boundary Current (BC-IWBC) system at 23°S. Realistic velocity sections were simulated by sectorial POM (Princeston Ocean Model) with the VBFM-derived temperature fields used to initialize the model along with the climatological salinity fields.

THE EFFECTS OF OCEAN ACIDIFICATION ON LYRE CRAB HYAS LYRATUS METABOLIC PROCESSES

Recent studies show that increasing amounts of atmospheric CO2 dissolving into the ocean cause acidification of the marine environment. Some predictive oceanographic models indicate that pH will drop up to 0.5 pH units over the next 100 years. It is well documented that ocean acidification (OA) inhibits the ability of organisms to form and maintain calcium carbonate structures. Examples of such organisms are diatoms, mollusks, and crustaceans. The physiological cost to crustaceans that must regulate internal pH and form a calcareous exoskeleton during larval and juvenile and adult moults is unclear. We measured standard metabolic rates of female lyre crabs, Hyas lyratus that were acclimated for one week at pH 4.8, 7.5, 7.0, and 6.5. Metabolic rates were significantly different between crabs held at pH 8 and pH 6 (0.55 vs. 0.43 ml O2/kg/min). Enzymatic rates of lactate dehydrogenase (LDH), pyruvate kinase, and citrate synthase decreased significantly with decreased pH. This decreased LDH activity could be detrimental to physiological processes requiring anaerobic metabolism. In fact, increased mortality was observed in crabs that were acclimated to pH 7.5, 7.0 and pH 6.5 and exposed to hypoxia for 24 hours when compared with control crabs held at pH 8.0. It is likely that there is an energetic cost to crabs associated with OA. This could have a negative impact on energetically costly physiological processes such as growth and reproduction.

RESTRATIFICATION OF THE OCEAN SURFACE MIXED LAYER BY FRONTAL INSTABILITIES

The ocean surface mixed layer is regularly remixed by small-scale, turbulent convective and dynamical processes that slump horizontal density gradients. Subsequent mixing events depend critically on the amount of restratification that has occurred. Processes as deep convection, mesoscale water formation, phytoplankton biology, and air-sea chemical and heat exchange are thus sensitive to restratification. The paradigm of dynamical restratification is the slumping of lateral buoyancy gradients through surface frontogenesis in regions of confluent flow. In this presentation we show that in the real ocean the bulk of restratification is associated with three dimensional instabilities that develop along fronts and not with the two-dimensional slumping associated with frontogenesis. We present scaling laws and a parameterization scheme for the rate of restratification by frontal instabilities. The scalings laws are applied to the real ocean to show that frontal instabilities are a leading order effect in the mixed layer heat budget and in the exchange of nutrients between the surface ocean and the thermocline.

LONG-TERM TEMPERATURE OBSERVATIONS PROVIDE USEFUL INSIGHTS INTO THE ACTIVITY OF MUD VOLCANOES

Submarine mud volcanoes have been discovered all over the world and are known to emit large amounts of methane into the water column. However, estimates of emissions have been based on individual observations during research cruises and neglect any temporal variability. The time scale associated with conduction and convection, long-term temperature observations yield important information about the dynamics of mud volcano activity on time scales in the order of months or years. A successful deployment of a temperature logger on Hakon Mosby mud volcano on the SW Barents Sea slope for a period of nine months documented an eruptive event associated with rapid temperature changes in the sediments that point to highly dynamic seepage and complex flow patterns. Preliminary results from an on-going temperature observation on Dvurechenski mud volcano in the Black Sea seem to be strongly influenced by gas hydrate formation in the near-surface sediments. Based on these experiences, further long-term observations of in-situ sediment temperature, pore pressure, and geochemical porewater composition at mud volcanoes are planned.

AN OBSERVED SUMMER TIME HEAT BUDGET ON THE INNER CONTINENTAL SHELF OFF THE NORTHEASTERN UNITED STATES

The transport of heat over the inner continental shelf (12-m water depth) is investigated using observations of water velocity and temperature, surface gravity waves, and heat flux between the ocean and atmosphere to calculate terms in a depth-integrated heat budget off Massachusetts during summer 2003. Heat transport due to surface gravity waves (Stokes’ drift) is included and is substantial. On time scales of weeks to months, the inner shelf is persistently cooled by a mean upwelling circulation combined with very weak surface heat stratification. The cross-shelf heat flux nearly balances the strong surface heating throughout mid-summer, so the water temperature is almost constant. The along-shelf heat flux divergence is apparently small. The cross-shelf heat flux agrees with a simple model in which the cross-shelf velocity profile, including the Stokes’ drift, is a steady, upwelling circulation. On time scales longer than the flushing time for the volume (a few days) the temperature profile is forced by the surface heat flux to adjust so that the slowly-varying surface heating and cross-shelf advection balance, and the inner shelf heat content is in a quasi-steady state.

CDOM DYNAMICS IN THE GLOBAL OCEAN: WHAT WE LEARN FROM DEcadAL TIME-SERIES OF SATELLITE-DERIVED CDOM ABSORPTION COEFFICIENTS

A thorough knowledge of surface CDOM dynamics in the ocean is fundamental to our understanding of organic carbon cycling and the biogeochemical effects of UV radiation in the ocean. Here, we implement an updated version of the SeaUV algorithm (Ficht et al., Remote Sensing of Environment, 2007) to ten years of monthly-binned SeaWiFS ocean color data (1997-2007) in order to examine the time-series of CDOM absorption coefficient at 320nm, a (320), and investigate the global scale dynamics of CDOM in the surface ocean. Time-series analyses and signal decompositions performed on a per pixel basis revealed that the world’s ocean exhibits distinct patterns of CDOM variability and year-to-year predictability. The analysis also revealed downward trends in a (320) of up to 30% in two areas of the Pacific ocean. We further examine these observed CDOM regimes with regards to their regulating processes using climatological data for the mixed layer depth (NMLD), UV incident irradiance and remotely-sensed SST, UV penetration, as well as other oceanographic data.

MODELING ECOLOGICAL COMPLEXITY IN THE COASTAL GULF OF ALASKA: FROM NPZD TO NEMURO

Ecosystem complexity in the northwestern coastal Gulf of Alaska (CGOA) is investigated by coupling two lower trophic level ecosystem models, with explicit iron limitation on nutrient uptake, to a three-dimensional coastal ocean circulation model. The first
ecosystem model is a simple 4-component NPZD model, while the second is the more complex 31-component NEMURO model, with multiple limiting nutrients. 3D nutrient transport, phytoplankton/bacterial, and zooplankton sizes and interactions are included. Iron limitation is included in both the ecosystem models by adding governing equations for micro-nutrient compartments representing dissolved iron and phytoplankton-associated iron. Simulated nitrate and chlorophyll concentrations with the NPZD model exhibit striking similarities with available remotely-sensed and in situ observations. In addition to reproducing the seasonal variability in a “climatological” sense over a 10-year period, the coupled model provides important information on the different modes of variability affecting the physical and biological variables as a function of cross-shelf position. The added ecosystem complexity present in NEMURO significantly improves the prediction of the vertical chlorophyll profiles on the shelf, and yields useful insight on the seasonal variability in phytoplankton and zooplankton community structure in the CGOA.

**CHRONIC TURBIDITY ON THE MOLOKAI FRINGING CORAL REEF: GOATS, SUGAR, AND WATERSHED CHANGE**

Major changes to south Molokai (Hawaii) watersheds, principally from agriculture and forest logging, have dramatically altered the physical character and overall hydrology of the adjacent coral reef. The increased sediment discharge poses a significant impediment to reef health by blocking light and inhibiting photosynthesis, directly smothering and abrading coral, and triggering increases in the growth of macro algae. Our studies on a 10-km segment of the fringing reef show that high levels of suspended sediment are chronic. Measurements of turbidity, suspended sediment concentration (SSC) and sediment composition were made in 2005 and 2007 during spring tides on the 800-m wide reef flat. SSC values during typical high-tide and trade-wind conditions were 10 to 60 mg/L (roughly 8 to 50 NTU's) within 250 m of the shoreline and 5 to 10 mg/L farther seaward; the mud is 65 to 95 % terrigenous in origin. Removal of particles by weak off-reef flow is a long-term process, resulting in particle residence times of years. As a result of watershed modification and sediment retention on the reef flat, coral cover is low to absent.

**NATURAL GEOLOGICAL RESPONSES TO ANTHROPOGENIC ALTERATIONS OF THE NAPLES BAY ESTUARINE SYSTEM**

The Naples Bay Estuary System (NRES), situated in southwest Florida, has undergone extensive modifications caused directly and indirectly by anthropogenic influences. These alterations include the substitution of mangrove-forested shorelines with concrete bulkheads, channelization of the shoreline and within the watershed, and channelization of the bay for recreational boating. The NRES consists of northern Naples Bay, southern Naples Bay, and Dollar Bay, whose shorelines are fully bulkheaded, partially bulkheaded, and natural, respectively. This project investigates the natural geological response of the bay for recreational boating. The NBES consists of northern Naples Bay, southern Naples Bay, and Dollar Bay, whose shorelines are fully bulkheaded, partially bulkheaded, and natural, respectively. This project investigates the natural geological response of the bay for recreational boating. This project investigates the natural geological response of the bay for recreational boating. This project investigates the natural geological response of the bay for recreational boating. This project investigates the natural geological response of the bay for recreational boating.

**DIURNAL VARIABILITY IN SEA SURFACE TEMPERATURE DERIVED FROM GEOSTATIONARY SATELLITE OBSERVATIONS: SEASONAL PATTERNS AND DEPENDENCE ON WIND SPEED AND INSOLATION**

During the day, the upper few meters of the ocean are heated by short-wave solar radiation, partially offset by net outgoing long-wave radiation and sensitive and latent heat fluxes. During the night, the surface layer cools due to these outgoing fluxes. This daily heating and cooling gives a diurnal cycle in the sea-surface temperature (SST). The typical amplitude of the diurnal variability of SST ranges from 0.1 to 4 K, depending on wind strength and resolution. We use the SSTs derived from the Spinning Enhanced Visible and Infrared Imager (SEVIRI) radiance observations to characterize diurnal variability on the scale of ocean basins. We derive seasonal average maps characterizing diurnal warming in the Atlantic Ocean and Mediterranean Sea. Using the solar surface irradiance observations from SEVIRI and wind observations from a combination of microwave sensors (SSMI, TMI, QUIKSCAT, AMSR-E) we calculate the dependence of SST on these parameters and time of day, to give an empirical, statistical model of diurnal warming.

**CONTRASTING N** fixation in the Chesapeake Bay outflow plume with surrounding coastal and shelf waters

Few measurements of N2 fixation have been made in coastal regions in comparison to the measurements made in oligotrophic regions where it is an important source of new nitrogen (N). Although the coastal region can be replete with N, N2 fixation can be an important component of the N cycle. Coupling N2 fixation rates with nifH gene probing allows us to link diazotrophic assemblages with in situ N2 fixation rates. Results from nine cruises along the Virginia coast affected by the Chesapeake Bay outflow plume showed N2 fixation rates between 0 and 35 nmol N L-1 d-1. For comparison, transects were conducted off-shore and within the mid-Atlantic Bight. Although rates were high along the shelf in the fall 2006 (17.6 nmol N L-1 d-1), during summer 2006 N2 fixation rates were lower (1.1-3.7 nmol N L-1 d-1), neither rivaling those observed in the plume. Genetic diversity was measured, and although N2 fixation was highest in the plume as opposed to contrasting shelf waters, nifH sequencing only detected α- and γ- proteobacteria while cyanobacterial unicells dominated the coastal and Gulf Stream influenced stations.

A SEASONAL STUDY OF ð¹³C(DIC) AND ð¹⁸O(H) IN THE BALTIC AND SKAGERRAK WATER COLUMN

The Skagerrak is influenced by water from the Baltic Sea, the North Sea, and the North Atlantic Ocean. To help understand the oxygen and carbon stable isotopic compositions of benthic foraminifera in the Skagerrak, we have collected monthly samples of ð¹³C(DIC), ð¹⁸O, temperature, salinity and nutrients from the water column at 10 stations in the Baltic and Skagerrak over a year. By sampling at different water masses, and by documenting the influences of water exchanges, stagnation periods, and productivity on ð¹³C(DIC) and ð¹⁸O(H) we hope to quantify the full range of oxygen and carbon isotopic relationships in this region, and to provide a foundation for paleoceanographic reconstructions using foraminiferal oxygen and carbon isotopic composition. The Baltic is dominated by large freshwater inputs and strong stratification at conditions prevail over large areas. The ð¹³C(DIC) values in the Baltic range between -7 and -4‰, the ð¹⁸O(H) between -5 and 1‰. In the Skagerrak oxygen isotopes vary between -0.4 and 0.4‰ and carbon isotopes between 0.6 and 1.8‰ depending on water mass and time of the year.

BEYOND THE DWBC, NADW PATHWAYS

High chlorofluorocarbon (CFC) concentrations have been repeatedly observed in the interior of the deep western North Atlantic Basin. They imply substantial input has been diverted over time from the Deep Western Boundary Current (DWBC) into the interior. The low values of the Atlantic MOC is usually viewed as a consistently western intensified current, which transfers water and properties smoothly through the subtropics into the Southern Hemisphere. However, the CFCs and other studies suggest that this pathway is not smooth, and it is not the only pathway. As compared with what would be based only on DWBC advection we present other likely interior pathways, which slow transport of NADW through the subtropics while ventilating the interior. Interior pathways result on DWBC advection we present other likely interior pathways, which slow transport of NADW through the subtropics while ventilating the interior. Interior pathways result.

MEGA COASTAL MORPHODYNAMIC FEATURES ON THE FLORIDA ATLANTIC CONTINENTAL SHELF: SHOREFACE TO UPPER FLORIDA- HATTERAS SLOPE FROM MIAMI TO JACKSONVILLE

Until recently, the range of morphodynamic features lying above the Florida-Hatteras Slope on the continental shelf along the east coast of Florida was relatively unknown. Mapping of mega- and mesoscale seafloor features from Miami to Jacksonville, a shelf area of about 20,500 km-2 extending up to 27 km offshore, was based on interpretation of airborne Laser Bathymetry (ALB), reclassified NOAA bathymetry, sidescan sonar, and seismic reflection profiling. Megascalar features include coralline-algal reef systems, drowned karst, hardgrounds, submerged paleo shorelines (drowned beach ridge plains), and buried paleo channels. Megascale features include inter-reefal sand troughs in the ETF, ebb-tidal deltas, transverse bars, shoals, sand waves, ridges, and banks. Morphodynamic units on the southern shelf are separated from morphosedimentary units on the northern shelf by the Bahamas Fracture Zone (BFF). Sedimentary deposits occur in two submarine physiographic provinces that are separated by the BFF. Use of ALB and reformatted NOAA bathymetry in the form of 3D terrain models permits classification of submarine landform topologies that was not previously possible using isobaths

PUMPING RATES OF THE GIANT BARREL SPONGE XESTOSPONGIA MUTA ON CARIBBEAN REEFS: SCALE SIZING, ENVIRONMENTAL CONTROLS, AND BLEACHING EFFECTS

The ability of sponges to remove DOM and POM from the water column contributes to the cycling of carbon and nutrients between the water column and the benthos. Given the filtering potential of a diverse and dominant sponge fauna, analysis of DOC cycling on coral reefs requires mechanistic understanding of sponge filtration rates. The giant barrel sponge, Xestospongia muta, comprises up to 60% of sponge biomass on Caribbean reefs with a size filtering potential of a diverse and dominant sponge fauna, analysis of OM cycling on coral reefs is needed. During volumetric pumping rates scaled linearly with tissue volume and ranged 40 ml-H-O h-1 ml-tissue. Pumping rates were constant over periods up to 24 h, although some specimens decreased pumping during rapid fluctuations in water temperature. Cyclic (non-fatal) bleaching did not affect filtration rates.

IDENTIFYING AND CHARACTERIZING POLLUTED SURFACE WATERS IN THE SOUTHERN CALIFORNIA BIGHT BASED ON METAL LEVELS IN KELP (M. PROPELLOSA) SEEVE TUBE SAP

Metal concentrations in kelp tube sap (STS) may be useful in determining the dispersal of coastal effluent plumes. Common trace metals average a 100-fold increase in concentration in STS as compared to their total concentration in seawater. In this study, concentrations of 19 different metals were measured in STS using ICP-MS. STS was collected from Macrocyathus pyrifera fronds obtained from several coastal southern California locations, including a presumed “non-polluted” reference site on the seaward side of Catalina Island. Results indicate the presence of 8 new elements not formerly identified within Macrocystis STS including, Rh, Pd, Ag, Sn, and Cs. Several metals (e.g. Cu, Zn, Pb) were found at significantly higher levels within STS collected from populations inside the Port of Los Angeles/ Long Beach in comparison to Catalina Island. Also, significant differences in levels of other metals (e.g. Fe, As, Ag, Cd) were found between populations within and outside the harbor breakwall. These results indicate the potential usefulness of this method in spatially describing metal pollution arising from coastal sources.

PACIFIC SUBTHERMAL EQUILATORIAL CURRENTS: A DEEPER CLIMATOLOGY FROM NEW SHIPBOARD ADCP

Because of its temporal variability and complex structure in all three spatial dimensions, the Pacific equatorial subthermocline circulation remains to be described fully. During the last four years, more than 50 velocity sections have been collected within 8 degrees
of the equation using new shipboard acoustic Doppler current profilers that reach 750-m depth or more, the range commonly available with the prior generation of instruments. Averaged by longitude, the new measurements show the Equatorial Intermediate Current (EIC) and the Lower EIC weakening from west to east. The average of western Pacific sections shows the Secondary Southern Subsurface Countercurrent from 5-6 degrees S with speeds exceeding 0.1 m/s extending from 280-670 m depth. It is similar in location but weaker in the central Pacific. Although eastward jets tend to have higher speeds, consistent and vertically extensive regions of westward flow such as the South EIC are also prominent in the mean sections as well as in synoptic sections.

FROM DEEP OCEAN SEDIMENTS TO GLACIAL LAKES: BACKTRACKING EVIDENCE FOR LATE PLEISTOCENE/EARLY HOLOCENE JÅ–KULHAUS USING CORES FROM ODP LEGS 169 AND 169S

ODP Legs 169 and 169S recovered remarkable turbidite deposits. Their sources were traced by shipboard researchers using a multiproxy approach of sedimentary petrology, radiometric age dating, paleoecology, and paleomagnetism to catastrophic late Pleistocene/early Holocene deglacial flooding events (jâkulaus) in the Pacific northwest. Teachers participating in the 2007 SOI School of Rock (SOR) professional development program described and interpreted the Leg 169 and 169S cores, without prior knowledge of the deglacial flood interpretation, following the SOR pedagogical approach of data and discovery, first, and discussion and interpretation second. Themes such as size sorting, mineral provenance, and benthic foramin fossil ecowraps were drawn out in group discussions, and were supported by data available in Ocean Drilling Program-related publications and database. The teachers also linked the science to popular culture by connecting what they observed in the cores with the movie Ice Age 2 which depicts a jâkulaus event in a cartoon format. This exercise demonstrated to teachers the importance of marine deposits in studies of environmental change on land and that rates of environmental change are sometimes very rapid.

REMOTE SENSING DETECTION OF RED TIDES IN A COASTAL UPWELLING SYSTEM 

The spectral reflectance of dense “red tide” blooms shows a peak in the NIR portion of the electromagnetic spectrum, at wavelengths 20 nm longer than that of the chlorophyll fluorescence peak. This signal has been used as a basis for mapping extreme surface blooms with remote sensing image data. Linear baseline algorithms measure the height of a spectral peak above a baseline determined from reflectance intensity at two wavelengths on either side of the peak. Variation in the wavelength center of the reflectance peak presents a challenge for consistent measurement of bloom intensity across different multispectral sensors, which have different band centers and widths across the NIR portions of the spectrum. Referring to situ hyperspectral reflectance measurements, we present examples from different satellite and airborne sensors used to measure bloom intensity in Monterey Bay, California. We discuss inconsistencies between measurements made across different sensors, and provide examples of how these results have described red tide bloom dynamics in the region.

THE STATE OF THE OCEAN CLIMATE: CLIMATE INDICES AND THEIR UNCERTAINTY AS A MEASURE OF OUR ABILITY TO OBSERVE THE OCEAN

The ‘State of the Ocean climate’ web site gives a rapid overview of ocean climate indices. This site has been developed by the Ocean Observations Institute, USA, www.oceanobs.org (2008). The site is a collaborative project, with contributions from the National Oceanic and Atmospheric Administration, the University of Delaware, National Aeronautics and Space Administration, the National Ocean Survey, and the National Geophysical Research Institute. The State of the Ocean Climate site provides a web interface for accessing the Ocean Observations Information System (OIS) data. The OIS provides a comprehensive collection of oceanographic data from the ocean surface to the ocean floor.

OVERVIEW OF THE COMMUNITIES ASSOCIATED WITH OIL, GAS, AND BRINE SEEPAGE, AND ASSOCIATED HARD GROUNDS IN THE DEEP GULF OF MEXICO

Hydrocarbon and brine seepage driven by salt tectonics is widespread on the continental slope of the Gulf of Mexico. Production of massive carbonates and hard grounds on the sea floor is a common byproduct of the activities of microbial consortia in areas of active methane seepage. In 2006 and 2007, 15 cold-seep/hard-ground sites at depths between 1000 and 2,850 meters and distributed over a 620-km E-W span were sampled using Alvin and/or Jason II. Of these, 10 had not previously been visited and were initially identified from a combination of geophysical and geochemical data collected from satellite observations and surface operations. Chemosynthetic fauna, including species harboring chemoautotrophic symbionts, were found at every site visited and several exceptional communities were encountered. These included a very extensive and dense aggregation of seep sponges (covering approximately 8,000 m2), numerous areas in the deepest sites where some of the most reduced sediments we encountered were occupied by the aggregation of large coraline crustose red algae, and aggregations of large sponges, tunicates, and rugose corals.

MODERN AND HISTORIC MERCURY DEPOSITION: INSIGHTS FROM DATED LAKE SEDIMENTS AND A VARIED ESTUARINE CORE

The geochemical cycling of Hg and assessing impact associated with human-related Hg emissions on its natural cycle. Dated lake sediments have been the primary source of secular data for reconstructing Hg accumulation / depositional patterns associated with preindustrial to the modern era. These lacustrine natural archives are particularly well suited for examining the global/regional nature of atmospheric Hg dispersion, deposition, and anthropogenic interferences. Here we present an evaluation of the impact of Hg contamination on calanoid copepods could not be explained by either UV or foodweb effects alone.

EVIDENCE FOR LATE PLEISTOCENE/EARLY HOLOCENE JÖKULHAUPS USING MODERN AND HISTORIC MERCURY DEPOSITION: INSIGHTS FROM DATED LAKE SEDIMENTS AND A VARIED ESTUARINE CORE

Contemporary and historical Hg depositional information is important for understanding the biogeochemical cycling of Hg and assessing impact associated with human-related Hg emissions on its natural cycle. Dated lake sediments have been the primary source of secular data for reconstructing Hg accumulation / depositional patterns associated with preindustrial to the modern era. These lacustrine natural archives are particularly well suited for examining the global/regional nature of atmospheric Hg dispersion, deposition, and anthropogenic interferences. Here we present an evaluation of the impact of Hg on local to global scales. The accumulation ratio or “anthropic global increase,” relative to preindustrial levels, is remarkably uniform at 3 ±1 based on 182 cores and 90 lakes from remote locations. Localized enhancements are evident in urban areas.

Hollander, D. Frisian Island chain. This observation could be used for the establishment of a water circulation in between the normal behavior. The dominant semidiurnal tide is totally balanced by wind and pressure estimated up to 50,000 m³. The current field during the storm is characterized by an ab storm conditions was a moot oceanographic question, approached by X-band observation. Ziemer, F. Oceanic islands with high topography drastically affect both atmospheric and oceanic flows. Sharp horizontal wind shear lines form on the edges of the island wake, resulting in rapid variations of wind stress and Ekman transport in the ocean, strong Ekman pumping, and mixed layers. Lumpkin, C. Atmospheric and oceanic flows associated with mountainous islands: Hawaii. Oceanic islands with high topography drastically affect both atmospheric and oceanic flows. Sharp horizontal wind shear lines form on the edges of the island wake, resulting in rapid variations of wind stress and Ekman transport in the ocean, strong Ekman pumping, and mixed layers. Schwartze, G. Potential for benthic primary production on Ship Shoal, Louisiana, USA. As a shallow (5-14 m) sandbank, Ship Shoal may support benthic microbial populations that are rare or absent in the phytoplankton-based benthos of deeper waters. To assess the potential for benthic production on Ship Shoal, we took samples for sediment and water column chlorophyll a (Chl a), light levels, and sediment algal composition during cruises in 2005 and 2006. The percent of surface light reaching the bottom was greater than 5% at most stations during spring 2006 and greater than 20% at most stations during the summer. Overall, sedimentary algal biomass was highest in August (33.5 ± 37.8 mg/m²) and May (42.4 ± 26.3 mg/m²) in 2005 and 2006, respectively, and was greater at the shallower western and central stations. Benthic chlorophyll a values were equal to or exceeded integrated water column values much of the year, and cell counts suggested that sedimentary algae typically contained less than 10% settled phytoplankton. Our results suggest that benthic microalgae are an important carbon source to the benthic food web on Ship Shoal. Flocks, J. Influence of antecedent geology on barrier island development: Northern Chandeleur Islands, Louisiana. A dense network of high-resolution seismic profiles collected around the northern Chandeleur Islands reveals three seismic facies that dominate the shallow (<100 m) stratigraphy. The first is an acoustically transparent lens-shaped unit with discontinuous reflectors, interpreted as distributary channel deposits associated with the St. Bernard complex of the Mississippi Delta. Stratigraphically adjacent to the first is a unit defined by low-angle parallel reflectors, interpreted to represent fine-grained interdistributary deposits. These two units underlie a seaward-thinning acoustically transparent unit, interpreted to represent fine-grained interdistributary deposits.
SUPPORT THE STEWARDSHIP OF LIVING MARINE RESOURCES

BENTHIC COMMUNITIES, ACOUSTIC BACKSCATTER AND ECOLOGICAL OBSERVATIONS

High-resolution bathymetric and backscatter studies in coastal and estuarine waters near NY are demonstrating that benthic communities and sea-floor acoustic properties, especially backscatter, are closely related. Areas are surveyed with high-resolution multibeam bathymetry and backscatter along with side-scan sonar, and sediments with a range of backscatter characteristics are sampled for sediment properties and for benthic organisms. These studies reveal complex but resolvable patterns in both benthic community structure and bottom sediment characteristics, and statistical analysis shows that benthic communities are highly correlated with acoustic backscatter. We have also observed temporal and spatial variability in acoustic backscatter related to temporal changes in the abundance of the polychaete Axinellidae also called on the inner shelf. This suggests that high-frequency acoustic backscatter may be a useful tool for assessing temporal and spatial changes in benthic communities. Indeed, changes in backscatter could occur if an anoxic event alters benthic communities or if an invasive species such as the tunicate Didemnum covers the bottom. Studies of temporal and spatial variability in acoustic backscatter patterns may be an important component of ecosystems-based management and of the ecological observing systems envisioned for the Integrated Ocean Observing System (IOOS).

Resource managers and researchers interested in obtaining information concerning the marine environment must often navigate and land-use changes and continued population growth threaten to affect community composition and functioning of numerous diverse habitats. My research investigates the connectivity across the land-sea interface and how the inputs from the land affect nearshore marine communities. Community dynamics in nearshore habitats may be significantly influenced by the delivery of dissolved and particulate fluxes from river sources. Effects from rivers can be especially important in short, steep watersheds where little filters the ocean. In two watersheds along the Big Sur coast in central California, I am investigating the role of terrestrial subsidies in nearshore communities by documenting the amount and types of subsidies being delivered, the impact on community composition, and how these subsidies affect habitat function. Data suggest these nearly pristine rivers are important sources of nutrients and particulates during non-upwelling conditions and may contribute to the functioning of this diverse nearshore community.

DEEP-OCEAN PARTICULATE-MATTER DYNAMICS AS INFLUENCED BY THE ANAXIMENES SEAMOUNT: A WEAK-TIDE ENVIRONMENT

In many parts of the world ocean abyssal hills and seamounts structure the seafloor on spatial scales of thousands of kilometers to tens of kilometers. The mere presence of the topographic features together with flow/topography interactions adds heterogeneity and complexity to the environment. Despite their very likely importance little is known on how these topographic features control the formation of the sedimentary record and ecosystem structure and dynamics. The most important kilometre-scale flow/topography interactions involve residual flow and tides. To help separate the influence of residual flow and tides at topographic features in the open ocean we sampled half a tidal neap-spring cycle at the Anaximenes Seamount in the Eastern Mediterranean which is a deep sea environment with very weak tides. Any signals in the particle-matter parameters analyzed should therefore mainly result from the residual flow. Water samples were taken with a CTD-rosette every 10 m above bottom for the first 50 m and every 100 m above bottom for the second 50 m respectively. Here we present the first data from this experiment judging it the short-lived natural particle-matter tracer 234 Thorium and particulate carbon and nitrogen.

DELIVERY AND APPLICATION OF OCEANOGRAPHIC SATELLITE DATA TO SUPPORT THE STEWARDSHIP OF LIVING MARINE RESOURCES

FROM RIVERS TO KELP FORESTS IN BIG SUR, CALIFORNIA

Understanding the connections between traditionally disparate systems has recently become an important area of study across disciplines. These studies are especially important in coastal areas where land-use changes and continued population growth threaten to affect community composition and functioning of numerous diverse habitats. My research investigates the connectivity across the land-sea interface and how the inputs from the land affect nearshore marine communities. Community dynamics in nearshore habitats may be significantly influenced by the delivery of dissolved and particulate fluxes from river sources. Effects from rivers can be especially important in short, steep watersheds where little filters the ocean. In two watersheds along the Big Sur coast in central California, I am investigating the role of terrestrial subsidies in nearshore communities by documenting the amount and types of subsidies being delivered, the impact on community composition, and how these subsidies affect habitat function. Data suggest these nearly pristine rivers are important sources of nutrients and particulates during non-upwelling conditions and may contribute to the functioning of this diverse nearshore community.

Surface concentrations and vertical fluxes of particulate organic carbon (POC) were assessed in Amundsen Gulf (AG) (Canadian Beaufort Sea, Arctic Ocean) from 2004 to 2006 by combining remote sensing and moored sediment trap measurements. Each year between June and September, distinct periods of increased surface POC concentrations (200–500 mg C m⁻³) were observed in southwestern AG. Concentrations distant from this area remained relatively low (<100 mg C m⁻³), suggesting that enhanced POC production on the surface was restrained to a small vicinity. The magnitude and extent of vertical POC fluxes generally followed the spatial and temporal variability of surface POC concentrations. Daily POC fluxes at 100 m depth were recurrently higher in western AG compared to southwestern AG. POC concentrations. Daily POC fluxes at 100 m depth were recurrently higher in western AG compared to southwestern AG. POC at 200 m depth fluctuated however similarly in both regions of AG throughout the three-year study period (1–30 mg C m⁻² d⁻¹). In addition to increased POC production in western AG, we proposed enhanced grazing pressure at the west (i.e. close to the superior food supply) and eastward advection of particles at intermediate depths to explain the variability of vertical POC fluxes in AG.

QUANTITATIVE AND DYNAMICAL ANALYSIS OF THE EDW VOLUME CYCLE USING AN OBSERVATION-MODEL SYNTHESIS.

The formation of North Atlantic Eighteen Degree Water (EDW) is analyzed using observations and the MIT General Circulation Model (GCM). We focus on the past several years during which there was unprecedented data coverage, including Argo profiles, moored SST, and observations from the CLIMODE project. Employing the (ECCO) adjoint modeling framework, observations are interpolated under GCM dynamics constraints leading to a quantitative and dynamical analysis of observed EDW signals. In the region of EDW formation, the constrained model solution faithfully represents the observed evolution of subsurface chlorophyll and surface outcrops. To realize the EDW volumetric census into perspective and discuss the formation and mixing processes at work, a volume budget of the EDW layer is computed (following Wain, 1982). EDW volume increases dramatically in February and March (35v-year), primarily due to convection triggered by air-sea heat loss south of the Gulf Stream (35v-year). EDW volume decreases in March and April due to air-sea heat gain and mixing during restratification (35v-year). Further EDW volume reduction occurs throughout the year due to internal oceanic processes (65v-year).

MORPHODYNAMIC HISTORY OF LONGBAY PASS, MANATEE COUNTY, FLORIDA

A study of evolutionary sequences of morphoedaphic features at Longboat Pass, central-west coast of Florida, was initiated to acquire a better understanding of sediment exchange between the ebb-tidal delta, tidal inlet, and adjacent downdrift segments of shoreline. Twenty sequential aerial photographs (1940-2006) were interpreted in a time-series analysis for changes in the position and morphology of the tidal channel and ebb shoal and the response of adjacent beaches to these changes. Little variation in inlet position (migrated within a 250 ft swath) and ebb tidal shoal area (1.22 km² to 1.68 km²) indicate that the Longboat Pass ebb shoal complex has been relatively stable over the 66 year period between 1940 and 2006. Although the area of the ebb-shoal has not significantly changed, the shape of the ebb shoal was deflected downdrift (southwards) 0.79 km. The inlet is classified as morphodynamically stable and the shoal is classified as a “Group 2” type of ebb-tidal delta.

BIOGRAPHY AND BIOGEOGRAPHY OF BRYOZOA IN COOK INLET, GULF OF ALASKA

Archived samples and specimens collected during intertidal and subtidal surveys in Cook Inlet were used to re-evaluate identifications and to review their geographic distribution, especially to look for similarities between species collected in western Cook Inlet and the parent stocks of Arctic-Boreal species. Specimens of Bryozoa were re-examined as part of an evaluation of disjunct Arctic fauna in Cook Inlet. Forty-six specimens of Bryozoa, collected by Dennis Lee, as part of intertidal and nearshore surveys, were considered. Of the Bryozoa first reported, twenty species were re-identified, and 33 additional species were added to the list. Fifty-four species, including 4 Cyclostomatida, 7 Cladocelida, and 43 Cheilostomatida, were identified from these samples. Thirty-four species have a Boreal-Arctic distribution, found in the seas surrounding the Arctic Ocean.
Nineteen species have a lower latitude Pacific Boreal distribution. Species from the western and northern Boreal, Cook Inlet have a distinct Arctic -Boreal affiliation, and differ distinctly from those on the east side of the inlet.

INFLUENCE OF THE CONGO AND NIGER RIVER PLUMES ON DISTRIBUTIONS OF FREE-LIVING AND SYMBIONT CYANOBACTERIA

The abundance of 4 diazotrophic populations was examined using a nifH gene quantita- tive polymerase chain reaction (QPCR) method. Samples were collected in the eastern equatorial Atlantic (EEA) during Summer 2007. Richelia associated with Hemiaulius hauckii diatoms was detected in all surface samples and highest abundances (>10^4 nifH copies L^-1) were found NW of the Congo River (CR) plume near the Niger River (NR).

In contrast, the Calothrix symbiont (het-3) of Chaetoceros had low abundances in the surface, but were 3.710^4 nifH copies L^-1 at 40m, in the Equatorial upwelling. This is the first report of the Calothrix symbiont in the Atlantic Ocean. Richelia associated with Rhizosolenia (het-1) were found in the Congo River plume and in the Equatorial upwelling. The highest densities of Trichodesmium spp. (>10^5 nifH copies L^-1) were found further east (>1500 km) of the CR influence. Thus the distribution of these various diazo- trophs, especially the 3 strains of symbiotic cyanobacteria were different, and appeared largely controlled by riverine inputs and upwelling.

VARIBLITY AND TRENDS IN OCEANIC OXYGEN: DETECTION AND ATTEIBUTION USING A COUPLED CARBON CYCLE - CLIMATE MODEL ENSEMBLE

Recent studies have reported substantial variations in oceanic oxygen over the last decades. Yet, the causes of these variations, natural or anthropogenic in origin, remain unresolved. We investigate oceanic oxygen variations along different sections in the North Atlantic and the North Pacific using a six-member ensemble from the NCM CSM1.4 carbon. We focus on the magnitude of natural variability in oxygen and its impact on the detection and attribution of seasonal to decadal-scale oxygen changes. Simulations including natural and anthropogenic radiative forcing result in a good representation of the mean present-day climate. The simulated oxygen inventory decreases with global warming mainly in the Pacific and Indian Ocean at shallow depth, and in the Atlantic at intermediate depth. Volcanic eruptions cause short-term cooling of the upper ocean and considerable increase in oxygen in the upper 500m. Simulated decadal variability compares well with recently observed changes in the North Atlantic, but the model appears to underestimate variability in the North Pacific. These observed changes in oxygen along the transects appear to rather be the result of natural internal variability than represent- ing long-term changes associated with climate change. Considerable natural variability in oxygen masks some of the simulated long term trends that are emerging in the 21st century projections, therefore complicating the detection of anthropogenic climate change using oceanic oxygen.

THE ROLE OF FRESHWATER ADVECTION, SUBPOLAR CIRCULATION AND ICE IN SPRING PHYTOPLANKTON BLOOMS IN THE LABRADOR SEA

The physical circulation exerts strong control on biological productivity. Across the high- temperate Atlantic, the seasonal cycle of phytoplankton is dominated by a rapid increase in productivity, the spring bloom. It results from the interplay between nutrients, light, mixing and grazing. However, light availability is not simply surface irradiance, but light per organism per day, which depends on stratification and ice cover. Climate impacts like warming and increased runoff affect the bloom, and through it, higher trophic levels. We investigate the variability in the Labrador Sea spring bloom using SeaWiFS chlorophyll-a, Seaglider data, sea surface height altimetry and ARGO data. Four distinct regions of pro- ductivity arise: (1) the central Labrador Sea, blooming late and weak, post deep convec- tion, (2) the West Greenland Current extension, blooming early and most intensely, due to offshore propagation of low salinity water and eddies, (3) the Hudson Bay outflow, with high annual productivity due to a source of nutrients and stratification, and (4) the Baffin Island Current, stratified by cold, fresh Arctic waters, but ice-covered for most of the year. With Sudervis's critical depth, we separate the effects of boundary current strength and other external processes on the bloom's interannual variability. The Labrador Sea bloom is contrasted with the Gulf of Maine and its relation withretreating ice-edges and topo- graphically bound surface fronts.

MODELING DOLLISHED OXYGEN IN A TIDAL FRESHWATER EMBAYMENT OF INVADE FLOATING VEGETATION WITH A HEAT BUDGET

We modeled the impact of the floating leaved plant, Trapa natans, on oxygen (DO) levels and biogeochemical cycles within a vegetated embayment and, through tidal exchange, the entire river ecosystem. Trapa reduced DO levels because oxygen production occurred primarily in the floating leaves whereas respiration occurred mainly subsurface in the top 1m of midsummer plant biomass, 20% of the 1.2-km wide embayment remained anoxic, while the rest received oxygenated water from the Hudson River main channel for a portion of each tidal cycle. Critical to our model was quantifying advection and dispersion of oxygen- saturated water across the embayment and net exchange between the embayment and river. We constrained the hydrodynamic components of our model with a heat budget, which was possible because the canopy shaded and thus cooled the marsh by up to 4°C. The heat budget was based on five months of continuous, high-frequency temperature and water elevation data collected throughout the embayment and air-bay heat exchange measured from a floating micrometeorological station. Met data included net radiation and eddy covariance sensible and latent heat fluxes.
study we attempt to tease out the biological factors, such as relationships between specific microorganisms and different physiographic species, which influence overall community patterns, in concert with the physical effects of the Columbia River Plume that inhibit or augment these biological interactions.

ON THE ACCURACY OF MODIS SEA SURFACE TEMPERATURE RETRIEVALS IN UPWELLING REGIONS

The measurement of SST by satellite-based infrared radiometry is a relatively mature subject and current uncertainties in the retrievals (bias errors of <0.2K with a scatter of 0.3-0.5K) approach those that are required for climate research. However, these estimates of accuracy are specified on a global basis and result from the application of global, empirically optimized atmospheric correction algorithms. There is evidence that the accuracy of the retrievals could be markedly improved by developing such algorithms with regional and temporal optimization, especially in situations, which are known to introduce larger errors into the current retrievals. One of these areas corresponds to upwelling regions, where anomalously large air-sea temperature differences exist and larger systematic errors in the SST retrievals can be expected. In this study we investigate the accuracy in SST retrievals in upwelling areas through the rigorous ship-based validation of the ocean surface and geophysical variables. Results from coastal and oceanic upwelling are presented.

INTEGRATION OF CURRENT-OFF-THE-SHELF (COTS) TECHNOLOGY INTO LOW COST COASTAL SENSING PLATFORMS

Real-time observation of near-shore, coastal environments has a variety of applications from science to educational outreach to environmental management. Sensors and networking capabilities have been developed, but their deployment is often hampered by the expense of the hardware, the initial installation, and the continued maintenance. We will present two novel instrument platforms with integrated telemetry and networking capabilities using readily available, low-cost components. The first platform is a swan-like data buoy designed with input from the students at the Pierce Middle School, and deployed in Turner’s Pond, Milton, Massachusetts to monitor water quality parameters in real-time. System design and analysis of environmental data were integrated into the seventh grade geometry curriculum (http://www.umb.edu/data/turndown.html). A second instrument package is a low-cost near-shore data buoy designed to monitor temperature at different depths in real-time and photysynthetically active radiation (PAR). Three such buoys were deployed in Nantucket harbor (http://www.umb.edu/data/nantucket.html) in support of an ongoing spot study by the local scallop fishermen. The data will be transmitted to a launchable platform, making XML-based web services and offered in a georeferenced graphical user interface (GUI).

SHIFTS IN THE ABUNDANCE OF AMMONIA-OXIDIZING ARCHAEA AND BACTERIA ACROSS ESTUARINE PHYSICAL/CHEMICAL GRADIENTS

Nitrification plays a critical biogeochemical role in coastal/estuarine systems. Despite its importance and free-stressing methods, it is not well understood how and why the system changes with the physical and chemical changes of the water column. In this study we report on the relative abundance of ammonia-oxidizing bacteria (AOB) and ammonia-oxidizing archaea (AOA) in freshwater and coastal systems and across different biotopes. The results of the present study indicate that the communities of AOB and AOA differ significantly in the same location and conditions of sampling. Our results suggest that these distinct flow branches and fronts may play a significant role in the ecology of a variety of commercial species, further suggesting the use of SST as a tool for fisheries management.

WAVE-CURRENT BOUNDARY LAYER INTERACTIONS

Wave-current bottom boundary interactions are examined using a quasi-three-dimensional non-hydrostatic numerical model, Dune. Dune resolves the Reynolds-Averaged Navier-Stokes (RANS) equations with one of several second-order closure schemes. The models are coupled with free-surface flows, and mean and low-frequency flows are prescribed at the bed. Dune’s unique structure allows for complex topography at a given angle. Dune simulations are compared to three applied engineer ing wave-current bottom boundary layer models (Grant-Madsen (1994), Soudby (1993), Styles-Glenn (2000)). Simulations are performed over both flat and rippled beds for wave-current angles ranging from 0 to 90 degrees and both free stream wave and mean velocities from 5 to 100 cm/s. The models are assessed with the non-dimensional mean bed stress, typically used to parameterize energy dissipation in circulation models, as well as the peak bed stress, used to quantify sediment transport. Dune predicts that an obliquely approaching current does not significantly impact the peak bed stress, but will affect the mean bed stress under large wave forcing. Predictions of the mean and peak bed stress by Dune and the engineering models are generally of comparable magnitude, with the exception of cases where the wave velocity is greater than the free stream velocity.

VISION IN THE DEEP

During research cruises funded by the NOAA Ocean Exploration Program (Operation Deep-Scope 2005 and 2007), novel collecting techniques were used to collect live deep-sea benthic crustaceans. Collections were made from the HBOI Johnson-Sea-Link (JSL) submersible under red and orange illumination, making it possible to collect animals without blinding them. Shipboard measurements of spectral sensitivity and temporal resolution were made from the photoreceptors of the anomuran crabs, Gastrocythus spinifer, Eumunida picta, Munidopsis tridentata, the brachyuran crab, Bathynectes longispina, the decapod shrimp, Eugonotopus crassus, and the isopod, Booralana tricarinata. The spectral sensitivity data indicate that all of these species have blue-sensitive visual pigments, but G. spinifer also appears to possess a UV sensitive visual pigment. The temporal resolution of all these eyes is quite low, indicating that these photoreceptors have a long integration time. The temporal resolution of B. tricarinata is so low that it is unlikely that this isopod could track any moving object. Rather, its photoreceptors appear to be designed for finding bioluminescence that glows rather than flashes, such as detritus covered with bioluminescent bacteria.

REGIONAL AND BASIN-SCALE ECOSYSTEM FLUCTUATIONS ASSOCIATED WITH THE NORTH PACIFIC GYRE OSCILLATION

The North Pacific Gyre Oscillation (NPGO) is defined as the second EOF/PC of sea-surface height anomaly. Decadal fluctuations in the NPGO are driven largely by variations in the surface wind stress. These variations control the strength and spatial patterns of upwelling and downwelling in the Northeast Pacific and beyond. Models and data from the California region show that changes in upwelling associated with the NPGO account for much of the decadal variability of nitrate and chlorophyll in the California Current eastern boundary system. Spatial and temporal variations in upwelling and nutrient fluxes exert a strong control over the size structure of the phytoplankton: higher nitrate fluxes lead to an increase in the total biomass, and an increase in the fraction of large plankton. Given the large-scale structure of the NPGO, we explore the evidence that these decadal fluctuations in upwelling and planktonic ecosystem structure in the Northeast Pacific are coherent with ecosystem fluctuations throughout the Pacific Ocean.

**Requires simultaneous measurement of physical and biological properties at high vertical resolution.**

Investigation of the relationship between thin plankton layers and their physical context is needed. Case studies featuring some of our most interesting and accomplished colleagues who are putting their Ph.D.s to work in extraordinary ways may surprise and inspire you.

**Using Optimal Multiparameter Analysis to Assess Mixed-Layer Iron Transport in Southern Drake Passage.**

Water mass distributions in the Shackleton Fracture Zone and the Ona Basin in Drake Passage are estimated on an isopycnal surface and in the mixed layer using Optimal Multiparameter (OMP) analysis of CTD and nutrient data. The OMP method is modified to account for non-conservation in the mixed layer by using estimated air-sea fluxes. For the most stations, the adjusted method shows improvement relative to the unadjusted case. The results suggest the presence of three distinct water masses. Water from the Antarctic Circumpolar Current (ACC) predominates off the shelf west of the ridge, as well as in the northern part of the region east of the ridge. Shelf waters from near the South Shetland Islands and the Weddell Sea are confined to the shelf west of the ridge, but spread off-shore to mix with the ACC downstream from the Shackleton Gap. These shelf waters deliver sedimentary iron off-shore and appear to play an important role in the high levels of phytoplankton productivity in the Ona Basin compared to the region upstream of the basin.

**Active Microbes in the Orinoco River Plume.**

In order to elucidate how physical/chemical gradients influence planktonic bacterial communities, a study of the Orinoco River Plume was initiated. The Orinoco plume forms an isolated surface layer with a sharp salinity gradient and high chl a signals extending thousands of kilometers into the Caribbean Basin. In October 2006, samples were collected from 12 stations at 4 depths along the plume axis and screened using ribosomal RNA genes by TRLFL. Both intact ribosomes and DNA (165 and 185) were analyzed to separate the active microbial community from the populations that were present but not growing. Initial comparison of 165 RNA fingerprints to their corresponding DNA fingerprints indicated between 58 and 70% of the population was active. Meanwhile, resident populations along the plume ranged in similarity from 56 to 61% in prokaryotes and 10 to 77% in eukaryotes. Additional effort in cloning/sequencing of samples is underway. It is hoped that by examining shifts in active microbes under dynamic conditions, our ability to understand the forces driving marine microbial diversity and how microbial community structure relates to function will be enhanced.

**Autonomous Investigation of Thin Phytoplankton Layers and Their Physical Context.**

Investigation of the relationship between thin plankton layers and their physical context requires simultaneous measurement of physical and biological properties at high vertical resolution, over large horizontal areas, and for extended periods of time. We report here on hydrographic profiles collected in Monterey Bay during the summers of 2003-2006 using fleets of high-endurance autonomous gliders. These measurements (physical, optical, and many of the chemical highlight variables) were taken in concert with optical sensors deployed at several kilometers, and vertical scales from centimeters to a few meters. We use synoptic horizontal maps, vertical sections, and statistics derived from nearly 50,000 multivariate water column profiles to characterize the vertical structure, spatial distribution, and temporal variability of thin phytoplankton layers.

**The North Atlantic Shelfbreak Current: An Adveective Link For Climate Variability.**

The North Atlantic shelfbreak front and jet form an extensive connected system that extends many thousands of kilometers, establishing an adveective link between the subarctic and subtropical domains. Through this pathway, the shelfbreak current transports high-latitude climate-driven variability equatorward. However, because the front acts as a barrier that inhibits cross-shelf exchange, it is not clear exactly how these signals are communicated to the interior of the Atlantic where they might have an impact on the larger climate system. Recent studies suggest that there are select geographical regions along the path of the current where mass and freshwater are lost, however little direct evidence of these pathways exists. In this study, 100 years of historical hydrographic data are used to investigate the role of the shelfbreak current in the propagation of climate signals, focusing on how and where such anomalies leave the boundary. Particular focus is placed on the current branching that occurs at the Tail of the Grand Banks of Newfoundland.

**Phytoplankton and Zooplankton Dynamics in a Buoyant River Plume.**

Rivers flowing through urban watersheds represent a major conduit of anthropogenic nutrients and contaminants. The fate of these materials is controlled, in large part, by physical dynamics as the buoyant, riverine plume moves over the coastal shelf and also by associated chemical and biological processes. During the Lagrangian Transport and Transformation Experiment (LaTTE) of April 2005, nutrient-laden water from the Hudson River was recirculated in a nearshore eddy before propagating seaward to mix with relatively saline water along the New Jersey coast. Within the eddy, phytoplankton rapidly assimilated nutrients resulting in extremely high rates of productivity (> 10 mg C m-3 h-1), with approximately 75% of carbon fixation ultimately attributed to large chain-forming diatoms (200 microns). Analysis of the phytoplankton community indicated a change in taxonomic composition and a downward shift in the size frequency distribution as recirculated, plume water became entrained in the southward flowing coastal current. There was a disproportionate accumulation of trace metals in the smaller phytoplankton size classes. Size-specific and taxon-specific microzooplankton grazing rates highlighted specific biological interactions with consequences for metal accumulation in the food web.

**The Fate of New Nitrogen Prior to and During a Trichocephusium Thiebaudii Bloom in the Subtropical Waters of the SW Pacific.**

It is well established that diazotrophs such as Trichodesmium species are an important source of new nitrogen to surface waters in the low latitude ocean. Evidence from stable isotopes of nitrogen suggests that the diazotrophic activity during the bloom of Trichodesmium is a major source of new nitrogen to surface waters in the low latitude ocean. Stable isotopes signatures point to the eventual conversion of a significant proportion of this new nitrogen to nitrate over longer timescales (years to decades). Although both laboratory culture and field experiments have revealed that there is considerable release of nitrogen, fixed by Trichocephusium, as dissolved forms including DON and ammonium, few studies have examined its short-term (days) fate. Here, we report the findings of two experiments, one prior to and the other during a bloom of nitrogen fixers in the subtropical LNLC waters north of New Zealand, in which the fate of diazotrophic-fixed nitrogen was tracked, using a range of approaches, through the pelagic ecosystem.

INFLUENCE OF COASTAL WAVE FIELD DEVELOPMENT ON ATMOSPHERIC DRAG
Air-sea momentum flux data were collected at the Field Research Facility pier of the US Army Corps of Engineers located in Duck, NC. The pier extends 560 m into the New Atlantic Ocean and is an ideal platform for both atmospheric and oceanographic measurements. Two sets of momentum flux instrumentation, including sonic anemometers and humidity sensors, were mounted at different heights and locations at the end of the pier. The directional wave field was measured by a nearby pressure gauge array in 8 meters water depth. Drag coefficients are inspected to determine deviations from open ocean parameterizations. In addition, drag coefficient dependence of wind speed, stability, and coastal wave field during high wind events are investigated. Wave influences are studied by isolating individual wind-sea and swell components and correlating drag features with wave field characteristics. The primary objective of this effort is to identify the critical factors influencing coastal wind drag.

DOES THE FALL PHYTOPLANKTON BLOOM CONTROL RECRUITMENT OF GEORGES BANK HADDOCK, MELANOGRAMMUS AEGLEFINUS, THROUGH PARENTAL CONDITION? In 2003, the Georges Bank stock of haddock experienced the largest recruitment event recorded during its assessed history. Several hypotheses have been advanced to explain recruitment variability in this much scrutinized stock including variability in the retention of eggs and larvae on Georges Bank, the timing of haddock spawning, and variability in the spring bloom, which influences larval growth and survival. Although these processes may contribute to the formation of successful year classes, none of the factors associated with these previous hypotheses provides an adequate explanation of the 2003 recruitment event. We analyzed data on the dynamics of the fall phytoplankton bloom the year prior to spawning and showed it to be highly correlated with subsequent recruitment. We suggest that the fall bloom affects recruitment through enhanced condition of adults and by increasing the quantity and quality of their reproductive output, which leads to a higher probability of survival of their offspring. Although synthetic data on the fall bloom are limited and our analyses are correlative, our purpose is to stimulate a rigorous test of this promising parental condition hypothesis.

SATELLITE-BASED BASINWIDE ESTIMATES OF SURFACE PCO2 IN THE NORTH ATLANTIC : A METHODOLOGICAL STUDY
A high resolution coupled-ecosystem model of the North Atlantic is used to simulate VOS-line floats and the relative sensitivity of PCO2 related parameters such as SST and Chlorophyll. We examine the quality of Neural-network (Kohonen Feature Map) based basin-scale mapping of PCO2 with regard to VOS-line and float coverage, remote sensing errors and the interpolation of missing data due to clouds. For a sampling corresponding to 2005 VOS-lines and cloud patterns, the neural net can reproduce PCO2 from remotely sensed SST and Chl with a basin-wide RMS-error of 11.9 ppm for a non-clouds scenario and 14.5 ppm when climatological surface temperature and chlorophyll values are used to fill in areas covered by clouds.

MUDRED: MULTI-DISCIPLINARY BENTHIC EXCHANGE DYNAMICS Controls on seabed erodibility and suspended particle properties are the two largest unknowns limiting accurate prediction of fine sediment transport in muddy coastal environments. These two parameters are difficult to predict in large part because biological effects fundamentally impact them over short temporal and spatial scales. The MUDRED study, funded by the NSF CoOP Program, is placing real-time observing platforms at locations of contrasting intensities of sediment transport and benthic biological activity within the York River estuary. Virginia, in order to gain insight into biological and physical controls on seabed erodibility and suspended particle properties. A combination of acoustics and video imaging of the sealed and lower water column, along with rapid-response and ground-truthing via direct sampling, are being used to identify changes in biologic activity, deposition, erosion, suspended sediment properties and bedform evolution that, in turn, trigger or otherwise indicate changes in bed erodibility. Open source numerical modeling of water column processes, erosion and deposition, and sealed evolution are being coupled to the observing effort with the goal of fundamentally advancing the predictability of fine sediment transport.

ASSESSING THE SKILL OF MARINE BIOGEOCHEMICAL MODELS THROUGH DATA ASSIMILATION Application of biogeochemical models to the study of marine ecosystems is pervasive; yet objective quantification of these models/performance is rare. One strategy for assessing and comparing the skill of these types of models involves the implementation of the variational adjoint method of data assimilation. Using this technique, data such as chlorophyll-a, nitrate, export and primary productivity are assimilated into biogeochemical models, and key biogeochemical rate parameters, such as growth, grazing, mortality and remineralization rates, are objectively optimized. By running multiple lower trophic level models in identical 1-D physical frameworks and optimizing each to the same degree, it is possible to quantitatively assess and compare the relative skill of these various models. Here cross validation experiments are used to assess the skill of marine biogeochemical models characterized by varying levels of ecosystem complexity in multiple pelagic regimes. Emphasis is placed on identifying why certain models and model formulations are best at the fit available observations.

DETECTION AND DISCOVERY OF CRUSTACEAN PARASITES BY 185 RNA TARGETED DENATUREN HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (DHPLC)
The significance of parasitism and disease in nature is broadly recognized, however, methodological limitations have hindered the exploration of the ecological significance of parasitism in most natural environments. In this study we present the development of a new PCR-based approach for parasite detection and discovery utilizing Denaturing High Performance Liquid Chromatography (DHPLC) technology. As a model, a DHPLC assay to detect protozoan parasites of the blue crab (Callinectes sapidus) was developed. Evaluation of 76 crabs caught in Wassaw Sound Georgia (USA) indicated a 97% correspondence between parasite detection by standard PCR and DHPLC. During these studies we discovered one crab infected by a kinetoplastid parasite. Phylogenetic analysis of the parasite indicated that it is most closely related to the free-living cryptobid, Procryptobia sorokini. Kinetoplastid parasites are well-known parasites of vertebrates, but to our knowledge this is the first report of this organism in a decapod crab and of P. sorokini exhibiting a parasitic life history. The availability of novel and robust DHPLC technology, we predict, will herald a new era in the study of parasitic and trophic interactions in nature.

THE INTERACTION BETWEEN PHYTOPLANKTON, ICE, ICE ALGAE AND KRILL (PIKA) MODELING WINTER ICE ALGAL BIOMASS IN RELATION TO SEA ICE AND PHYTOPLANKTON DYNAMICS
The role of sea ice microbial communities (SIMCO) in supporting krill energetics during their furculia/irrivalle stages is recognized. However, specific information relating SIMCO biomass with krill feeding, growth, survival and recruitment over winter seasons is lacking. We are presently evaluating the dynamic interactions between phytoplankton...
Reviewing the impact of space-time-lagged correlation in SSH anomalies from merged altimeter data, the presence of more than one satellite altimeter simultaneously in the past 15 years has been crucial. Recent studies, such as the work by Fu, L. L., have described the new ZPulse technique and gone through deployment results. The technique reduces ping number by 50% when using two frequencies, thereby decreasing the time required for deployment and reducing the potential for marine growth.

Major advantages of the Doppler principle are accuracy, low or absent calibration drift, and low or absent drift from marine growth. The technique can provide high-resolution data even in areas with low visibility, making it suitable for monitoring the dynamics of the ocean's response to external forcing. The prospects of a wide-s swath altimeter based on radar interferometry for studying the ocean variability are promising.

Understanding the spatial distribution of such planktonic size structure in the Eastern Tropical Pacific can provide insights into the potential carbon sequestration along the ORP. Observations suggest that internal ocean dynamics can convey to the Southern Ocean a perturbation induced by surface buoyancy change restricted to the Northern Hemisphere or just to the North Atlantic sector. Specifical y, while keeping the surface conditions in the Southern Hemisphere fixed, a hypothetical northern hemisphere surface warming induces the weakening of the deep AMOC that causes an increase of the ACC transport and the Southern Ocean overturning circulation. A change of the Atlantic Meridional Overturning Circulation (AMOC) on multidecadal and centennial time scales has a potential to significantly modify the intensity of the Antarctic Circumpolar Current (ACC) and the Southern Ocean overturning circulation with a substantial climate impact. In the ocean, the AMOC transports freshwater to the Southern Ocean, and its interbasin exchange and ventilation rates in the Southern Ocean therefore modify the ocean's role in climate dynamics. The result is present in both single- and two- basin configurations containing a circumpolar channel in the Southern Hemisphere, and robust to variations in vertical mixing and parameterization of mesoscale eddies.

The planktonic biomass size structure of tropical and subtropical oceans has been studied to exert significant control on the ocean's atmospheric carbon sequestering potential. Understanding the spatial distribution of such planktonic size structure in the Eastern Caribbean waters, under the influence of the Orinoco River Plume (ORP), may provide further insight on the role of the latter in carbon sequestration. Phytoplankton and zooplankton biomass, size structure and taxonomic composition were estimated in the ORP, and the results suggest that the planktonic community structure and planktonic biomass size structure are influenced by the ORP. Planktonic biomass size structure and taxonomic composition were estimated in the ORP, and the results suggest that the planktonic community structure and planktonic biomass size structure are influenced by the ORP.

Caloosahatchee responds rapidly to hydrodynamic forcing over timescales from a tidal cycle to few weeks. Along the estuary, DO levels vary dramatically and are associated with the rapidly moving ETM. Chlorophyll concentration, a proxy for phytoplankton density, is associated with along estuary variations in hydrodynamic forcing. The data also predict the level of heavy freshwater discharges that can completely flush the ETM out of the river and introduce large pulses of suspended sediment into the adjoining San Carlos Bay.

THE VALUE OF ADDING OPTICS TO ECOSYSTEM MODELS: A CASE STUDY
Optical processes have been incorporated into an ecosystem model for the equatorial Pacific region. The bio-optical model is able to reproduce many measured optical properties and key biogeochemical processes in the region. In order to achieve such good agreement between data and model results, however, key model parameters, for which no field measurements are available, have to be constrained. Coupling explicit optics to ecosystem models provides advantages in generating: (1) a more accurate subsurface light field—which is important for light regulation on biogeochemical processes, (2) additional constraints on model parameters that help to reduce uncertainties in ecosystem model simulations, and (3) model results which are comparable to basic remotely-sensed properties. Sensitivity analysis of the model results to optical parameters reveals a significant role played by colored dissolved organic matter through its influence on the quantity and quality of the ambient light. In addition, the coupling of biogeochemical models and optics paves the road for future assimilation of ocean color and in-situ measured optical properties into the models.

SALINITY VARIABILITY IN THE TROPICAL AND SUBTROPICAL PACIFIC IN THE MIR MULTIVARIATE OCEAN VARIATIONAL ESTIMATION (MOVE) SYSTEM
Multivariate Ocean Variational Estimation (MOVE) System is an ocean data assimilation system developed in Meteorological Research Institute (MRI). MOVE system adopts a 3DVAR scheme for coupled Temperature-Salinity (T-S) Empirical Orthogonal Function (EOF) modes, and can therefore estimate salinity variability from temperature and satellite altimetry observations through coupled T-S variability even when there is no salinity data. This scheme appropriately reproduces the variability of the subsurface high salinity maximum in the equatorial Pacific (i.e., South Pacific Tropical Water: SPTW), although some research report that this maximum is analyzed much lower in the conventional analysis scheme in which the model salinity field is not corrected with the result of objective analysis with observation data. In the system, the amount of SPTW oscillated according to ENSO cycles. The analysis of salinity budget shows that the oscillation is caused by the change of the easterly trade wind and the equatorial upwelling. Relationships between near-surface heat content and the thickness of the barrier layer is also, clearly reproduced in MOVE System.

MECHANISMS OF MIXED-LAYER TEMPERATURE BALANCE IN THE NINO3 AREA ON ANNUAL TO INTERANNUAL SCALES
The mixed-layer temperature (MLT) in the eastern equatorial Pacific Ocean is studied using an ocean data assimilation product for the period from 1993 to 2003. We focus on the mechanisms of the large-scale changes over the NINO3 area (150°W, 90°W, 5°S-5°N). We especially elucidate the role of advection by explicitly evaluating it with the assimilation product. The seasonal cycle of advection is that the zonal, meridional, and vertical advection cool the area due to the large-scale inflow of cold water from surroundings. On interannual scales, the meridional advection tendency is dominated by the variations in the Ekmans advection through the meridional boundaries of the NINO3 domain. The zonal advection tendency is one of the dominant terms in the NINO3 MLT balance during the 1997-98 El Nino. The three advective contributions are governed by the large-scale circulation associated with large-scale wind forcing rather than eddies. On interannual scales, the three advective contributions are in phase with NINO3 MLT change. The signs and strengths of the advective contributions differ from the balance analyzed at point-locations (and from the spatial average of them).

EFFECTS OF THE COLUMBIA RIVER PLUME ON THE DYNAMICS OF UPWELLING OFF OREGON
The Regional Ocean Modeling System (ROMS) has been utilized to study the effects of the plume from the Columbia River (CR) on the dynamics of upwelling south of the river mouth over the Oregon shelf, where the river water is advected with a coastal current. The study period is summer 2001, for which observations from the COAST and GLOBEC programs are available to verify the model, including shelf mooring observations and hydrographic sections. Effects of the CR are analyzed by comparing simulations with and without CR. The depth of the surface boundary layer (SBL) and the level of turbulent kinetic energy in the SBL are influenced by both the enhanced vertical stratification and increased vertical shear in the horizontal velocity, which is related to the plume-induced horizontal gradient of density. Within the plume, the Ekman transport is distributed in a thinner SBL, resulting in larger surface cross-shore velocities. Analyses in an idealized alongshore-uniform configuration show that if the plume is attached to the coast, upwelling is concentrated closer to the coast than in the case without the fresh water layer.

HOT FLASHES AND DYNAMIC LANDSCAPES - TRACKING THE FATE OF NITROGEN THROUGH SPACE AND TIME IN A DELTAIC COAST
The fluxes of dissolved inorganic nitrogen and dinitrogen gas have been measured in a variety of environments along the Mississippi River deltaic coast of Louisiana. Previous work has shown that benthic mineralization could contribute approximately 40% of the nitrogen needed by phytoplankton in the Louisiana shelf system; and a significant portion of river nitrate can be transformed in shallow coastal bays and wetlands. Now, almost two decades later we are re-examining the fate of nitrogen in this ecosystem with an emphasis on the role of dinitrogen gas. A historical analysis of wetland, sub-tidal, shallow coastal bay, deltaic, and river plume benthic nutrient and dinitrogen gas fluxes will be compared with recent measurements in these environments. Particular attention will be paid to highlighting spatial and temporal patterns of intense nitrogen cycling (hot spots and hot moments). These modified budgets of benthic fluxes will evaluate the importance of benthic remineralized nitrogen in stimulating water column productivity in this deltaic coastal system.

GLOBAL MAPPING OF WIND-INDUCED INTERNAL WAVE ENERGY IN THE DEEP OCEAN
The distribution of wind-induced internal wave energy in the world’s oceans is investigated using a full three-dimensional primitive equation model. The model is driven by JRA-25 winds for 1 year; although wave-mean flow interactions as well as wave-wave interactions are both not taken into account. Emphasis is placed on the global energy input to the surface mixed layer and the downward energy propagation into the deep ocean. We find that the distribution of near-inertial energy in the mixed layer agrees with that from the slab model, and the depth-integrated equatorward energy fluxes of internal waves are consistent with the observations. It is also found that most of the wind-induced energy resides in high vertical modes, 70-80 % of which is dissipated in the upper 150 m. This implies that the contributions of wind-induced internal waves to deep ocean mixing is much less than previously expected.

SPATIAL AND TEMPORAL GENETIC CONNECTIVITY OF A DEEP-SEA HYDROTHERMAL VENT SIBOGLINID TUBEWORM, RIFTIA PACHYPTILA
The decoupled nature of hydrothermal vent systems from processes at the sea surface suggests that observed patterns of connectivity are determined in part by processes outside of the influence. Nevertheless, processes at deep-sea hydrothermal vents on fast-spreading mid-ocean ridges are punctuated by frequent physical “disturbance” often accompanied by population turnover. Despite local extinction events, larval dispersal among disjunct vent sites facilitates the persistence of sessile invertebrate species in these geologically and chemically dynamic habitats. Regional population extension and rapid recolonization by the siboglinid tubeworm, Riftia pachyptila, have been well documented along the East Pacific Rise and the Galapagos Rift. In order to resolve patterns of population connectivity in time and space, eight microsatellites were used to assess the genetic structure of the East Pacific Rise and the Galapagos Rift. In order to resolve patterns of population connectivity in time and space, eight microsatellites were used to assess the genetic structure of the
infrastructure programs such as the International Ocean Drilling Program and the Ocean success rate for NSF proposals has dropped from 30% to 20% over the past six years. Major changes have occurred in the funding of ocean research and education. The

LONG-TERM PHYTOPLANKTON DYNAMICS IN THE RHODE RIVER, MARYLAND (USA)

Studies of phytoplankton biomass in the Rhode River, a mesohaline tributary of Chesapeake Bay, date back to the early 1970's. More recent studies include phytoplankton species identifications, light saturation curves, and nutrient concentrations. For some parameters, such as light-saturated photosynthetic rate normalized to chlorophyll, inter-annual differences are as large as seasonal differences. The main factor governing interannual variability in planktonic productivity is the presence or absence of extraordinary spring blooms of the dinoflagellate, Prorocentrum minimum. In years with extraordinary blooms, primary production peaks in spring with the high biomass of P. minimum, in contrast with the main stem Chesapeake Bay, where primary productivity always peaks in summer. Long-term trends in summertime phytoplankton chlorophyll have not been observed, though temporary directional trends related to precipitation patterns have sometimes persisted for a decade before reversing. Currently there appear to be a trend toward reduced water clarity and increased chlorophyll during winter, though the cause is not presently known. These observations underscore the need for multi-decadal observations to document trends and anthropogenic impacts in coastal systems.

ZONOSTROPHIC TURBULENCE: A PARADIGM OF ZONATION IN THE EARTHS OCEANS AND ON GIANT PLANETS

The regime of zonostrophic turbulence is a subset of geostrophic turbulence with a small-scale forcing and is distinguished by a strongly anisotropic internal energy cascade and zonation, i.e., the emergence of stable systems of alternating zonal jets. Being discovered in barotropic flows, this regime can also develop in the barotropic mode of fully three-dimensional baroclinic flows. This regime can explain the physics behind the generation and maintenance of the zonal jets in the terrestrial oceans and on solar giant planets. By analyzing the spectral energy transfer it will be shown that anisotropization and zonation are intrinsic properties of zonostrophic turbulence. Consideration of the energy and enstrophy spectra and corresponding spectral transfers sheds light on many aspects of this strongly anisotropic and complicated flow regime. Using spectral analysis in the frequency domain, we shall classify different kinds of waves inherent in zonostrophic turbulence, their interactions amongst themselves and with turbulence. This interaction can be described neither within a theory of weakly anisotropic nor wave turbulence. We shall identify a parameter space conducive to the development of the regime of zonostrophic turbulence and outline some basic features of the horizontal diffusion characteristic of this regime.

EXTREME BURIAL EFFICIENCY OF TERRESTRIAL CARBON IN THE HIMALAYAN SYSTEM

The Himalayan erosion generates one of the largest sediment flux to the ocean. Each year, 1 to 2 billion tons of sediments are exported by the Ganga-Brahmaputra (G-B) fluvial system and delivered to the Bengal fan turbiditic system. The corresponding terrestrial organic carbon (Corg) flux represents 10 to 20 percent of the global burial flux and must have a significant impact on the global C cycle. A comprehensive Corg budget including Himalayan source rocks, G-B fluvial sediments and Bengal fan oceanic sediments shows that terrestrial Corg burial efficiency is almost complete. This contrasts strongly with other deltaic systems, such as the Amazon, where up to 70 percent of terrestrial Corg is oxidised prior to burial. In the Himalayan system, extreme Corg burial efficiency is sustained by intense physical erosion of the Himalayan range producing high sedimentation rates and low O2 availability in the Bay of Bengal. Enhanced physical erosion of active orogenic systems therefore favours有助periodic Corg burial that buffers atmospheric CO2 thereby exerting a negative feedback on the long term climate.

TOPOGRAPHICALLY INDUCED UPWELLING INTENSIFICATION OVER THE SHELF IN THE NORTHERN SOUTH CHINA SEA

The processes and forcing mechanisms governing the intensification of upwelling (IOU) in the northeastern South China Sea (NCS) are investigated by observational and a three-dimensional modeling studies. The prevailing IOU in the NCS occurs over a distinctly eastward widened shelf (EWS) where the shelf topography veers abruptly offshore. The IOU is formed by an intensified upslope advection of dense deep waters that crosses the mid shelf over the EWS toward the inner shelf. The advection is amplified by the converging isobaths of shoreline convex isobaths (SCI) at the head of the EWS over the mid shelf and by the coastline and near-shore topography at the lee of the coastal cape over the inner shelf. The strong shoreward cross-isobath transport over the mid shelf of the EWS is formed by a westward-along-isobath pressure gradient force (PGF) as a result of the net rate of the momentum influx over the converging isobaths of the EWS, and by an intense bottom frictional transport induced by the momentum contributions near the SCI. The transport is subsequently advected toward the inner shelf where the PGF, formed by the variable coastline and the near-shore bottom topography, regulates upward motion over the inner shelf. These quasi-barotropic pressure gradients geostrophically alter cross-shelf transport in the interior and in the boundary layers. The study demonstrates the interactive effect of topographically induced cross-isobath transport over the inner and mid shelves.

THE APPLICATION OF AN OPERATIONAL CIRCULATION MODELING SYSTEM TO THE MID-ATLANTIC REGION

The basic elements of a prototype operational data assimilation modeling system employing the Harvard Ocean Prediction System model includes protocols for (1) the production of model initial fields from an objective blending of climatological and feature model hydrographic data with Slocum glider temperature data, (2) the “warm start” of the model to provide a realistically initial model fields; (3) converting the initial model fields into forecast wind and/or operational wind measurements to model wind stress forcing fields; and (4) the assimilation of satellite-derived sea surface and glider-derived temperatures. These protocols are shown herein to evolve the initial model fields, which were dominated by climatological data, toward more dynamically balanced, realistic fields. This data assimilation model system was applied to the Cape Cod to New Jersey segment of the Mid-Atlantic Coastal Ocean System (MACOOS) domain using satellite SST temperature measurements from the first glider transit from Massachusetts to New Jersey in March 2007, 28 day trip. The model system was applied to the winter-like conditions of March-April 2007. The model/ CODAR-derived observed surface current comparisons will be presented.

EXTENSIVE NITROGEN LOSS FROM PERMEABLE INTERTIDAL WADDEN SEA SEDIMENTS

Sandy sediments dominate the intertidal region of the Wadden Sea but, so far, little is known about their role in the coastal N-cycle. We investigated the potential N-loss rates along a coastal transect from the Netherlands to Germany by using a modified whole core incubation technique. In view of the high permeability and strong pore water advection in these sediments, the percolation method better represents the in situ conditions and we observed high rates of N-loss, ranging from 3.2 to 21.2 mmol N m-2 d-1 at all investigated sites. Denitrification was identified as the main N-loss process with less than 13% being attributable to anaerobic ammonium oxidation (anammox). Denitrification rates in Janssland, as a typical research site of the Wadden Sea, varied across the sand flats, with rates near the low-water line exceeding those of the middle and upper flat. In contrast to the conventional views, our preliminary results indicate that permeable sediments could play a significant role in N-removal from the shelf environments, which account for 50-70% of oceanic N-loss.

utilizing voltage measurements on a submarine cable to estimate Florida current transport operationally: A real-time observing system

Submarine cable measurements have been used since 1982 to monitor changes in the Florida Current transport at 27°N. For most of the first twenty years of this well-known NOAA project the data was collected in a research mode, and was only made available for outside scientific analysis years after it was collected. Recently this program, presently in the Western Boundary Time Series project, has sought to transition the collection and processing of the voltage data from research mode into a real-time operational mode. This transition has led to some important changes in the processing methodology for the voltage data. Details of the removal of tide and magnetic field fluctuations will be presented and discussed in the context of other geomagnetic data sets. Calibration of the cable voltages into volume transport is done via comparison with ship section data collected in the same area. Submarine cables provide new tools for managers to cope with climate change.

Garcia, S.

BIOGEOGRAPHY AND PATHOGENICITY

Labyrinthula has been described as an agent involved in seagrass mass-mortality events during episodes of high salinity, temperature, and siltate porewater concentration. However, Labyrinthula also has been found widely in healthy seagrass beds, although there has been no systematic study of biogeographical distribution of the organism. Thus, the distribution and pathogenicity of Labyrinthula in the Mediterranean is unknown, preventing an evaluation of the potential role of this agent in the widespread decline of Posidonia oceanica is experiencing in the Mediterranean. In this study, we assessed the distribution of Labyrinthula in seagrass meadows of the Balearic Islands, and tested the pathogenicity of the isolates on seagrass species from the Mediterranean (Posidonia oceanica, Zostera noltii and Cymodocea nodosa), the temperate Atlantic (Zostera marina), and the Gulf of Mexico (Thalassia testudinum). The pathogenicity of isolates was tested through cross infection experiments on healthy shoots of these five seagrass species. The results show a widespread distribution of Labyrinthula in the Balearic Sea and some isolates being able to infect most seagrasses tested.

EVALUATION OF GROUNDWATER DISCHARGE INTO A KARSTIC COVE IN THE WESTERN MEDITERRANEAN SEA USING RA ISOTOPES

Many karstic Mediterranean islands have limited water reserves that are intensively exploited by the demographic and tourism pressure. In Minorca (Balearic Islands, Spain), the most important aquifer is highly eorostilized by karstification processes, with springs visibly discharging in some coastal areas, such as the Akuafar cove. Concentrations of radium isotopes (226Ra, 228Ra and 222Rn) were determined in water samples from the cove, sea, submarine springs and wells. The relationship between Ra and salinity points out an evident mixing process occurring between springs and seawater endmembers. Two detectable groundwater flows out through the sea bed. Ra mass balances of the four radium isotopes provided very comparable estimates of the groundwater fraction in cove waters, averaging 17 ± 4 %. Taking the Ra-derived residence time for cove waters of 1.6 days, a submarine groundwater discharge (SGD) flux of 2–105 m³ s⁻¹ was estimated. When extrapolating this groundwater flow to the entire karstic coastline of the island, a total SGD of approx. 4 × 10⁷ m³ s⁻¹ was estimated, in good agreement with estimations derived from hydrological balances.

REEF TRACT: SPATIAL VARIABILITY IN CORAL BLEACHING AND DISEASE

KRAMER, P.

Significant spatial and temporal variation in bleaching and disease prevalence has been correlated to thermal stress, light, and bleaching history. While the exact causes of this variability remain poorly quantified, the underlying predictability of this variability itself may provide new tools for managers to cope with climate change.

QUANTIFICATION OF OIL SEEPS IN THE NORTHERN GULF OF MEXICO BY SATELLITE REMOTE SENSING

Satellite Synthetic Aperture Radar (SAR) has proven to be a successful tool for identifying ocean features. Natural oil seeps can be detected as elongated, radar-dark “slacks” in SAR images. Use of SAR images for seep detection is enhanced by a supervised texture reaction filter classifier algorithm, which delineates areas where layers of floating oil spread and reduces scattering. The effect is strongly influenced by wind strength and sea state. Statistical analysis of multiple images is used to partition variation in discharge from environmental effects. The goals of the analysis are to determine the following: 1) total number of individual seeps, 2) their geographic location and association with geological features, and 3) the temporal variability of discharge from individual seeps. Analysis of 176 images from Radarsat-1 in Standard and Wide Beam Mode covering Green Canyon areas from 1997 to 2007 are underway. Preliminary results show persistent seepage from many tens of discrete locations. Numerous of the identified seeps correspond to locations of known geophysical anomalies and/or chemosynthetic communities. Others remain un-explored. Temporal comparisons indicate episodic variation in the discharge rate of individual seeps.

THE EFFECTS OF TURBULENCE ON LARVAE OF THE WHITE SEA URCHIN

Marine invertebrates commonly have a planktonic larval stage that is important for dispersal. Dispersal depends on planktonic predator interaction in larvae that affects food availability. Fluid turbulence is considered to play an important role in planktonic predation behavior. The purpose of this experiment is to determine whether turbulence affects grazing, morphology, and development of larvae of the white sea urchin Lytechinus pictus. The hypothesis is that low levels of turbulence, which theoretically increase rates of encounters between predator and prey, leads to increased grazing and ingestion. We predict that due to increased ingestion, larvae in the turbulence treatment will change their morphology and develop faster compared to larvae in still controls. The methods involve exposure of larvae to turbulence using simple Couette flow, and calculation of ingestion rates based on changes in cell concentration of the algae Rhodomonas lens. Larval growth and development will be determined by measuring post-oral arm, midline, stomach and horizontal rod lengths. Results will indicate whether low levels of turbulence lead to increased ingestion, grazing, and development of L. pictus larvae. In conclusion, turbulence may be an important environmental factor that can affect development and dispersal of sea urchin larvae.

UTILIZING VOLTAGE MEASUREMENTS ON A SUBMARINE CABLE TO ESTIMATE FLORIDA CURRENT TRANSPORT OPERATIONALLY: A REAL-TIME OBSERVING SYSTEM

Submarine cable measurements have been used since 1982 to monitor changes in the Florida Current transport at 27°N. For most of the first twenty years of this well-known NOAA project the data was collected in a research mode, and was only made available for outside scientific analysis years after it was collected. Recently this program, presently in the Western Boundary Time Series project, has sought to transition the collection and processing of the voltage data from research mode into a real-time operational mode. This transition has led to some important changes in the processing methodology for the voltage data. Details of the removal of tide and magnetic field fluctuations will be presented and discussed in the context of other geomagnetic data sets. Calibration of the cable voltages into volume transport is done via comparison with ship section data collected using a droopsonde float, which is a free-falling float that carries a GPS receiver. The methods of processing and tide correction for the droopsonde float observations, and the error estimates inherent to the droopsonde system, will also be presented.
High resolution, four-dimensional measurements in and below the Mississippi River plume were conducted in August 2007 utilizing the Unmanned Boston ECOShuttle, a small, undulating vehicle providing in situ measurements and a continuous pumped flow of uncontaminated seawater. This survey revealed the presence of subsurface layers with elevated concentrations of colored dissolved organic matter (CDOM) relative to the regional CDOM-salinity mixing curve. In some, but not all, cases these layers coincided with subsurface chlorophyll maxima. The layers will be characterized by its situ fluorescence, temperature, salinity and optical backscatter data. An AC-9 (Wet Labs, Inc.) absorption/attenuation instrument plunged into the water flow will provide additional insight into the nature of the CDOM maxima. Discrete samples obtained from the flow allow verification of the in situ measurements as well as determination of the relationships between CDOM fluorescence and dissolved organic carbon (DOC). The relationship between the distribution of these subsurface layers and the Mississippi Canyon as well as the movement of these layers over time will be discussed.

SOURCEnE CURRENT MAPPING PRODUCTS TARGETED FOR TWO EVENTS IN THE GULF OF THE FARALLONES

The California Coastal Ocean Currents Monitoring Program (COCMP) responded with targeted products to two events in the Gulf of the Farallones since the systems were installed in late July of 2006. These are the NOAA sponsored SeaSonde’06 (SSS06), a simulated oil spill drill off the Golden Gate in August 2006, and then in October 2007 monitoring the potential plume from the San Francisco Public Utilities Commission sewage outfall off Ocean Beach after the failure of the discharge pipe endcap. For each of these events, the COCMP team produced different products to assist the regulatory agency in charge of the events. During SSS06 three products were delivered: vector fields for the previous 24 hours, a 24 hour current forecast, both in netCDF format, and vector fields for import into GIS programs. In October 2007 the failure of the service endcap on the San Francisco Public Utilities Commission sewage outfall prompted concerns that a buoyant plume could possible foul beaches. Two different plume tracking products, one for 24 trajectories of the input of a plume, and a second with continual input allowed tracking of the potential plume reaching shore. The product development for these events assisted with management decisions, ultimately illustrating the process of providing targeted products for regulators.

THE ROLE OF LANGMUIR SUPERCELLS IN SEASONALLY TUNED CROSS-SHELF TRANSPORT OF BIOACTIVE MATERIAL

Langmuir supercells are arguably the dominant horizontal transport mechanism for sediment and bioactive material on shallow inner shelves. First observed to 15m depth off New Jersey, supercells were recently found extending to 30m on the Georgia shelf. Such large shelf areas on the US eastern seaboard experience episodic, strong and highly directional transports in supercell related events associated with strong wind/wave forcing during storms. Net horizontal transport during supercell events is approximately downwind and associated cross-shelf transport is dependent on the angle between storm wind direction and shelf orientation. Net cross-shelf transport will be modulated by seasonal variability of storm frequency and directional wind. With strong storm winds typically from the NE off much of the US east coast, supercell events offer directed onshore transport across the inner shelf, acting as vectors for springtime movement of bioactive material towards the coastal. Year-class success of fish stocks that spawn near the shelf break but rear in coastal lagoons may be determined by the frequency of storms affecting the inner shelf during a crucial spring period.

NEARSHORE TRANSPORT OF LAND-BASED CONTAMINANTS EXPORTED FROM ELKHORN SLough, CALIFORNIA

The nearshore transport of terrestrial inputs to the ocean is an issue of growing concern worldwide. Our aim is to define a “zone of impact” for tidal outflow from Elkhorn Slough, recognizing that one can expect a characteristic pattern of transport for all water-borne pollutants. At short time scales, biogeochemical reactions are expected to be secondary to physical transport in defining the spatial distribution of contaminants exported from a given source. Summer transport is primarily due to tidal flows to/from the Slough and nearshore waters, with some variability associated with winds. A 10-km array of near-surface temperature-salinity (TS) sensors was deployed alongside of Elkhorn Slough from August to October 2006. The nearshore outflow water temperature TS values can be defined in TS space and is most prevalent near the source. With increasing distance from the source, exposure time and concentration decrease. A similar decrease in exposure to terrestrial water/contaminants can be expected, including trace metals (monitored using solid-phase DGT devices). This work is directed at obtaining a first estimate of the exposure of sea otters to the water-borne pathogen, Toxoplasma gondii.

EXPLOREING THE VARIABILITY OF EXPORT PATHWAYS OF LABORATORIUM SEA WATER FROM THE SUBPOLAR NORTH ATLANTIC USING SIMULATED TRAJECTORIES

The Deep Western Boundary Current (DWBC) has long been considered the sole conduit transporting water masses of the northern North Atlantic to the subtropics. Recent RTOFS and RAFOS trajectories and modeling studies, however, have provided evidence for an interior pathway from the subpolar gyre to the subtropical gyre; a pathway first hypothesized from hydrographic data. The interior pathway runs southwest along the western flank of the Mid-Atlantic Ridge and may be eddy-driven. We used simulated Lagrangian trajectories and RAFOS trajectories to examine spatial and temporal patterns in the mid- and lower frequency pathways from the Labrador Sea to the subtropical gyre. As in previous studies, few particles (real or simulated) follow a path along the western boundary of the North Atlantic. In multi-year simulations, most particles seeded in the DWBC in the Labrador Sea enter an eddying region off the Grand Banks, pass through the subtropical gyre interior; and return to the DWBC south of Cape Hatteras. We quantify interior pathway variability with trajectory clustering techniques. Possible mechanisms for the generation and variability of the interior pathway are discussed.

INTENSE EDDY MIXING AND TRANSPORT IN THE LOFOTEN BASIN

The dynamical role of fresh water, transport and mixing by eddies is clearly illustrated by recent observations taken in the Loften basin during MAIA* and ASOF** (EU funded projects) showing strong interactions between the Norwegian Atlantic Current (salty) and the Norwegian Coastal Current (fresh) at the eddy scale. These observations were based on quasi-lagrangian (isobaric) floats, transient tracers and hydrological data combined with satellites data (Sea Level Anomaly). Eddies are a very efficient mechanism not only to explain how water masses are interacting to exchange properties but also to transport heat, salt and tracers. In this presentation we will describe some relevant and pertinent observations in order to document this process driven by eddies and we will draw some conclusions concerning numerical modelling applications for the general circulation in the northern Norwegian sea and the Barents sea and also the relevance of this process for the ecosystem in one of the most productive area in the world ocean. *MAIA: Monitoring the Arctic Inflow towards the Arctic **ASOF : Arctic Subarctic Ocean Fluxes

INTERACTION OF A SLOPE EDDY WITH THE SHELBREAK FRONT IN THE MIDDLE ATLANTIC BIGHT: CONTRASTING SUMMER AND SPRING CONDITIONS

The shelfbreak front in the Middle Atlantic Bight is a region of large variability in both stratification and velocity shear. A important contribution to the variability is the interaction of slope eddies with the front. These eddies act to enhance lateral shear near the shelfbreak jet and also alter the waveguide in which internal waves propagate. We compare and contrast observations from two separate time periods: August-September 2006 and May 2007, obtained in the course of the Shallow Water 06/NLIWI/AWACS experiment off New Jersey. An anticyclonic slope eddy was present immediately offshore of the shelfbreak front during both surveys. In late summer of 2006-the near-surface water over the eddy was less dense than that over the outer shelf. Consequently, the sense of vertical geostrophic shear was reversed near the surface, resulting in a maximum jet velocity located deeper in the water column (40 m depth). In contrast, in spring 2007 the shelf water was present in the upper 70 m of the water column within the slope eddy, density gradients did not reverse near the surface, and the shelfbreak front had its more usual configuration with an alongshore velocity maximum at the surface. During the spring 2007 cruise, the mid-depth acoustic duct associated with the Cold Pool water mass over the outer shelf extended a large distance offshore. During the late summer of 2006, this duct abruptly terminated adjacent to the slope eddy.

FORCING OF SEMIDIURNAL CURRENTS BY TIDES, WINDS AND BATHYMETRY IN A SMALL FJORD IN PRINCE WILLIAM SOUND, ALASKA

From June to August 2007, diurnal (26 hr) tidal currents and hydrography within Simpson Bay, Prince William Sound (PWS) Alaska, revealed a complex flow structure forced by interactions of tides, bathymetry and winds. A prominent feature of the circulation is a northward tidal jet (~0.3 m/s) generated by flow across a shallow shelf on the western side of the mouth. When enhanced by up-fjord winds (7-10 m/s) this inflow results in exten-
sive intrusions of PWS water into the northeastern region of the fjord. A secondary hydro-
dynamic response to sampling with outliers near the eastern shoreend suggesting the eastern shoreend and ultimately re-circulates water via an anticlocky eddy. During ebb tides the cross-channel flow structure is reversed by an outflow of estuarine water from the northern (inner) basin along the western side of the fjord. This current is initially generated by acceleration of the tide through a narrow channel formed by a shallow reef that separates the northern and southern basins. The imbalance in flow generated by the topography possibly forces a net exchange of PWS water into the northern (inner) basin.

NEARSHORE SPORE DISPERSAL OF GIANT KELP: INSIGHTS FROM THEORY AND EXPERIMENT

Propagules like invertebrate larvae and algal spores are often dispersed across a spectrum of spatial scales using wind, wave, and current vectors. We used water flow models to examine short- and long-distance spore dispersal in the habitat-forming giant kelp, Macrocystis pyrifera. Results of a physically based model were compared to settlement data acquired in the field. Findings indicate that short-distance dispersal patterns quantified over limited durations are noisy and likely due to characteristics of turbulent mixing. Waves smear dispersal patterns in Macrocystis; may exceed 100 million spores per individual. Fertilization and recruitment appear possible at distances beyond 1 km, modulated by current speed, forest size, and the viability of life stages derived from spores. In forests, levels of self-fertilization may reach 10% or more. Such characteristics influence propagation supply, population connectivity, and inbreeding in this key nearshore seaweed.

SLOWLY VARYING BIAS CORRECTION OF NEAR-SURFACE WIND FIELDS BASED ON WIND SCATTEROMETER DATA

A new approach for blending scatterometer data into NWP surface wind fields driving surface wave and ocean models has been developed, to cope with sparsity of sampling that limits the effectiveness of methods like OI. Temporally/spatially varying bias is corrected using satellite scatterometer, local parameters are estimated from satellite scatterometer data. Alternative model structures, spatial/temporal scales and estimators were evaluated based on predictive skill. In the choice of estimator, robustness against outliers and overfitting are important. We tried (in order of increasing skill) robust regression (total least squares, regression on ordered samples) with outlier removal, a Neural Network technique with advanced training method, and a new highly effective least-squares method which finds a solution along the path of steepest descent based on cross-validation. Experiments with ECMWF surface winds over the Mediterranean using ERS1/ERS2 scatterometer data reprocessed with CMODs show that largest bias reduction is achieved on small spatial (0.5°) and large temporal (month) scales, suggesting local but persistent bias. Additional work on the impact of model structure and use of QuikSCAT 25 km will be presented.

CREATING SUCCESSFUL COLLABORATIONS TO SUPPORT OCEAN SCIENCE EDUCATION: EXAMPLES FROM THE GLOBE PROGRAM AND THE COALITION FOR EARTH SYSTEM EDUCATION.

Leveraging the resources and capabilities of formal and informal science education organizations to promote Earth System literacy is a primary goal of the Coalition for Earth System Education. Actively engaging students and teachers with scientists in research on the environment at local, regional, and global scales is a primary objective of the GLOBE (Global Learning and Observations to Benefit the Environment) Program. This talk will use examples from both the Coalition for Earth System Education and GLOBE to highlight successes and challenges in creating effective partnerships between diverse scientific and educational stakeholders. More specifically we will discuss lessons learned and used in the following areas: (a) mutual goal, benefit, and priority setting, (b) agreement on roles, responsibilities, and resource allocations, (c) creation and support of scientist, school, and organizational networks, (d) integration of ocean science learning into K-12 classrooms, and (e) development of evaluation metrics to measure the success of collaborations.

AMS ONLINE OCEAN STUDIES FOSTERING OCEAN SCIENCE LITERACY IN AMERICAN UNDERGRADUATE EDUCATION

Online Ocean Studies is an introductory college-level course in ocean science developed by the American Meteorological Society (AMS) in cooperation with the National Oceanic and Atmospheric Administration (NOAA). This semester-length course explores the ocean in the Earth system via investigations keyed to near real-time environmental data derived from ocean and coastal observing systems. The course, including textbook, investigations manual and course website, can be offered as a traditional lecture/lab offering, hybrid course or totally online. Since 2005, 100 colleges and universities have licensed the course. The AMS was funded by the NSF CCLI-ND program to introduce Online Ocean Studies to undergraduate faculty members from 75 Minority Serving Institutions over three years ending in 2009. Two faculty training workshops have already taken place in Seattle at the University of Washington and NOAA facilities and at the subsequent AMS Annual Meetings. The workshop includes course implementation discussions, presentations by oceanographers on a variety of course topics, and visits to the Pacific Marine Environmental Laboratory and the Northwest Fisheries Science Center. The University of Washington School Of Oceanography is a major partner in the conduct of the faculty workshops.

A CASE STUDY: THE IMPACT OF THE 1962 NOR’EASTER ON DELAWARE’S ATLANTIC COASTLINE

The 1962 Nor’easter, called by many The Storm of the Century, is Delaware’s most devastating coastal storm recorded in centuries. This project presents a case study of the catastrophic impact of the Nor’easter of 1962 on Delaware’s Atlantic Coast shoreline using historical aerial photographs, flood insurance maps, and building codes. Within a GIS framework, historic aerial photographs were analyzed pre- and post-storm to identify changes in shoreline, beach width, and extent of overwash and the extent of building destruction. The impact across Delaware was compared to earlier storms and other coastal impacts. Correlations were made between pre-storm coastal morphology and observed storm impacts. The historic photographs were then compared to 2002 aerial photographs to determine changes since the storm. Housing codes and Delaware flood insurance maps were used to compare development codes, and evaluate areas of sensitivity. The 1962 Nor’easter had a significant impact on Delaware’s coastline and communities. Forty-five years later, with increased development and better standards of building, when a storm this large occurs again, how susceptible is Delaware’s Atlantic coastline?

THREE INTERACTING BUOYANT PLUMES IN THE NORTHERN CALIFORNIA CURRENT

The northern California Current is impacted by two freshwater sources: the Strait of Juan de Fuca (JDF) and the Columbia River, resulting in three distinct buoyant plumes: the plume from the Strait, and two plumes from the Columbia, one tending north and one tending southwest of the river mouth. In June 2006, downwelling winds associated with a spring storm were followed by persistent, strong upwelling winds. Moored sensor and satellite data show that the Columbia plume that developed during the storm extended over 200 km northward along the Washington coast and into the Strait. The plume water subsequently folded around Strait water in the IDY eddy. Drifters deployed in the Columbia plume near its origin tracked plume water northward along the coast almost to the Strait, then moved seaward and reversed direction at the onset of upwelling-favorable winds, tracking the aging plume water southward along the coast. As it neared the river mouth, this aged plume water mixed with the newly emerging southwest-trending plume, forming a distinctive ‘suck’ shaped Columbia plume inshore of the water of Strait origin.

Determined to be 10^-4 m^2s^-1. The diffusion equation is employed to model this change and estimate the diffusion coefficient, with seasonal temperatures in the Bight having greater amplitude and peaking earlier in the year. Dynamics in the Bight differ significantly from those found either to the north or south, with north-western and Sahel. The maximum deposition fluxes were observed during winter when large quantities of dust are carried out of north-western Africa, in particular from Saharan source regions. Winter events account up to one third of the total annual flux to the Canary Basins. Highest Fe/Al and Co/Al ratios were observed during summer dust outbreaks.

Charcteristics of Metal Deposition Fluxes to Northeastern Subtropical Atlantic: Canada Island Region.

African dust transport constitutes a large fraction of the annual atmospheric deposition in the Canary Islands. In this work, an 8-year data record of total suspended particles (TSP) and the possible impact of dust pulses on metal fluxes to the Canary Islands Region are discussed. The TSP samples were collected at three stations on Gran Canaria Island (Talierce at sea level, Tafira 269 m a.s.l. and Pico de la Gorda 1930 m a.s.l.) during CLIMACT and CLIMARCOST (INTERREG IIIB) projects. Spatial and temporal variability of total suspended particles (TSP) as well as the influence of meteorological conditions were examined. The characterization of the collected mineral aerosol and back trajectories of the air masses appear to indicate two main regional African sources of dust: north-western Africa and Sahel. The maximum deposition fluxes were observed during winter when large quantities of dust are carried out of north-western Africa, in particular from Saharan source regions. Winter events account up to one third of the total annual flux to the Canary Basins. Highest Fe/Al and Co/Al ratios were observed during summer dust outbreaks.

Morphodynamics of an Ebb-Tidal Delta in Response to Anthropic Changes.

Prior to the early 1900s, the shorelines of southwest Washington and northwest Oregon accreted at long-term average rates of 1-2 m/yr. This net progradation is attributed to sand supplied from the Columbia River that was temporarily stored in the ebb-tidal delta, then distributed both north and south of the entrance by wave and current processes. Construction of entrance jetties (1885 and 1917) to improve navigation promoted scour, causing the main channel to deepen and stabilize and the ebb-tidal delta to move offshore into deeper water. Concurrent with morphologic changes in the ebb-tidal delta, the shoreline advanced along the beach face to the jetties and then progradation reversed or reversion to erosion during the 1950s to present. A process-based numerical model (OMSI3D) is applied to gain insight into the wave and current processes responsible for sediment bypassing in the vicinity of the inlet.

High Resolution Turbulence Measurements Beneath Young Waves.

The turbulence field beneath surface waves is rather complex and provides great challenges for detailed observations. Only in recent years the direct link between wave breaking and enhanced near-surface turbulence levels has been shown. In a recent field experiment we used simultaneous remote and in situ measurements of breaking waves to test the Duncan-Phillips formulation for spectral energy dissipation. Pulse-coherent Doppler sonars were used to monitor the near-surface velocity field, the surface elevation and the breaking activity. The turbulence field is resolved to within a few centimeters of the free surface, and includes the most dynamically active near-surface regions. Turbulence characteristics and the interplay of turbulence and bubbles as well as the total wave dissipation will be discussed.

Traditional methods for measuring phytoplankton production and mortality, where the organisms are enclosed in containers or transferred to the laboratory, are potentially biased due to their intrusiveness. We developed a non-intrusive, in situ technique, based on measuring the change in phytoplankton density in water parcels tracked for 3-4 hrs. The experiment was carried out at the upper 40m of the photic layer in the oligotrophic Gulf of Aquh (Red Sea). Grazing exceeded production during both night and day, indicating a net heterotrophic state in that part of the water column. To maintain a phytoplankton population in that layer, an allochthonous subsidy must occur, possibly by lateral intrusions or vertical mixing with waters from the deeper productivity maximum. Extensive concurrent measurements of turbulence, currents and CTD profiles allow an evaluation of those sources. Phytoplankton mortality rates measured with our technique were three times greater than those measured with the traditional dilution experiment. Our findings indicate that our understanding of the processes governing the dynamics of phytoplankton in the upper water column may need to be revised.

Profiles of Ocean Heating (POSH): A New Model of Upper Ocean Diurnal Thermal Variability.

In situ radiometric measurements of diurnal warming at the ocean surface and profiles through the diurnal thermocline were utilized to assess the temporal and vertical variability of diurnal warming and to develop a new physics-based model of near-surface diurnal warming. The in situ data and model simulations were inter-compared, with the goal of comprehensively evaluating differences between the data and model results. Based
on these results, the model was refined, while attempting to maintain agreement with the in situ measurements. By modeling diurnal warming profiles, the new model provides a straightforward methodology for modeling differences, due to diurnal warming, between measurements made at different depths (e.g. 1 m in situ, 1 cm microwave, and 10 μm infrared). These results will have direct application to the GODAE High-resolution SST project and will be useful in providing insight into the physical processes in the upper ocean.

ELWHA RIVER DELTA: GEO MORPHOLOGY OF A MIXED-SEDIMENT BEACH

The Elwha River drains the Olympic Peninsula of Washington and forms a mixed-sediment delta in the Strait of Juan de Fuca. The Elwha River has been damned for almost a century, and a pending dam removal project is expected to reconnect upstream sediment sources to the river mouth. Topographic and grain-size mapping of the sub-aerial delta during 1999-2007 is reported and the geomorphology and shoreline changes of this system are described. The delta is divided into three geomorphic regions: west delta, river mouth and east delta. The river mouth is the most complex region due to the river channel movement, side-channels, and nearshore bars immediately offshore of the mouth. The east and west delta differ in geomorphology and shoreline change rates. The west delta is steep, cuspat, lacks a low-tide terrace, and exhibits little semi-annual or inter-annual shoreline change. In contrast, the east delta has a steep foreslope, a flat low tide terrace dominated by cobble, and has shown a consistent trend of erosion during the surveys. Cuspat formations on the east delta are more spatially variable than on the west delta.

OBSERVATIONS OF TURBULENT KINETIC ENERGY AND DISSIPATION RATE IN THE OCEAN SURFACE BOUNDARY LAYER

Estimates are made for several terms in the turbulent kinetic energy (TKE) budget in the ocean surface boundary layer in an effort to test predictions made by turbulence closure models. Data were collected at a depth of 2 m below the surface in 16 m of water south of Martha's Vineyard, Massachusetts, at the Martha's Vineyard Coastal Observatory. We estimated the dissipation rate, the magnitude and rate of change of TKE, and the buoyancy production, and we placed bounds on the shear production and Stokes-shear production. As found by previous authors, dissipation rates are enhanced relative to those found in wall-bounded shear flows. The remaining terms in the TKE budget do not balance the dissipation rate, suggesting that the transport of TKE, which is not directly measurable, is important in turbulence energetics in the surface layer. Our estimates of the turbulent kinetic energy are less certain, but are smaller than predicted by turbulence closure models that include a surface flux of TKE from wave breaking. Our estimates of TKE are close to those found in wall-bounded shear flows.

DIURNAL VARIABILITY OF SURFACE INHERENT OPTICAL PROPERTIES AND FLUORESCENCE, AS MEASURED IN THE NORTHWESTERN MEDITERRANEAN SEA (BOUSSOLE MOORING)

A one-year time series of inherent optical properties and phytoplankton fluorescence has been collected at a deep ocean mooring (BOUSSOLE project) in the north western Mediterranean Sea (60 km offshore Nice, France). All data are simultaneously recorded every 15 minutes at 4 and 9 m depth. This data base allows identification of the shape of the diel cycles of particle beam attenuation (cp at 680 nm) and backscattering (bfp at 442 and 555 nm) coefficients, which vary throughout the phytoplankton annual cycle: stable biomass in summer, growing phase of the vernal bloom, post-bloom decay, etc. Variations in cp reflect the variations of the bulk of all particles, while fluorescence is more directly linked to phytoplankton. In some particular cases, the average time of the day when phytoplankton division occurs is tentatively inferred.

 PARTICULATE FLUXES OF NATURALLY OCCURING RADIOISOTOPES AS MEASURED FROM SEDIMENT TRAPS AT THE SAN PEDRO BASIN, SOUTHERN CALIFORNIA

A bottom-anchored mooring in San Pedro Basin, CA has been operational since January 2004 with sediment traps at 550m and 800m. Total mass, carbon, and silica fluxes have been measured. Mean mass fluxes in 2004 and 2005 were 559.5 and 606.5 mg/m2-day, respectively. Synchronicity of fluxes in the traps indicates that most of the particle flux settles at speeds of 85-150m/day. Variations of total flux reflect seasonal events such as spring algal blooms, which are dominated by opal-rich rain. Occasional peaks of terrigenous material do not correlate with major rainfall events. Fluxes of the isotopes 210Pb, 228Th and 234Th were measured. Concentration variations of 210Pb and 228Th do not clearly correlate with the total flux or its biogenic fraction. While most of the shorter-lived 210Th isotope fluxes are supported by production in the overlying water, the particulate fluxes of 210Pb exceed the local production rate by a factor of ~5, requiring transport of dissolved 210Pb from offshore and its removal to sediments. The 210Pb flux into traps agrees with the seafloor 210Pb inventory.

ESTIMATION OF TURBULENCE LENGTH SCALE IN ESTUARINE BOUNDARY LAYER FLOWS AND WAKES

As part of the COHSTREX study of turbulent structure in estuaries, the turbulence length scale was measured in the Snounou estuary using a ship-mounted, rigid mast with a vertical array of turbulence-resolving sensors. Measurements were obtained in stratified and unstratified boundary layer flows and in the wake of a partially submerged jetty. The turbulence length scale, dissipation rate (ε) and turbulent kinetic energy (TKE) were estimated from analyses of the vertical and horizontal velocity spectra between the inertial subrange and the energy-containing scales of the turbulence (frequency range 0.02 – 12 Hz). In the boundary-layer flow conditions, the analysis confirms the transition from wall-layer to log-layer when the Ozmidov scaling Lo ~ z/ε^1/2 (where ε is von Karman’s constant, z is the height above the bed, and h is the water depth). Turbulence production and dissipation were nearly in balance for both the stratified and unstratified measurements. In the wake conditions, the TKE and dissipation were more than an order of magnitude higher than in the boundary layer, and the length scale was approximately twice the boundary-layer value. The measured length scales are consistent with remote-sensing observations of boils at the same location. The energetics of the turbulence were consistent with non-local generation due to the obstacle, with a spatial decay scale of the wake of approximately 100 m based on the magnitude of TKE and ε.

AN APPROACH TO CORRECT FOR ADJACENCY EFFECTS PRESENT IN MERIS DATA OVER LAKES: EFFECTS ON CHLOROPHYLL ASSESSMENT

Envisat-MERIS full resolution data (pixel-size 300 m) offer an excellent choice in terms of revisiting time, spectral and radiometric resolutions to monitor near-shore and inland water quality. Currently, MERIS data are delivered in two modes: at satellite radiation values (L1b); normalised water leaving radiance plus geophysical product, including chlorophyll-a, suspended solids and yellow substances concentrations (L2b). L2b products may be directly used for monitoring purposes but two main factors limit their use: first, a limitation in the current standard products is the applied atmospheric correction. In particular a problem for the atmospheric correction over lake pixels is the adjacency effect. A second constraint is the bio-optical model used in L2b processing, which does not take into account the broad variety of optical properties of the different water types typically met in fresh waters. This study presents a simple image-based approach to correct L1b data for significant adjacency effects, observed over narrow Sub-alpine lakes (northern Italy) surrounded by steep vegetated sides. Using specific inherent optical properties of the lakes, the effect of such a correction on chlorophyll-a assessment is discussed.

VERTICAL OCEAN MIXING BY FOSSIL TURBULENCE WAVES

Turbulence is an eddylke state of fluid motion where the inertial vortex forces vwx of the eddies are larger than any other forces that tend to damp the eddies out, where w is velocity and x is vorticity. Therefore irrotational flows are not turbulent, even though they may supply energy to turbulence at Kolmogorov scales where turbulence is produced. Turbulence always cascades from small scales to large by a process of eddy merging driven by vwx forces. Fossil turbulence is a perturbation in any hydrophysical field produced by turbulence that persists after the fluid ceases to be turbulent at the scale of the perturbation. Fossil turbulence waves are radiated near vertically (~45 degrees) from turbulence patches at the Ozmidov scale at fossilization in an efficient mason rager. Secondary turbulence events (zombies) are produced when FWTs tilt fossils of previous FWTs. Zombies patches re- radiate and channel the energy they collect forming mixing chnneys to the sea surface and brightness patterns. Thus information about bottom topography and submerged turbulence can be detected by optical and acoustic sensors. Patterns of mixing enhanced by submerged turbulence from the Sand Island municipal outfall, Honolulu, HI were detected in 2002, 2003 and 2004 international studies using satellite images and microstructure profiles in Mamala Bay. The mechanism appears to be generic to oceanic and atmospheric mixing of stratified fluids.

DREAMS - ENHANCING RESEARCH, ACADEMIC AND LEADERSHIP TRAINING OF UNDERREPRESENTED STUDENTS IN MARINE SCIENCE

Diversity in Research in Environmental and Marine Science (DREAMS) is a collaborative program between Hampton University (HU) and Virginia Institute of Marine Science (VIMS). The goal of this program is to increase diversity in the environmental and marine sciences fields by providing rigorous research, academic, and leadership training to HU marine science students. By instituting a new curriculum, research seminars, career seminars, ethics activities, presentation skill workshops, and new equipment, DREAMS has brought many new activities and resources to both campuses, greatly improving the research and learning environment for HU students. Each year a selected group of talented students conducts a full year long and summer research under the guidance of faculty mentors from various research institutions. These research internships allow the students to build long-term relationships with their mentors, and to gain in-depth understanding of the science professions. Students share their knowledge with the larger community through presentations, publications, outreach activities, and as peer mentors to K-12th grade students. Since the program began in July 2003, DREAMS students have collected a total of seven awards in regional and national conference presentations, and logged in over 60 days of community outreach. Seven student scholars successfully graduated from the program, six of which have been accepted to graduate or professional schools.

THE INFLUENCE OF SHOAL/CHANNEL INTERACTIONS IN A SHALLOW, MACROTIDAL ESTUARY ON FRONTOGENESIS, TRANSVERSE CIRCULATIONS AND VERTICAL MIXING

The dynamics of the Snohomish River Estuary are examined utilizing in-situ and remote sensing data collected during July 2006. Results from the field experiment highlight the need for understanding shoal/channel interactions in order to interpret tidally averaged quantities. Moorings with bottom mounted acoustic Doppler current profilers (ADCP); acoustic Doppler velocimeters (ADV); pressure sensors; and conductivity, temperature, depth (CTD) sensors at three depths were deployed for over twenty days. The moorings along with high resolution ADCP and CTD transecting surveys and an autonomous underwater vehicle, REMUS, are utilized to examine the interactions between complex bathymetry induced frontogenesis, transverse circulations, and vertical mixing and stratification in this system. In addition to detailed in-situ measurements, concurrent infrared remote sensing from both near-field oblique views as well as far-field imagery help corroborate the frontogenesis mechanism.

REGIONAL PREFERENCES OF THE RCA (ROSEOBACTER CLADE AFFILIATED) CLUSTER AND THE SAR11 CLADE: SOUTHERN OCEAN VS. TEMPERATE SEAS

The SAR11 clade ranges worldwide and often dominates the marine bacterioplankton. However, there is still scarce information on the quantitative distribution of this clade relative to other groups in marine waters other than tropical and subtropical regions. The RCA cluster, a narrow phylogenetic lineage of the Roseobacter clade, only occurs from temperate to polar regions, but not in tropical and subtropical waters. We determined the RCA cluster, a narrow phylogenetic lineage of the Roseobacter clade, only occurs from temperate to polar regions, but not in tropical and subtropical waters. We determined the

DEGRADATION PATHWAYS

Dimethylsulfoxonipropionate (DMSP) is an osmotically produced intermediate that has important implications for the global sulfur cycle and climate regulation. Marine bacteria are able to incorporate and degrade DMSP via one of two pathways. The cleavage pathway converts DMSP to the volatile sulphur compound DMS which is eventually released into the atmosphere. The demethylation pathway converts the sulfur in DMS into methanethiol and eventually into cellular biomass in the form of protein sulfur, which may stay in surface waters or sink to depth. Marine bacteria thus serve as important mediators for the fate of oceanic sulfur. The gene responsible for the demethylation pathway, dimD, has recently been identified, and approximately one third of surface ocean bacteria were previously found to harbor a dmAD homolog. However, the majority of genes involved in the processing and regulation of DMS degradation remain unknown. We examined marine bacterium Silicibacter pomeroyi’s transcriptional response to DMSP, DMS, and acrylate using a whole genome microarray. We identified candidate genes for DMS metabolism, and found that acrylate maybe a signaling compound in regulation of bacte
phlic response at all sites studied, whereas the temperature response of anammox activity was site dependent. Our preliminary results reveal rapid N2 production rates in perennated sediments via denitrification and anammox, and the temperature response of anammox activity appears to change more dramatically across a latitudinal gradient.

GLOBAL OXYGEN TRENDS IN THE COASTAL OCEAN AND OPEN OCEAN

Despite the commonly held view that oxygen levels are generally declining in coastal ocean bottom waters due to human-induced increases in atmospheric and river nutrient fluxes, this has not been tested in a global analysis of coastal ocean oxygen trends. Oxygen time series from long-term monitoring sites, mostly from the northern hemisphere, were selected for our analyses. We present maps displaying oxygen concentration trends at these sites for 10-year, 25-year and 50-year reference periods. Groupings of these trends by category (estuaries, shelf, open ocean) allow us to compare oxygen trends from diverse time and environment conditions. Our results show that in certain regions of the world ocean, the primary factor driving oxygen trends in the coastal ocean is open ocean forcing.

Consequently, it is important that we improve our capability to monitor oxygen variability and trends in the open ocean in order to anticipate ecosystem impacts on the adjacent shelf and coastal ocean. To this effect, we present preliminary results from a four-year pilot program of oxygen measurements on Canadian Argo floats in the northwest Atlantic and northeast Pacific.

THE ALLIANCE FOR COASTAL TECHNOLOGIES: SENSOR NEEDS FOR COASTAL OCEAN OBSERVING SYSTEMS

The Alliance for Coastal Technologies (ACT; see http://act-us.info) was established to foster the development and application of new ocean coastal sensor technologies to address the needs of coastal decision makers. New sensor technologies are required to make observations of biological and geochemical parameters that are needed for many management issues in a long-term, sustainable manner. Pilot programs for the US Integrated Ocean Observing System mostly are restricted to observations or models of physical variables, because that is what is possible with present technologies in an automated, sustained fashion. Bio-optical sensors, automated genetic sensors, and nutrient sensors are under development and are utilized in a few pilot projects; however, monitoring for human health by regulatory agencies still requires human intervention. Pilot programs such as manual cell counts. ACT facilitates the transition of new sensor technologies from research to operations through targeted workshops and verification trials of emerging technologies. Recent examples include trials of dissolved oxygen sensors, chlorophyll fluorometers, turbidity sensors, and nutrient sensors.

DIAGNOSTIC PATTERNS OF SEASONAL AND INTERANNUAL MIXED LAYER DEPTH CHANGE OFF BAJA CALIFORNIA

Seasonal and interannual variations of the isothermal layer depth (ILD) and the isopycnal layer depth (MLD) in the southern part of the California Current are examined using harmonic and EOF analysis applied to the 9 years of IMEOCAL data collected between 1997 and 2006. The sampling interval is approximately 3-month. In agreement with the equatorward geostrophic flow, the mean of each layer is shallower in the zone adjacent to the coast than offshore. The ILD is shallower than the MLD. The layers are parallel, and their phase difference changes with time more or less randomly throughout the day. Although Argo floats sample less frequently in time than moored buoys can, they have the important advantage of collecting measurements more or less randomly throughout the day. Although Argo floats sample less frequently in time than moored buoys can, they have the important advantage of collecting measurements more or less randomly throughout the day.

During April, the seasonal MLD and ILD anomalies show a double-signed structure, where the anomaly is negative at the coastal zone and positive offshore. The spatial distribution of the first EOF of MLD anomalies shows a single-signed loading pattern where the variability increases from the coastal zone to offshore. The first EOF of ILD anomalies shows similar behavior. Those results are consistent with the Lynn and Simpson’s domain. Additionally, data shows that sea surface height is most closely correlated with the MLD. The layers are modulated at interannual time scale by external forcing. As a result of these effects of El Niño 1997-1998, both the ILD and MLD were equal and anomalously deep (90 m). During La Niña 1998-1999, the ILD variability was more intense than the MLD variability.

ISLAND WAKES IN NUMERICAL MODELS OF SHALLOW WATER REGIONS

During recent years field studies of flow around islands in shallow water have generated detailed observations of wakes and eddy streets. Nellii & Elliott (2004) document one of many applications of a vertically integrated two-dimensional model. In such a model the effect of bottom friction on the flow is expressed through a bottom drag coefficient CD and the equivalent vertical eddy turbulent viscosity generated in the bottom boundary layer can be estimated with a parameterization. With the parameterizations of bottom friction used in two-dimensional vertically integrated models the Island Parameter (Wolanski et al. 1984) becomes independent of the free-stream velocity and is thus not suitable for the classification of island wakes. This presents us with a conundrum: Either the argument of Wolanski et al. (1984) and Tomczak (1988) that the state of flow around islands in shallow water is appropriately described by the Island Parameter is incorrect, or the vertically integrated model owes its success in simulating flow around islands to incorrect model physics. We attempt to clarify this issue with numerical simulations applied to the COHERENS (Luyten et al. 1999). Luyten et al., 1999 MUMM Report, Management Unit of the Mathematical Models of the North Sea, 914 pp. Neill, S. P and A.J Elliott (2004) Ocean Dyn. 54, 324-332. Tomczak, M. (1988) J. Geophys. Res. 88 (C6), 10553-10569. Wolanski, E, J Imberger and ML Heron (1984) J. Geophys. Res. 93 (C5), 5133-5138.

EVIDENCE FOR SUBMESOSCALE BARRIERS TO MIXING IN THE OCEAN FROM Ocean subsoscale (2-20 km) mixing processes have major impact on the large scale circulation, on the ecologic system, and on the dispersal of pollutants. Observing and understanding such mixing in the ocean is difficult, yet is crucial for devising better parameterizations needed to correctly simulate and predict climate and coastal regions. Most ocean and climate models use diffusion-like parameterization for processes on scales smaller than the grid resolution, which means that mixing is assumed to be isotropic and that dispersion is proportional to the square root of time. We investigate horizontal mixing in a unique data set of surface currents measured by high-frequency radar. Our results show the complexity of ocean mixing on scales of a few km and the existence of temporary barriers to mixing. For the first time, these barriers can also be seen by airphotographs. The existence of such barriers requires a new approach to the way mixing is parameterized in ocean and climate models.

CHARACTERIZATION OF THE MULTI-ANGULAR POLARIZED REFLECTANCE FROM COASTAL WATERS

Polarization properties of water leaving radiance provide important information about scattering characteristics of marine particles and potentially assist in the retrieval of the atmospheric composition, however, atmospheric-air-water interface and surface roughness impacts must be dealt with. To study these effects, a modified Satlantic hyperspectral radiance sensor with very high sensitivity was used to measure polarization components of the water leaving radiance from a research vessel for viewing angles from -70 to +70 degrees in both scattering planes along several stations in Jamaica Bay and Hudson River, NY, with varying concentrations of chlorophyll and mineral particles. Total reflectance spectra, as well as water absorption and attenuation spectra were also measured at the same stations together with (CHL), organic and inorganic components of TSS from the water samples. Results of these measurements are analyzed and presented together with simulations using a coupled air-ocean polarized radiative transfer code to assess the sensitivity of retrieval to errors in the atmosphere model, as well as sensitivity to coastal water parameters. The results of the analysis are then used to develop criteria for effective polarization sensors.

DIURNAL SEA SURFACE TEMPERATURE VARIABILITY FROM SATELLITE COMBINED WITH ARGO

The Advanced Microwave Scanning Radiometer for the Earth Observing System (AMSR-E) flies on a sun-synchronous orbit, measuring sea surface temperature at approximately 1:30 am and 1:30 pm local time. In contrast, Argo floats measure upper ocean temperature profiles more or less randomly throughout the day. Although Argo floats sample less frequently in time than moored buoys can, they have the important advantage of collecting measurements at all latitudes and providing full profiles of upper ocean temperatures. For this work, individual Argo temperature profiles were paired with AMSR-E measurements collected within 48 hours before or after the profile. Temperature differences between Argo and AMSR-E show evidence of a clear diurnal cycle, with an amplitude that decreases with increasing latitude, about 0.1°C near the Antarctic Circle and 0.0°C near 60°N. The results suggest that maximum temperatures occur 2 hours after the AMSR-E daytime overpass, around 3:30 pm. Minimum temperatures appear to occur just before sunrise, around 5:30 am, though the precise phasing of the temperature diurnal cycle appears to vary with latitude.

DANUBE DELTA: A BIOSPHERE RESERVE AT RISK

Exploited since Neolithic times and engineered for commercial shipping since the early 18th Century, Danube delta has paradoxically remained one of the most pristine deltas in the temperate climate region. For preserving its diverse wetland ecosystem, the delta was established as a Biosphere Reserve in 1998. Economic and environmental interests among and within riparian nations are often divergent, leading to environmental pressure both from upstream factors and from downstream changes in the Black Sea basin. We review the state of knowledge on the development of the Danube delta and its functioning in natural conditions in order to provide a baseline for identifying anthropogenic threats. Long term pressures on the delta include the acceleration of the sea level rise and the chronic deficit of sediments. However, the sediment redistribution inside the delta leading to increased sedimentation and shoaling of deltaic lakes as well as the expansion of commercial navigation inside the delta and the growth of the tourist infrastructure are acute problems that should immediately be addressed if the delta's ecosystem is to be preserved into the next century.

RELATING MICROBIAL DISTRIBUTION TO GEOCHEMICAL GRADIENTS IN DEEP-SEA HYDROTHERMAL VENT CHIMNEYS

Recent efforts have sought relate the distribution of microbes to geochemical factors in a variety of habitats. Hydrothermal vent sulfides present an ideal setting for such studies due to the defined gradients in temperature and geochemical conditions over short spatial distances. Here we examine the distribution and abundance of microbial phylotypes from the inner to outer walls of a hydrothermal vent sulfide (chimney) at the Juan de Fuca Ridge. Microbial incubators replete with sterile substrates and temperature arrays were deployed in holes drilled within the structures. The inner wall of the chimney are characterized by high temperatures (> 300°C) and high concentrations of energetically-rich electron donors. The outer walls of the chimney are much colder and contain high concentrations of potential oxidants. DNA extractions were performed on a time-series of deployments (from a few days to over 1 year) to examine changes in the microbial community and geochemistry over time. The abundance of select microbial phylotypes were determined using qPCR and FISH. The abundances of phylotypes common to short term deployments (Epuloproteobacteria and Crenarchaeota) changed over time and were correlated to changes in habitat conditions. Other select phylotypes also exhibited significant relationships to geochemical parameters, suggesting links between microbial physiology and temporal shifts in habitat characteristics.

DENMARK STRAIT OVERFLOW EDDIES AS A PROXY FOR THERMOHALINE CIRCULATION VARIABILITY

Cyclonic eddies observed in satellite sea-surface temperature (SST) imagery are an intriguing feature of the Denmark Strait and have been linked to pulsations in the dense overflow from the Nordic Seas. We report on a survey of 3 years of 1-km resolution imagery from the Advanced Very-high Resolution Radiometer database, concentrating on two annual and interannual variability. As expected, annual cycles are apparent in background SST and sea ice extent, but not in eddy size or frequency. Contrary to expectations, we find that a significant amount of cloud-free imagery of at least part of the Denmark Strait is available in all months of all years, leading to the possibility that the eddies could serve as a proxy for overflow variability. Nearly every cloud-free image revealed the presence of eddies, with only small deviations in position from the principal pathway along the Greenland shelf break and upper slope. The size and shape of the eddies is variable, ranging from simple bumps in the temperature front to fully-developed spirals. This variation appears to be related to pre-existing conditions (including sea ice) as well as to the eddy life cycles as they move through the strait following the overflow. The relationship between these SST eddies and statistics from satellite altimetry and moored current meters is also discussed, along with progress toward automated eddy detection algorithms and monitoring procedures.

HARMONIC ANALYSIS OF SOUTHEAST ALASKA TIDAL CURRENTS: SUMMER STRAIT AND TONOWEK NARROWS.

NOAA's National Current Observation Program deployed 42 Acoustic Doppler Current Profilers (ADCP) subsurface moorings during the period of May - September 2006 in Southeast Alaska throughout the region of Sumner Strait and Tonowek Narrows. Results of the harmonic analysis of this unique tidal current data set are described. The time span of the deployments varied from 38 to 88 days and the depths of the ADCP stations ranged from 9 to 155 m. Eddy currents predominantly were stronger than flood currents. Maximum mean speeds were registered during the ebb at Sumner Strait (155 cm/s), Warren Channel (139 cm/s) and Tonowek Narrows (123 cm/s) in the upper 10 m of the water column. Tidal harmonic amplitude ratios (K1+O1/M2) indicate a strong semidiurnal signal at almost all locations at all depths. M2 is the dominant constituent followed by S2, N2, K1 and M4. Rotary tidal currents were also encountered during the survey. Rotary reduction analysis showed a more detailed picture of the mean current vectors throughout a complete tidal cycle.

OCEAN ACIDIFICATION OF THE GREATER CARIBBEAN REGION 1996 - 2006

The global oceans serve as the largest natural sink for increasing atmospheric carbon dioxide (CO2) concentrations. As this CO2 is absorbed by seawater, it reacts to form bicarbonate and hydrogen ions resulting in a reduction in seawater pH (or acidification). This results in a decrease in the availability of the carbonate ion which has been demonstrated to play an important role in calcification processes. Ocean acidification could affect some of the most fundamental biological and geophysical processes of the sea in coming decades. Observations obtained in situ from Volunteer Observing Ships have been extended using satellite remote sensing and modeled environmental parameters to derive estimates of sea surface alkalinity (AT) and surface carbon dioxide partial pressure (pCO2,sw). Pairing estimates of AT and pCO2,sw has permitted characterization of the changes in sea surface carbonate chemistry that have transpired over the past decade throughout the Greater Caribbean Region as a consequence of ocean acidification. The results reveal considerable variability both spatially and seasonally throughout the region. As a consequence of ocean acidification, a secular decrease in aragonite saturation state (Omega_arg) is observed at a rate of ~ -0.12 ± 0.01 Omega_arg decade⁻¹ (r² = 0.97, P<0.0001).

PRODUCTION AND OCCURRENCE OF SPECIFIC ORGANIC IRON COMPLEXES (SIDEROPHORES AND HEME B) IN THE ATLANTIC OCEAN.

Iron concentrations in the oceans are very low, varying between <0.5 nM in the open ocean to approximately 20 nM in coastal waters. Iron is known to influence productivity and biodiversity in many parts of the world's oceans. A complete understanding of the influence of iron on ocean biology depends on our knowledge of (1) the processes controlling iron inputs and losses from the surface of the oceans and the (2) mechanisms governing iron uptake and iron utilization by marine organisms. In this presentation we describe investigations into two types of iron complexes produced by marine phyto- and bacteriochlorophyll. Siderophores are high affinity iron complexing ligands produced by bacteria as part of their iron uptake mechanism and are iron porphyrins, produced by almost all living organisms and used in many essential metabolic processes. We describe the variation in siderophore production, the distribution of siderophores in the dissolved phase and the distribution of heme b in particulate material across the different biogeochemical provinces of the Atlantic Ocean. We discuss the implications of their distribution for iron biogeochemistry in the Oceans.
OBSERVING STORM-INDUCED SEDIMENT RESUSPENSION PROCESSES IN THE MID-ATLANTIC RIGHT WITH SLOCUM GLEIDERS

Storm-induced sediment resuspension events are examined using physical-optical sensors deployed on Slocum Gliders. Two types of storm response are found. In summer, the intense seasonal stratification limits sediment resuspension even during hurricanes. In contrast, in winter storms, sediment resuspends throughout the full water column. The full transition between seasons starts with surface cooling that preconditions the shelf for mixing during fall storms. Focusing on a classic fall northeaster, sediment resuspension was limited to below the weakening pycnocline early in the storm. After the pycnocline was eroded, particles immediately filled the water column. The optical signals suggest that suspended particles are likely similar materials, which implies the reduced slope of the backscatter profiles is caused by an increase in vertical transport or turbulent mixing. Wave bottom orbital velocities during this time were decreasing, and glider vertical velocities show no indication of enhanced vertical velocities reflecting full water column Langmuir cells. We conclude that enhanced mixing is related to the interaction of the surface and bottom boundary layers as the stratification is eroded, and the observed variability is associated with the tide.

PRELIMINARY INSIGHT FROM THE FIRST GENOME SEQUENCE OF A HARMFUL ALGAL BLOOM SPECIES, THE BROWN TIDE ALGA, AUREOCOCCUS ANophagefferens

Aureococcus anophagefferens is the causative species of harmful brown tide blooms which have plagued the eastern US seaboard for more than twenty years. While brown tide is sporadic, the concurrent outbreak of massive A. anophagefferens blooms in NY, NJ, and MD during 2007 attested to their persistence and pervasiveness. The sequence of the A. anophagefferens genome has been completed by the Department of Energy's Joint Genome Institute, a process which will facilitate a better understanding of this organism's ecology, as well as provide impetus for the development of novel molecular tools. A combination of expressed sequence tags (ESTs, ~50,000) and raw genomic data (~7-fold coverage of the organism’s 56 megabase genome) have been completed and are undergoing analysis. Preliminary bioinformatic predictions suggest that > 11,500 identifiable genes exist within the genome. The common HAB species tend to be mixotrophic, can take advantage of a range of multiple sources of nutrients, and alter their nutrition strategies with changing light and nutrient conditions as blooms progress. Finally, better monitoring tools are now available, including continuous in situ nutrient sensors to track the dynamic short term changes which these blooms experience.

SUBMESOSCALE ANISOTROPY (FRONTS, EDDIES, AND FILAMENTS) AS OBSERVED NEAR BERMUDA WITH OCEAN COLOR DATA

Submesoscale and mesoscale physical variability strongly modulate the structure, biomass, and rates of marine ecosystems and their functioning in the ocean. Characteristic time and space scales of key ocean physical-biological phenomena range from the submesoscale (0.3-10 km in space; day-week in time) to mesoscale (10-300km, week-months).

In Doney et al. [2003], we characterized for the first time the geographical patterns of the magnitude and spatial scales of mesoscale ocean biological variability globally for a single year. Now, we present interim results characterizing the submesoscale component of ocean color variability using semivariogram techniques applied to high spatial resolution (1 km), regional satellite data near Bermuda. In the previous work, using SeaWiFS standard mapped level 3 products, we were unable to resolve between a true geophysical signal in the submesoscale versus instrument noise; here we show how the submesoscale (~10km) accounts for approximately 50% of the total resolved variance, the remainder found at mesoscales. Quantification of anisotropic submesoscale variability is an essential first step in deriving physical-biological models with parameters that may deviate significantly from purely physical, conservative tracers.

BIOLGICAL IMPACTS ON THE GENERAL CIRCULATION: THE ROLE OF WATER CLARITY

This work demonstrates that the carbon cycle (defined broadly) can influence the climate system not only through altering the transmission of longwave radiation in the atmosphere, but through altering the absorption of shortwave radiation in the ocean. A series of simulations was made in a global coupled climate model where anomalous shortwave absorption was removed from different locations. The results demonstrate that anomalous absorption can have profound impacts on the global circulation. Increasing shortwave penetration in the central Pacific subtropical gyres tends to spin up the Hadley circulation, while increasing it over the shadow zones tends to warm the cold tongue and decrease the Walker circulation. The effects of such changes in atmospheric circulation include shifts in gyre boundaries, changes in watermass transformation pathways and shifts in a number of overflows. We explore implications for the feedbacks of climate change on biogeochemical cycles, past changes in climate, and for potential impacts of mitigation strategies such as iron fertilization.

rays comprising these wavefronts. This paper provides a theoretical explanation of the phenomenon of wavefront stability. It is shown analytically that, at propagation ranges that are large compared to the correlation length of the environmental perturbations, end points of rays launched from a point source and having a given eikonal (phase) are scattered primarily along the wavefront corresponding to the same eikonal in the unperturbed environment. Roles of wave dispersion and of scalar (sound speed, buoyancy frequency, oceanic depth) and environmental inhomogeneities are analyzed. An intuitive physical explanation of the theoretical results is proposed. The relative stability of wavefronts compared to rays is shown to follow from Fermat's principle and dimensional considerations. Implications of the results for ocean acoustic tomography and predictability of tsunami travel times over an uncertain bathymetry are discussed.

COMPARATIVE HEAVY METALS PROFILES IN BOTTOM SEDIMENTS FROM A STRONGLY CONTAMINATED BAY AND AN ADJACENTE PRISTINE BAY Sepetiba bay is a semi-enclosed lagoon (447 km2) located 60 km western from Rio de Janeiro city. It is severely contaminated with heavy metals, in particular Zn and Cd. In contrast, Ribeira bay, located nearby, is an important tourist resort of Rio de Janeiro state. Although much less impacted, this site receives the liquid effluents from Angra dos Reis nuclear power plants due to the lack of number of private marinas. Bottom sediment cores were sampled at four stations inside Ribeira bay and dated by 210Pb. Constant sedimentation rates were observed with a gradient from its back-end to its discharge opening to Ilha Grande bay, with values from 0.1 cm y−1 to 0.34 cm y−1. Additionally, a sediment core was taken at the Saco dos Cocos, a northern coast, sediment core near the discharge of its two main tributary rivers, taken as its more contaminated area. Lead-210 dating was a show a varying sedimentation rate pattern, with changes coincident with man-made modification on its drainage basin as channeling. Comparing the metal content of sediments from both rivers, only the concentrations of Zn and Cd in Sepetiba bay can be taken as significantly altered in relation to Ribeira bay.

FROM LOCAL TO EXTREME ENVIRONMENTS (FLEXE) - Bringing the DEEP-SEA TO the GLOBAL NETWORK

While deep-sea extreme environments are a great hook for learning, helping K-12 students understand these complex, remote environments at a deeper level is challenging. FLEXE is an innovative project of the GLOBE Program that involves middle and high school students in engaging environments in which students can explore many important questions that reflect the information on the effects of convection, shear stress, and Coriolis force on the entrainment, in comparison with the nonpenetrative deepening. We also obtained the evolutions of profiles of temperature, salinity, velocity, and their fluxes, and examined the nonlocal mixing of heat and moments. Based on the analysis results, we suggested the parameterization of convective mixing.

DEVELOPING INSTRUCTIONAL MATERIALS IN MARINE SCIENCE THAT BRING REAL-TIME DATA INTO THE SCIENCE CLASSROOM: A COLLABORATIVE MODEL FOR DESIGN

Ocean Observatory Systems (OOS) make available a diverse array of large data sets that are easily accessible and provide a unique opportunity to develop inquiry-based learning environments in which students can explore many important questions that reflect the interactions of the main circulations of ocean and sea. However, developing educationally sound curricula materials that foster an understanding of ocean science ideas and practices is a challenging endeavor for many reasons. In this session we will describe the efforts of the Centers for Ocean Sciences Education Excellence - Mid Atlantic (COSEE MA) to develop instructional materials, in which students use real-time data (RTD) to generate explanations about important ocean phenomena. We will discuss our challenges and successes in:

(a) developing an effective collaborative design team composed of scientists, educational researchers, and teachers;
(b) using education frameworks to guide the design of scaffolded curriculum materials in science;
(c) developing and implementing teaching supports both in the curriculum materials and in associated professional development workshops;
(d) developing a research agenda for studying the effectiveness of the curriculum materials as they are used in real classrooms.

INTERANNUAL TRENDS IN PHYTOPLANKTON DYNAMICS IN THE ARABIAN SEA LINKED TO EURASIAN WARMING

For the past seven years, the western half of the Arabian Sea has witnessed a >300% increase in summer-time phytoplankton blooms due to strengthening of the southwestern monsoon winds and intensification of coastal upwelling caused by the warming trend over Eurasia. Our recent observations show that the warming trend is undermining convective mixing responsible for nutrient enrichment during the boreal winter condition of the monsoon cycle. Consistent with the weakening trend of winter convective mixing, winter-time concentrations of phytoplankton have been on the decline in the eastern Arabian Sea. In the western Arabian Sea however, chlorophyll concentrations have been on the rise. We present data to show that this unusual increase in phytoplankton biomass seen in the ocean color data is being caused by unprecedented blooms of N. milii, whose appearance appears to be tied to mesoscale eddy activity and the uplight of sub-surface, nutrient-rich, oxygen-poor waters seen off the coast of Oman.

CONVEXTIVE DEEPTING OF THE OCEAN MIXED LAYER SIMULATED BY LES

The deepening of the ocean mixed layer under the various conditions of surface cooling, wind stress and Coriolis force was investigated by LES. Analysis of the LES data provides the information on the effects of convection, shear stress, and Coriolis force on the entrainment, in comparison with the nonpenetrative deepening. We also obtained the evolutions of profiles of temperature, salinity, velocity, and their fluxes, and examined the nonlocal mixing of heat and moments. Based on the analysis results, we suggested the parameterization of convective mixing.

SEASONAL VARIATION IN NUTRIENTS AND MICROALGAL COMMUNITY COMPOSITION IN MOBILE BAY, ALABAMA, AND THE NORTHERN GULF OF MEXICO

A transect was sampled from Mobile Bay, Alabama to 40 km offshore at monthly to bi-monthly intervals from March, 2007. Horizontal salinity gradients ranged from 8 to 18 PSU in surface waters. Temporal changes ranged from 16 to 32 C. Maxima in chlorophyll-a concentrations and total microalgal numbers were associated with maxima in nutrient concentration. Nutrient concentrations were in turn inversely correlated with salinity, indicating the importance of Mobile Bay as a source. The highest chlorophyll-a concentrations were found in July-August. The highest cell counts were found during a bloom of the dinoflagellate Pyrocystis noctiluca in Mobile Bay. The community composition showed a seasonal succession from dinoflagellate- to diatom-dominance in spring, followed by mixed assemblages of chlorophytes, prasinophytes and cryptophytes in summer. There were also horizontal gradients, with dinoflagellate-dominance occurring only in Mobile Bay during the Prorocentrum. There were higher proportions of prasinophytes in Mobile Bay and higher proportions of chlorophytes offshore in the mixed-dflagel late-assemblage in summer.

WEATHERING AND CO2 CONSUMPTION POTENTIAL OF ANDESITIC-DACITIC TERRAINS, DOMINICA, LESSER ANTILLES

Previous studies of chemical weathering on high standing islands (HSIs) have shown some of the highest observed rates of chemical weathering and associated CO2 consumption yet reported. Recent geochemical studies of andesitic-dacitic terrains in New Zealand, Guadeloupe, and Martinique have reported silicate weathering rates and CO2 consumption so high that they fall only in the range previously determined for basaltic terrains, which are considered the high end of weathering rates for island systems. The Silicate fluxes and associated CO2 consumption determined from this study are amongst the highest known. Chemical fluxes calculated from this study confirm the weathering potential of andesitic-dacitic terrains and that additional studies of these terrains are warranted.

CYBERINFRASTRUCTURE AND MIDDLEWARE APPLIED TO OCEAN OBSERVING SYSTEMS

Engineers and scientists at the Monterey Bay Aquarium Research Institute (MBARI), Scripps Institute of Oceanography (SIO), National Center for Supercomputing Applications (NCSA), and the University of Washington (UW) have spent time building technologies to enable science on ocean observatories. From our experience building observing technologies we have learned many valuable lessons about supporting long-term observations consisting of large numbers of heterogeneous instruments. This collaboration is now applying those technologies and lessons learned to the next generation of cyberinfrastructure. This application covers a wide range of observatory functionality from plug and play instrument interfaces, to the application of observatory-wide functionality on an Enterprise Service Bus (ESB). We will discuss how the ESB technology enables us to apply cross-cutting features such as policy enforcement. We will illustrate how we applied this group of cyberinfrastructure technologies to deployed instrumentation and how we are using that existing infrastructure to develop and test other technologies to meet the issues associated with large-scale, federated ocean observatories.

CHARACTERIZING SUMMER TIME SHELF-SLOPE EXCHANGE PROCESSES ON THE NEW JERSEY SHELF

Fleet of autonomous Webb gliders occupied cross-shelf transects on the New Jersey outer continental shelf during summer 2007. Observations consisted of depth-averaged sweeps at the outershelf crossed the climatological location of the foot of the shelf-slope front. Depth-averaged currents flowed 10 cm/sec along-shelf to the southwest, indicating a transit time of 7-10 days for features through the study site. Four types of slope water salinity intrusions were identified: surface, pycnocline, sub- pycnocline, and bottom-intrusions. The pycnoline intrusions were affected by strong shelf-slope separation. Sub- pycnocline intrusions were possibly associated with the separation of the bottom boundary layer at the foot of the shelf-slope front. The intrusions were persistent and highly variable in space and time, likely forced by offshore eddies. On average the mid-depth intrusions could together account for one-third of the slope water salt in the sampling volume. Tropical Storm Ernesto dissipated and mixed away significant portion of the intrusions. The gliders enabled quantitative understanding of initiation, spatial distribution and dissipation of the highly dynamic shelf-slope exchange process.

THE ROLE OF THE SHIP OF OPPORTUNITY PROGRAM IN THE GLOBAL OCEAN OBSERVING SYSTEM

The Ship Of Opportunity Program (SOOP) is an international program coordinated by the World Meteorological Organization (WMO) and the International Oceanographic Commission (IOC). The primary goal of the SOOP is to fulfill upper ocean thermal data requirements established by the international oceanographic community. The SOOP is directed primarily towards the continued operational maintenance and coordination of the expendable BathyThermograph (XBT) network, but other types of measurements are also made (TSG, CTD, ADCP, pCO2). Upper ocean observations provided by the program are assimilated into ocean models and the results support the operational needs of global fisheries, shipping, defense industries as well as climate and weather prediction efforts. Ships from the SOOP also deploy other instruments such as satellite tracked surface drifters and profiling floats. In this presentation we emphasize XBT transects maintained by NOAA. These transects are operated in three different deployment modes characterizing the spatial and temporal sampling frequency: low density, frequently repeated and high density. We present a summary of all the XBT deployments made during the last decade in each of these modes along with several key scientific contributions.

HIGH RESOLUTION RECORD OF ORGANIC MATTER FLUXES IN THE CARIACO BASIN OVER THE PAST TWO MILLIANNA

The Cariaco Basin provides a unique opportunity to investigate climatic and oceanographic phenomena in the tropics at a variety of time scales ranging from seasonal to millennial. The focus of this investigation was to determine the compositional changes in the export of organic matter from the euphotic zone and link them to physical forcings (e.g., upwelling/stratification intensity, precipitation/runoff) and climatic phenomena (e.g., migration of the intertropical convergence zone - ITCZ). In this paper, we evaluate these changes by determining the elemental (carbon:nitrogen ratios), stable isotopic (delta-13C and delta-15N) and biomarker (sterols) compositions of sinking particles and accumulated sediments from the eastern sub-basin of Cariaco. The sample set includes sediment trap samples, collected bi-weekly for several years as part of the Cariaco - Ocean Time series, surface sediments collected via multi-core and deeper sediments collected via gravity core. We examine the seasonal and inter-annual differences in the sinking organic matter flux and composition and use these results to inform our interpretation of the accumulation fluxes and compositions determined from the combined multi-core, gravity-core records. The sediment record, which expands the last 2,000 years or accumulation study, with a time resolution of about 5 years, is used to evaluate changes in the oceanographic conditions in Cariaco Basin during the late Holocene.

EFFECTS OF STATUS AND DENSITY OF A THREATENED CORAL SPECIES, ACROPORA CERVICORNIS, ON CORAL REEF FISH RECRUITMENT: IMPLICATIONS ON FISHERIES MANAGEMENT

Acropora cervicornis, a "threatened" Caribbean coral species (U.S. ESA, 2006), is an important reef builder. Since it is structurally complex (i.e. density/health status of thickets) and often occurs in large monospecific patches, it is thought to be an important habitat for coral reef fish recruitment, including commercial fishes. Therefore, its recent demise could result in significant reduction in the abundance and diversity of coral reef fish assemblages. This study is aimed to understand the effect of status (i.e. alive/dead) and density (5, 20 and 25 branches) of A. cervicornis on fish recruitment. Fish abundance and diversity were estimated every 2 weeks for 5 months. Data was analyzed following a two-factor design which involved manipulation of coral density (3 levels) and status (2 levels). No detectable effect between live/dead treatments was found; however recruitment was dependent on coral density (G = 41.21, df=2, P < 0.001). Preliminary results show that structural complexity is the major factor affecting fish recruitment being Haemulon spp. the most abundant species (96.52%, n=2588). This highlights the importance of density as a key factor for fisheries management.

THE INTENSIFICATION OF HURRICANE GEORGES IN THE EASTERN CARIBBEAN REGION THROUGH ITS INTERACTION WITH AN ANTICYCLONIC EDDY

Hurricane Katrina intensified upon moving over an area of positive sea surface height anomaly (SSHA) in the Gulf of Mexico, therefore fueling interest in understanding oceanic mesoscale eddy - tropical cyclone interactions. Oceanic heat content (OHC) in the area where Katrina interacted with the anticyclonic eddy was found to be high, ranging from 23.90 - 33.46 Kcal/cm2. The Western Tropical Atlantic and the Eastern Caribbean region exhibit considerable anticyclonic activity, suggesting the occurrence of particularly elevated OHC areas in this region. A study of four tropical cyclone systems in the Eastern Caribbean (EC) region has shown that SSHA exerts a greater influence on OHC than sea surface temperature (SST) does. In the EC Hurricane Georges was the only one among these four systems that moved over waters with comparable OHC (38.5 to 43.5 Kcal/cm2) to that of the Katrina case and the only system to undergo a similar intensification.

FROM ALL SIDES - REAL AND PERCEIVED THREATS IN THE BENGAL DELTA

Among a long list of potential threats to sustainability of the Ganges-Brahmaputra delta and its 150 million occupants, which pose the greatest risks? Sea-level rise is regarded as a critical threat to >40,000 km2 of the delta <3 meters in elevation. However, various inundation scenarios do not account for high rates of vertical accretion or morphodynamic feedbacks between the delphian and inner shelf. At least 200 million tons of the river’s annual sediment load is trapped in this zone, largely during the period of elevated sea level and high discharge forced by the summer monsoon. Furthermore, tide-gage records from much of the delta indicate sea-level rise rates less than the global average. Thus, scenarios of large-scale inundation in the coming century may be mitigated through natural system responses and feedbacks. In contrast, anthropogenic effects on the delta are greatest during the 8-month dry season when the sedimentary system is comparatively inactive. At this time, the impact of water diversion on channel stability, groundwater extraction on local subsidence, and resulting saltwater intrusions may represent a greater threat to the regional population.

EMERGING TECHNOLOGIES FOR PUBLIC HEALTH APPLICATIONS OF COASTAL OBSERVING SYSTEMS

This presentation will provide an overview of how molecular methods offer the possibility of rapidly identifying multiple genetic signatures with the aim of better protecting human health and coastal resources. Targeted nucleic acid extraction on local subsidence, and resulting saltwater intrusion may represent a greater threat to the regional population.

ASSIMILATION OF HF RADAR DATA INTO OCEAN CIRCULATION MODEL. DURING AN EXTREME WEATHER EVENT

A HF Radar based surface current observation system has been developed in Raritan Bay, NJ and the New York Right Apex, which consist of four standard range (25MHz) Coastal Ocean Dynamics Application Radar (CODAR) Seasonal systems located at Sandy Hook, NJ; Breazy Point, NJ; Bayshore Water Front Park, NJ; and on the south shore of Staten Island, NY. The current work focuses on the utilization of the HF Radar data by assimilating it into an estuarine and coastal ocean circulation model which provides nowcasts and forecasts for the study domain. This model, forced by an extensive real-time observational network, is called the New York Harbor Observing and Prediction System (NYTHOPS), which is based on the Estuarine Coastal and Ocean Model (ECOM). Assimilation of HF Radar data into the NYTHOPS model is performed using a nudging scheme. An extreme weather event of high wind and coastal flooding were considered for the data assimilation experiment. The assimilated model simulations were critically analyzed with respect to density profile variations and coastal upwelling / downwelling processes measured during this extreme weather event.

DIFFUSION OF PARTICLES IN ISOTROPIC TURBULENCE USING HIGH SPEED DIGITAL HISTOLOGIC CINEMATOGRAPHY

High speed in-line digital histologic cinematography is used for studying turbulent diffusion of several diameter. In several examples, it is observed that diffusion is faster than pure molecular diffusion. The experiments are performed in a 50x50m sample volume in a controlled, nearly isotropic turbulence facility. Diffusion rate is calculated by integration of the Lagrangian velocity autocorrelation. Droplet diffusion rate in horizontal (Dx) and vertical direction (Dz) are found to be significantly lower than that of fluid at low turbulence level and exceeds it at higher turbulence level. Dx is greater than Dy for most of the data due to horizontal droplet velocity RMS exceeding the vertical one. The vertical droplet diffusion timescale (Ty) is higher than the horizontal timescale (Tx). The droplet diffusion coefficient is calculated by quiescent rise velocity (Uq) times turbulence integral length scale, UqT or UqTy monotonically increases as a function of fluid RMS scaled by Uq. Experiments with phytoplankton, in salt water with Kolmogorov scale (k) imm as observed in the ocean, show that since phytoplankton size – (1/15k) their diffusion is similar to fluid diffusion.

INDONESIAN THROUGHFLOW [ITF] 2004-2006, AS OBSERVED BY INSTANT

The INSTANT program measured the ITF from the Pacific intake at Makassar Strait and Lembata Passage to the Nusa Tenggara export channels to the Indian. The time series began in December 2003, completed in December 2006; during mostly a weak El Niño state, interrupted by a ~6 months La Niña in early 2006. A +1OD event peaked in October-November 2006. A composite view of along-channel speeds within each passage reveals variability across a wide range of scales, marked with month long periods of inflow during November-December 2003, February-March 2004, and February-March 2005. A second goal of this project is to measure cross-shore variations in orientation and rotational direction of tidal ellipses. Here we wish to expand upon previous studies that have showed a switch in the rotational direction of tidal ellipses for certain tidal constituents and a shift in the dominance of tidal constituents at the continental shelf break.

SPATIAL AND TEMPORAL VARIABILITY IN MOLECULAR COMPOSITION OF RIVERINE ORGANIC MATTER DELIVERED TO THE US ATLANTIC COAST

An assessment of six large rivers along the US Atlantic coast was conducted under low and high flow conditions to identify compositional variability and downstream transformations of riverine particulate organic matter. Lipid biomarkers were used to evaluate the relative intensity from allochthonous and autochthonous sources to each system. A high carbon preference index within the hydrocarbon composition indicated an important terrigenous contribution to the particulate OM pool to all rivers systems. Across-river differences in hydrocarbon abundance were apparent. A significant input from fossil organic matter was also evidenced through short-chain hydrocarbon distributions. Phospholipid content and composition revealed a particle-associated bacterial community that was low in abundance and diversity under high flow conditions in all sampled areas. Overall, allochthonous inputs dominated the organic matter flux during high flow conditions, regardless of land-use patterns or lithology. Current research efforts aim to evaluate the change in organic matter source during low flow conditions.

THE NAVAL OCEANOGRAPHY PROGRAM: A BUSINESS MODEL TRANSITION AND WORKFORCE TRANSFORMATION COLLIDE

The Naval Oceanography Program (NOP) recently underwent a 29% workforce reduction, from 3900 personnel to 3000. This reduction forced a shift in the NOP business model and the development of a new strategy, called Battlespace On Demand (BonD). These changes increased functional differentiation and led to problems with: (a) control of organizational technology and communications; and (b) management of organizational learning and development of sustained workforce competencies. These problems, and the approaching exodus of 50-60% of the workforce as Baby Boomers retire, require the importance of strategic workforce transition planning. This planning is being conducted as part of the NOP workforce development program, which is designed to prepare a highly flexible, competent, and adaptable body of workers with the knowledge, skills, and competencies required to execute NOP's long-term strategic plans. NOP requires a new cadre of workers armed with the knowledge and competencies to support exploitation of the 21st Century battlespace. This in turn requires national, local, and organizational partnerships to ensure development of a common vision and initiatives for creating the knowledge, skills, and competencies needed to implement BonD.

A LOOK AT CROSS-SHORE VARIATIONS IN TIDAL CURRENTS USING HF RADAR

Three high frequency radar (CODAR) instruments began monitoring sea surface currents in the Gulf of the Farallones off the Coast of San Francisco, California in May 2006 as part of the State Coastal Conservancy funded Coastal Ocean Currents Monitoring Program (COCMP). This has provided an unprecedented spatial and temporal view of sea surface currents in this region. Previous studies have examined the complex surface currents in the Gulf of the Farallones using Acoustic Doppler Current Profilers (ADCPs) and the results of these studies did not have a year of continuous hourly data nor 3km resolution that is now available. One of the aims of this project is to develop and test a process in which harmonic tidal analyses using T_tide are performed on HF radar sea surface currents to separate out calculated cross-shore currents from meso-scale currents. Once the tidal currents are separated out, the residual currents can be compared to subtidal forcing mechanisms such as wind forcing. Hourly wind direction and wind speed data are provided by NDRC buoy 46026 which is situated within the study region. A second goal of this project is to measure cross-shore variations in orientation and rotational direction of tidal ellipses. Here we wish to expand upon previous studies that have showed a switch in the rotational direction of tidal ellipses for certain tidal constituents and a shift in the dominance of tidal constituents at the continental shelf break.

NUMERICAL REPRESENTATION OF INTERNAL WAVES IN THE HYBRID COORDINATE OCEAN MODEL (HYCOM)

Internal wave breaking is one of the primary sources for turbulent mixing in the ocean interior and consequently plays an important role in maintaining the strength of the thermohaline circulation. It is therefore important to have a good representation of these waves and their associated mixing in oceanic general circulation models. First, HYCOM is configured for a barotropic tidal flow interacting with a seamount and with isopycnic vertical coordinates. The wave characteristics and tidal rate of conversion derived from the numerical experiments are then compared to the analytical solution. Second, the ability of current diapycnal parameterizations (KPP, Mellow-Yamada, etc.) to represent the mixing associated with internal wave breaking is evaluated in a HYCOM configuration with a realistic tidal flow over Fieberling Guyot. The results are quantified by a comparison to observations taken during the Flow over Abrupt Topography initiative.

TEN YEARS OF SATELLITE OCEAN COLOR IMAGERY: ASSESSING SPATIAL AND TEMPORAL OPTICAL VARIABILITY IN THE NORTHERN GULF OF MEXICO

We examine optical variability in the northern Gulf of Mexico over a ten-year period (1998-2007) using satellite ocean color imagery (SeaWiFS). We have measured these values with consistent atmospheric correction and bio-optical models to evaluate these data suitable for long-term trend analysis. Weekly and monthly composite images of a broad suite of satellite-derived optical and biogeochemical properties (phytoplankton, detrital, sediment, and colored dissolved organic matter absorption coefficients; organic and inorganic suspended particles; fluorometry) are statistically analyzed. We examine regional-scale spatial variability in several coastal and offshore regions, including coastal Louisiana, Mississippi Sound, Mobile Bay, and the Mississippi River delta. Through examination of temporal anomalies, correlations, analysis of variance, and optical water mass classification, we examine how changes in coastal and offshore regions, the dominant optical characteristics in each region. Across all regions and years, absorption by dissolved organic matter represents the single largest absorbing component. We relate the observed patterns in the optical properties to physical forcing (river discharge, winds, currents) to better understand the oceanographic processes impacting the optical distributions.

VALIDATION STRATEGY FOR JOINT SSS/SST OBSERVATIONS IN THE CONTEXT OF SALINITY MONITORING FROM SPACE
Historically, strategies for validating satellite observations focused either on subdatasets for which reference in-situ measurements are available, or subdatasets of crossover points. Therefore, most observations are not used in the validation process, and a long time is required to gather the requisite validation data. In the upcoming years, spaceborne radiometers will provide salinity observations with high noise levels and external contaminations. It is thus important to adopt a validation strategy that takes advantage of the entire dataset in order to provide quality assessment with reasonable delays, filtering out spurious data before producing regularly spaced salinity fields.
Consequently, a global salinity validation strategy is proposed and tested with in-situ data. A global Argo profiler dataset is used to derive low-pass filtered salinity and temperature fields and anomalies to these mean fields. Large statistical anomalies are detected. We propose to take advantage of the observed temperature and salinity pair and independent co-located satellite data to validate the observations. Examples are presented using local wind and sea level to check for correlations with the salinity observations. Discrimination of geophysical anomalies from non-geophysical ones is achieved.

EXPLORE MECHANISMS OF SPECIES COEXISTENCE THROUGH MOLECULAR IDENTIFICATION OF GUT CONTENTS IN HYDROTHERMAL VENT GASTROPODS
Species diversity may be lower at hydrothermal vents than other deep-sea habitats, as result of the steep environmental gradients and chronic disturbance associated with seafloor volcanism. However, the diversity of some taxonomic and functional groups is unusually high compared to analogous shallow-water marine communities on hard substrates. For example, there can be as many as 13 species of grazing gastropods in a single aggregation of Riftia pachyptila, which is just a fraction of the regional gastropod species pool. Some gastropods are ubiquitous and others are found in specific microhabitats, stages of succession, or associated with different foundation species. Despite the abundance and diversity of vent gastropods, little is known about their diet and feeding ecology. We used molecular genetic identification of gut contents to determine the food sources of vent gastropods and to explore the role of gut contents as a mechanism for either species coexistence or species turnover in the spatial and temporal dynamics of vent communities.

COMPARISON OR MARINE X-BAND RADAR DERIVED SURFACE ELEVATIONS WITH ASSIS BUOY EVOLUTIONS OF NON-LINEAR INTERNAL WAVE EVENTS
During the summer of 2006, the Nonlinear Internal Waves Initiative (NILWI) experiment took place off the New Jersey coast near the shelf break. Extensive in-situ instrumentation were deployed to collect an unprecedented data of nonlinear internal waves propagating onto the shelf. The intensive set of surface and sub-surface measurements also included surface vessels, satellite and ship-based radar. Marine X-band radar images readily detect and image internal waves. During such NILWI events the radar backscatter images were inverted to surface elevations maps and compared to surface elevations from an array of wire wave gauges on the ASSIS buoys. Also estimates of surface currents are derived and compared with near-surface ADV measurements from the ASSIS buoy.

RECOVERY RATE OF SEAGRASS FROM BOAT PROPELLER SCARS IN MOSQUITO LAGOON, FLORIDA
We have designed a manipulative experiment to compare restoration techniques that maximize habitat recovery when boat propellers scar shallow seagrass beds. This study has identified four propeller scar severities and documented the frequency of each scar severity in Mosquito Lagoon. Out of 110 scars measured, the most severe scars (Type 1) were most common (56%). Type 4, the least severe scars were the second most common (27%), followed by Type 2 (10%) and Type 3 (7%) scars. Scar measurements were used to design an experiment to test the recovery rate of each scar severity and three restoration methods over a one year period. Restoration methods include planting with garden staples in the scar trench, filling the trench with sand, and filling with sand and planting garden staples. Here we present seagrass recovery results for Halodule wrightii after two months: Type 4 scars have recovered to 100% of the surrounding density, Type 3 scars to 20%, Type 2 scars to 3%, and Type 1 scars have shown no recovery. All restoration methods have been eroded or buried after 2 months.

ARCTIC PRESSURE RIDGES - REFUGIA FOR SEA ICE FAUNA?
The information on the biology of Arctic pressure ridges is very scarce, likely due to the difficulties in sampling this environment. We conducted a survey of the occurrence of sea ice meio- and macrofauna along pressure ridges in the Canada Basin in summer 2005 using ice samples and in-situ counts provided by divers. These results were compared with species occurrence at adjacent levels of the ice. Our data indicate that both sea ice meiofauna (e.g. turbellarians) and macrofauna (mainly amphipods) inhabited the pressure ridges in enhanced abundances compared to the level sea ice. The presentation will discuss likely reasons for this observation and implications for species distribution and survival in a warming Arctic.

RESPONSE OF MICROZOOPLANKTON GRAZERS TO SIMULATED HETEROSIGMA AKASHIWOO BLOOMS
Heterosigma akashiwo is a bloom-forming, planktonic Raphidophyceae that occurs worldwide and can lead to severe ichthyotoxicity. Negative effects of H. akashiwo on microzooplankton grazers may partially explain how blooms of this harmful species arise. This study describes the effects of a local 2006 Heterosigma akashiwo isolate (CCMP2809) on predator-prey interactions within laboratory cultures and natural planktonic communities. Results suggest that the excess of H. akashiwo was exposed to varying proportions of two algal species: Heterosigma akashiwo and a beneficial dinoflagellate, Heterocapsa triquetra. Ciliate growth or mortality rates and feeding levels were measured to determine the toxicity of H. akashiwo. The response of natural planktonic communities was observed in samples collected from northern Puget Sound, Washington, USA. Samples were exposed to bloom-density concentrations of H. akashiwo for 24 hours. Ingestion of the alga by individual grazer species was measured with episulfurous microscopy. Microzooplankton community responses were determined from abundance changes and feeding rates.

THE IMPORTANCE OF ALLELOPATHY FOR HAB BLOOM FORMATION AND EXTERNAL FACTORS INVOLVED IN THIS PROCESS
The ability of some algae to produce and release chemicals able to kill or inhibit the growth of other algal species is called allelopathy. The effect of the allelochemics on the target seems to be stronger in ichthyotoxic non-ichthyotoxic species. While for some algal species, like e.g. the flagellate Prymnesium sp., the allelochemics seem to be the same substances as their toxins, for other algae it is not. Although Alexandrium spp. are able to allelopathy, their internal toxins (saxitoxins) are not able to inhibit the growth of other algal species. Allelopathy enables the producer to out-compete other algal species for inorganic nutrients, but for some species, also to ingest the target (even grazers) after immobilising and killing them with the help of the allelochemicals. Allelopathy can be considered as either a N or P deficiency in the same manner as toxicity. We can assume thus that a consequence of the increased input of N and P to aquatic ecosystems, by creating an unbalanced NP situation favor HAB species able to produce higher amounts of allelochemics under such conditions.

Granéli, W., Lund University, Ecolgy dept, Lund, Sweden, wilhelm.graneli@imu.lu.se
THE BROWNIFICATION OF S SWEDISH LAKES - CAUSED BY INCREASED PRECIPITATION, DECREASED SULFUR DEPOSITION OR CHANGED LAND USE?
Running waters and lakes contain high concentrations of DOC. There is increasing evidence that most of this is of allochthonous origin. DOC concentrations in surface waters are not stable, but show pronounced fluctuations and trends on multyear time scales. In S Sweden DOC concentrations in freshwaters have increased considerably during the last 20 years. If this is a long-term trend, or just decadal fluctuations, and what is the cause, is controversial. There are three, not mutually exclusive candidates: more precipitation (in combination with less ground frost), lower sulfur deposition (reversed acidification) and a change in land use (less agriculture and more coniferous forests). Data for 40 lakes in S Sweden from July 2007, a period with exceptionally high precipitation, indicate that climate factors may be important. However, monitoring data of lakes from the last 20 years are also consistent with the Sulphur Deposition Hypothesis. In a multidisciplinary project we are making experimental manipulations of sulfur deposition, paleoecological reconstructions of lake DOC and land use, and investigating the ecological effects from increased lake DOC on plankton and submerged vegetation.

CORES, KIDS, CLIMATE AND THE K-T TO POINTS IN THE LEARNING'S School of Rock - 2007 participated in laboratory exercises and field work at the Integrated Ocean Drilling Program’s (IODP) Gulf Coast Repository at Texas A&M, then collaborated on curriculum activities for middle grade, high school and college students at their home institutions. Sample some simple classroom activities that introduce students to Deep Ocean Drilling, and examine field work developed at a late Cretaceous site in New Jersey.
INVESTIGATION OF MESOSCALE BIOLOGICAL INTERACTIONS WITHIN A CYCLONIC EDDY IN THE NORTH PACIFIC SUBTROPICAL GYRE

As part of the 2007 summer training course “Microbial Oceanography: from Genomes to Biomes”, hosted by C-MORE and sponsored by the Agouron Institute, we conducted a 10-day research expedition to study the physical, chemical, and biological properties in and around a cyclonic eddy located at 21.7°N 158.08°W in the North Pacific Subtropical Gyre. The location of the eddy was tracked using satellite imagery, shipboard ADCP measurements, and hydrographic and biogeochemical transects. We sampled inside and outside the eddy to compare microbial abundance, biomass, diversity, primary and secondary production, and export of C, N, P, and Si. We also conducted manipulation experiments to investigate bottom-up and top-down controls on microbial production and diversity. Primary production at the center of the eddy (85 mmol C/m²/d) was nearly twice that at the eddy’s periphery. While particulate silica export at 150 m showed a 3.8-fold increase from the periphery to the eddy’s center, carbon export was high (2.7 mmol C/m²/d) but relatively constant, with a corresponding high PSiPC export ratio (180 μmolSi/mmolC).

R., University of Alabama-Huntsville, Huntsville, USA, kkeiser@itsc.uah.edu; SSCOOP DISTRIBUTED INFORMATION MANAGEMENT SERVICES FOR COASTAL MODELING

The University of Alabama in Huntsville is developing a suite of advanced technologies to provide a data and information infrastructure for SSCOOP (SSURA Coastal Ocean Observing and Prediction). Through its SSCOOP program, SURA (Southeastern Universities Research Association) is developing a distributed coastal laboratory, linking oceanographic sensors, models and data. SSCOOP’s goal is to create a scalable, modular system for forecasting storm surge and wind-driven waves, as an Integrated Ocean Observing System (IOOS) test bed. UAF’s Scientific Catalog for Open Research Exchange (SCORE) includes an extensible catalog and inventory of SSCOOP models, forecasts and observations. An interactive user interface integrates semantic searching, browsing and data ordering across the catalog and distributed data archives. Remote software provides direct access to these capabilities in a service oriented architecture. SCORE provides the data and information management foundation for the SSCOOP cyberinfrastructure, which also includes data transport, translation, archives, application management, monitoring, validation and visualization. This infrastructure provides data and forecasts in near real-time, for more reliable, accurate and timely information to help plan for extreme events, facilitate safe maritime operations, and support coastal security.

L., Scripps Institution of Oceanography, La Jolla, USA, drudnick@ucsd.edu; AESS 2006: SUBMESOSCALE OBSERVATIONS OF RESTRATIFICATION AT A FRONT IN THE CALIFORNIA CURRENT WITH A LAGRANGIAN FLOAT AND TOWED PROFILERS

Observations of physical characteristics along and across a front in the California Current were made during the AESS 2006 project, focusing on the interplay of dynamics between mixed layer turbulence and submesoscale features. A neutrally buoyant Lagrangian float built at APL/UW measured temperature, pressure and salinity, surface wave spectra, and acoustically tracked position along the front, while the Triaxus towed profiler resolved the three-dimensional volume around the float in the drifting reference frame. A second towed profiler executed larger scale surveys focused on characterizing mesoscale variability associated with the front. Taken together these measurements document frontal evolution at 5 - 10 km scales. The analysis of the combined data sets is compared to existing operational models to assess how well current models simulate the observed mixing and restratification.

Greb, S. B., Wisconsin Department of Natural Resources, Madison, USA, steven.greb@wisconsin.gov; ADVANCING THE USE OF REMOTE SENSING FOR WATER QUALITY

In March of 2007, a workshop on Inland and Nearshore Coastal Water Quality Remote Sensing was held by the Group on Earth Observations (GEO). The goal was to bring together remote sensing data providers and expert users to improve our ability and capacity to remotely assess and monitor inland and nearshore coastal water quality. More specifically, the objectives were to evaluate existing and planned remote sensing capabilities; identify gaps relative to user needs in the acquisition, processing, distribution and utilization of remote sensing data and derived products for water quality research and applications; and formulate potential solutions. This paper presents the outcomes and recommendations of the workshop. The author also presents one example of closing the gap between providers and users in a collaborative effort involving the university, management agency and user groups in Wisconsin. Joining, this group is producing state-wide water clarity maps from remote sensing data (LandSat) and in situ measurements.

Variable sea ice duration, low seawater temperature, and low zooplankton populations in the spring in the northern Bering Sea result in high export of labile organic carbon to the sediments. Both sediment oxygen uptake (short-term indicator of carbon supply to the benthos) and benthic biomass (longer-term indicator of carbon export) respond at different time scales to organic carbon reaching the sediments. Approximately 60 experimental stations were occupied in 2000 and 2007 on USCGC Healy as part of a continuing multi-decadal effort to assess status and change in the highly productive northern Bering Sea benthic ecosystem. Sediment oxygen uptake ranged from c1-27.8 mmol O₂ m⁻² d⁻¹ and reoccurrence of some stations during the cruise facilitated tracking the timing and impact of export production on the benthic sediment as sediment oxygen uptake rates increased following low carbon export from the spring bloom. Measurements of benthic infan- nual biomass (2.2–48.1 g C m⁻²) show that the dominant bivalve, polychaete and amphipod
communities vary depending upon overlying water masses and sediment type, but overall biomass has declined, possibly as a result of changing environmental conditions.

ENGAGING TEENAGE GIRLS IN THE OCEAN SCIENCES VIA THE OCEANOGRAPHY CAMP FOR GIRLS: BARRIERS, SOLUTIONS, AND SUCCESSES
This presentation will provide an overview of the barriers encountered, solutions, and successes experienced during the 17-year voyage of the Oceanography Camp for Girls. This NSF model program provides an excellent case study of how to provide an inclusive science program for minority and non-minority students of multiple learning abilities. We will share what has worked, what has not, and what key elements have led to sustained success. Evaluations indicate that intervention has made a difference. Alumna have: 1) taken on math and science courses in high school; 2) gained a realistic and positive image of science and scientists; 3) improved their understanding of the research process; and, 4) strengthened their commitment to pursue careers in math, science or engineering. Nearly 20% of alumna in college are pursuing science-related degrees. Particular attention will be paid to the role of the participating ocean scientists in this program. We will provide a number of strategies developed to achieve successful inclusion of scientists and learners through group learning, team building, open dialogue, positive asset building, and introspection.

THE ROLE OF SYMBIOTIC BACTERIAL SIDEROPHORES IN PROMOTING PRIMARY PRODUCTIVITY
The development of primary productivitiy in the marine environment is critical to the marine food web and the sequestration of anthropogenic CO₂. While phytoplankton fix CO₂ in to biomass, the remineralization and major biogeochemical cycles are driven by bacterioplankton – the microbial miles that surrounds phytoplankton at various spatial scales. While phytoplankton cells in the field and laboratory culture act as ‘hot spots’ for bacterial activity because of the exudates they excrete, emerging evidence suggests that some bacterial associates of phytoplankton are important to the growth and physiological well-being of algal cells. However, our understanding of the nature of such inter-kingdom interaction is still in its infancy. One hypothesis for such a phenomenon may be that phytoplankton ‘hijack’ iron, an element that often limits their growth, from extracellular siderophores produced by bacterial associates. Here we report the isolation of a range of Marinobacter species from different phytoplankton cultures, and the chemical isolation and characterization of the extracellular siderophores produced, coupled with genomics analysis of one producing strain. Strains belonging to two species clusters were found to produce the dicarboxylic siderophore, Vibrioferrin (VF), and contained genes necessary for its production. Our evidence suggests that VF could have a role in supplying phytoplankton with their limiting nutrient.

FRONTLINE MENTORING: DEVELOPING EFFECTIVE MENTOR TRAINING FOR POST-DOCTORAL FELLOWS AND JUNIOR FACULTY
Post-doctoral fellows and junior faculty, our front-line mentors, benefit from training in a variety of mentorship skills, teaching pedagogies and assessment strategies, enabling them to effectively meet the challenge of broadening access and participation within the ocean sciences throughout their careers. The Center for Coastal Margin Observation and Prediction (CMOP) piloted a REU program which includes a training component designed to build mentorship skills and foster an interdisciplinary, student- and team-centric approach. Participating post-doctoral fellows and junior faculty received materials and training related to various student development theories, enabling them to collectively design an internship curriculum which features the development of laboratory skills, writing skills, fieldwork techniques, presentation skills, and individual and group problem-solving skills. The REU Program included a structured process for individual and collective communication and evaluation of each student and of the cohort as a team. Challenges include incorporating senior faculty mentors, working across institutional boundaries, and finding time for intentional collaboration in a busy academic environment. With more development and assessment, we expect mentorship training to become an integral part of CMOP academic culture.

OBSERVATIONS OF THE SPRING BLOOM ON THE INNER SCOTIAN SHELF
The 2002 spring bloom on the inner Scotian Shelf is examined using a mooring array deployed to provide physical, chemical and biological measurements with high temporal and vertical resolution. These measurements are complemented by bi-weekly occupations of a station near the mooring site (HL2). Results show that coastal upwelling played an important role in the initiation of the spring bloom near the coast and, during this period, very strong horizontal gradients in peak chlorophyll were observed. The bloom at HL2 is sustained for most of the mooring period with peak chlorophyll levels reaching 6 mg m⁻³. Following the draw down of nutrients in the upper 20 m of the water column, the surface bloom continued for 9 days and then disappears at the surface but remains at the depth of the nutricline (30-50 m). Mesozooplankton biomass does not change significantly until the very end of the mooring period indicating the grazing by this component of the zooplankton may not have had as important a role in the termination of the bloom as the exhaustion of near-surface nutrients.

MULTIPLE REGRESSION MODELS FOR HINDCASTING AND FORECASTING MIDSUMMER HYPOXIA IN THE GULF OF MEXICO
Statistical models suggest that spring nitrate load from the Mississippi River and climatic/hydrologic variations in the Basin explain much of the variability in midsummer hypoxic zone area in the Gulf of Mexico. However, managing nutrients across the Mississippi River Basin requires improved understanding of the relative importance of river flow and riverine nitrogen and phosphorous concentrations since both are important in biogeochemical processes leading to hypoxia. Stepwise multiple regression analysis and error estimation was used to evaluate relationships between Mississippi River flow, in-stream N and P concentrations and the midsummer size of hypoxia. Up to 25% of the variability in midsummer hypoxia was explained by river flow alone. Multiple regression relationships incorporating May flow, May nitrate and February total phosphorus concentrations explained up to 60% of the variation in midsummer hypoxia. Model hindcasts suggest that significant hypoxia was present back to 1950. Monte Carlo simulations were used to forecast the effects of changing river flow and reduced N and P concentrations on hypoxia, and included an evaluation of uncertainty resulting from both natural variability and limitations of model skill.

Janicki, A., Janicki Environmental, Inc, St. Petersburg, USA, JanickiEnv@aol.com

REVERSAL OF EUTROPHIC CONDITIONS IN TAMPA BAY, FLORIDA, USA
Recovery of seagrass coverage in Tampa Bay, Florida to levels observed in 1950 (15,400 ha) is a long-term goal adopted by local, state, federal and private partners participating in the Tampa Bay Estuary Program. Nitrogen controls initiated in 1980 and continuing through progress (from wastewater treatment facilities, stormwater treatment, fertilizer manufacturer, and power plants) resulted in a 60% TN load reduction compared to the mid-1970s. As a result, annual water clarity and chlorophyll targets necessary to support seagrass recovery are being met, and seagrass coverage in 2006 was the highest recorded since 1950 (but still 5500 ha lower than 1950 coverage). The largest contributors towards future reduction targets are expected to be local power plant emissions controls and reuse of wastewater. However, reductions from many sources will be required to maintain the gains made towards reversal of eutrophic conditions in Tampa Bay, as population is expected to double within the next 10-15 years in the watershed. Public and private members of the Tampa Bay Nitrogen Management Consortium have pledged to collectively meet load reduction targets through 2012.

Gregg, W. NASA/GMAO, Greenbelt, USA, watson.gregg@nasa.gov

OCEAN COLOR CLIMATE CONDITIONS USING MULTIPLE DATA SOURCES AND MODELS
The satellite ocean color data record spans multiple decades. It is potentially a critical resource for understanding how global ocean ecosystems have responded to modern warming. This time series is constructed from many sensors. Unfortunately, global and regional ocean color model estimates from overlapping missions show substantial biases, limiting their use to construct consistent data records. SeaWiFS and MODIS-Aqua differed by >10% globally in overlapping time segments, late 2002-2004. Thus each time series begins and ends with the launch of each mission. We report that mission-to-mission biases can be reduced by using a combination of in situ data and models. Using in situ data in new directly for bias reduction (i.e., calibration) and in post-processing analysis methodologies, along with data assimilation can produce a consistent long-term time series. We define ocean color climate records to meet the broad definitions of NRC, but additionally impose more stringent requirements specific to the science of ocean color: 1) all mission-dependent biases removed or quantified, 2) no obvious interannual discontinuities unattribut-

LARGE-SCALE AND SMALL-SCALE LABORATORY SIMULATIONS OF GRAVITY-DRIVEN COASTAL CURRENTS

Laboratory experiments simulating gravity-driven coastal currents are described. In natural environments such currents develop when estuarine fresh-water discharges into ocean. Results from three complementing experimental studies are discussed and compared to a new geostrophic model. The first study was conducted in a small-scale (1m diameter) water-filled rotating tank. The other two studies were carried out at the large-scale Coriolis turntables at Grenoble (1m diameter) and Trondheim (3m diameter). Currents were generated by releasing buoyant fresh-water continuously from a small source at the fluid surface. The height, width and length of the currents were studied as a function of the background rotation rate, the volumetric discharge rate at the source and the density difference between fresh and ambient fluid. The small-scale experiments and the Grenoble study focused on the simplest case of currents flowing along vertical coastlines in an, effectively, infinitely extended domain. The Trondheim study generalized these results by investigating how the dynamics are affected when currents flow along inclined coastlines with different inclination angles with respect to the horizontal.

RESOLVING THE UNRESOLVED COMPLEX MIXTURES OF HYDROTHERMAL PETROLEUM USING COMPREHENSIVE TWO-DIMENSIONAL GAS CHROMATOGRAPHY - TIME OF FLIGHT MASS SPECTROMETRY

Sedimentary organic matter in hydrothermal systems can be altered by high temperature fluids resulting in petroleum generation. These hydrothermal petroleums are compositionally similar to conventional oils except they often contain substantial mixtures of coal-tar products that produce a dramatically rising gas chromatogram termed an unresolved complex mixture (UCM). Little is known about these UCMs or why and how they form. Apolar fractions of four hydrothermal petroleum samples from the Middle Valley, Juan de Fuca Ridge and Escanaba Trough, Gorda Ridge in the NE Pacific Ocean and the Guaymus Basin, Gulf of California were analyzed by comprehensive two-dimensional gas chromatography-Time of Flight Mass Spectrometry (GC×GC-ToFMS). The GC×GC chromatograms of these samples elucidate two hydrocarbon subsets. The first consists of common hydrocarbon series such as n-alkanes, naphthalenes, steranes, and hopanes. The second subset is dominated by UCM forming compounds, which elute as continuous series of configurational isomers that become increasingly refractory with increasing chain length. The effect of estuarine fresh-water discharge to the coastal ocean offshore northern Puerto Rico was studied using long-term time series CTD profiles, dissolved oxygen and temperature data, and observations from a nutating benthic sediment trap located at 17°13'N, 66°10'W. In this highly productive area, bacterial respiration rates range from 3 to 4 mmoles of CO₂ m⁻² h⁻¹, which is comparable to rates reported for tropical coastal oceans. The CTD profiles revealed a distinct seasonal cycle in the vertically integrated (0-250 m) salinity and nutrients, with low values in summer and high values in winter. The high nutrient and oxygen levels in summer are likely due to enhanced upwelling and increased photosynthesis. The sediment trap data revealed a seasonal cycle in the cumulative flux of particulate organic carbon (POC) and nitrogen (N), with high values in summer and low values in winter. The summer high POC flux is likely due to enhanced primary production and increased resuspension of sediments from the bottom. In contrast, the winter low POC flux is likely due to decreased primary production and reduced resuspension of sediments. The seasonal cycle in the cumulative flux of dissolved inorganic nitrogen (DIN) is more complex, with high values in spring and low values in summer. The spring high DIN flux is likely due to enhanced nitrification and enhanced resuspension of sediments from the bottom. In contrast, the summer low DIN flux is likely due to enhanced denitrification and reduced resuspension of sediments. The seasonality of the cumulative fluxes of POC and DIN is likely due to the combined effects of seasonal changes in upwelling, resuspension, and primary production. The seasonal cycle in the cumulative fluxes of POC and DIN is likely due to the combined effects of seasonal changes in upwelling, resuspension, and primary production. The seasonal cycle in the cumulative fluxes of POC and DIN is likely due to the combined effects of seasonal changes in upwelling, resuspension, and primary production.
Food webs on sand shoals may differ substantially from off-shoal locations, because the shallowness of depth and sandy substrate supports the growth of benthic microalgae (BMA), which may serve as an important benthic carbon source rare or not present in the phyto- detritus based benthos of deeper waters. Carbon stable isotopes of BMA are typically different than phytoplankton. Consequently, if importance of BMA and phytoplankton as basal carbon sources differs between on and off shoal locations, it should be reflected in the isotopic values of consumer tissues. To compare benthic food webs on shoal and off-shoal locations, δ13C and δ15N values were determined for several species from multiple trophic levels. Preliminary results indicate δ13C for BMA (-196) and phytoplankton (-197) are similar, while larger differences exist for δ15N (5.1 and 7.3 for BMA and phytoplankton, respectively) and, therefore, δ15N may be a useful indicator of basal food sources. Preliminary results indicated that the δ15N values of phytoplankton feeding mysids and barnacles were ~4‰ higher than sediment burrowers such as lancelets and sipunculids.

The influence of the Mekong River discharge (South China Sea) was investigated during its lowest annual outflow in April 2007. The river plays an essential role in providing nutrients for the adjacent sea. The effects of nutrient inputs (NO3, PO4, Si) on nitrogen fixation (< and >10µm) and phytoplankton community structure were examined. The influence of the Mekong River discharge (South China Sea) was investigated during its lowest annual outflow in April 2007. The river plays an essential role in providing nutrients for the adjacent sea. The effects of nutrient inputs (NO3, PO4, Si) on nitrogen fixation (< and >10µm) and phytoplankton community structure were examined. High nitrogen fixation rates were detected in both size fractions within a salinity gradient (15-33 PSU). Altogether, a clear shift was observed in the composition of phytoplankton (>10µm) from autotroph dominated towards filamentous cyanobacteria. Inside the river plume, Chaetoceros, Rhizosolenia and Hemiaulus dominated and diatoms/cyanobacteria associations were considered to be responsible for the N2 fixation. Nevertheless, the measured N2 fixation rates were in an equal range in both size fractions. Further offshore, at stations with low nutrient concentrations, Trichodesmium probably accounted for the fixation. The measurements indicate that the Mekong River plume sets favorable environmental conditions for diatoms/cyanobacteria associations nearshore.

ACQUISITION AND ALLOCATION OF CARBON IN BLEACHED HAWAIIAN CORALS

Temperature-induced coral bleaching threatens to significantly reduce coral cover globally within the coming decades. To assess why some corals appear to be more tolerant of bleaching than others, we investigated how carbon is acquired and allocated in bleached Porites compressa and Montipora capricornis corals using 13C-labeled bicarbonate in seawater and 15N-labeled nitrate as labeling techniques. Photosynthetically acquired carbon was taken up from bicarbonate by the zooxanthellae transferred to the host tissue, respired, and taken up by the skeleton at dramatically lower rates in bleached corals relative to controls, but was not incorporated into either the zooxanthellae or host tissue for long-term storage. In contrast, heterotrophically-derived carbon (i.e., rotifers) was rapidly translocated between the zooxanthellae and host tissues in bleached and non-bleached M. capricornis and non-bleached P. compressa (but not bleached P. compressa), and was not a source of carbon for calcification. Thus, long-term recovery from bleaching will depend on a balance to acquire fixed carbon via heterotrophy to support its tissues while bleached, and to regain photosynthesis in order to stimulate calcification.

CAN WE DETECT A DECadal TREND IN THE SOUTHERN OCEAN CARBON SINK IN DATA FROM THE INTERIOR OCEAN?

Oceanic models and atmospheric data have suggested that the Southern Ocean carbon sink has substantially weakened in the last few decades, primarily as a consequence of an intensification and southward shift of the westerly wind belt. This weakening carbon sink appears to be primarily driven by an anomalous outgassing trend of natural CO2. In the region south of 35°S, our model finds a total loss of natural carbon between 1980 and 2004 of nearly 4 Pg C. Detection of this trend in the available observations represents a formidable challenge, particularly given the presence of a substantial trend in the anthropogenic CO2. Preliminary model-based results suggest that the interior ocean changes associated with the Southern Ocean circulation trends tend to be restricted to the upper ocean, and leave distinct signals that could be exploited in the observations.

ESTIMATES OF RIVER DISCHARGE BASED ON REMOTELY SENSED SURFACE VELOCITIES AND WATER LEVELS

One promising technique for river runoff estimates from space is the retrieval of surface currents on the basis of synthetic aperture radar along-track interferometry (ATI). The German satellite TerraSAR-X, which was launched in June 2007, will permit ATI measurements. Based on numerical simulations, we present first findings of a research project in
which the potential of satellite measurements of various parameters with different temporal and spatial sampling characteristics is evaluated and a dedicated data synthesis system for river runoff estimates is developed. We address the achievable accuracy and limitations of such estimates for different local flow conditions at selected test sites. High-resolution three-dimensional current fields in the Elbe River (Germany) from a numerical model are used as reference data set and input for simulations of a variety of possible measuring and data interpretation strategies to be evaluated. For example, discharge estimates on the basis of measured surface current fields and river widths from TerraSAR-X and water levels from radar altimeter are simulated. We discuss the applicability of the measuring strategies to a number of major rivers around the world.

ASSESSING IMPACTS OF PROTIST MOVEMENT BEHAVIORS ON FORMATION AND DISPERSION OF THIN LAYERS AND OTHER FINE-SCALE STRUCTURES

Most protists and many other marine microorganisms use active swimming or buoyancy to escape overlying water masses and to search for food. Selective vertical movements can result in high locally aggregated concentrations of protists, as thin layers. However, other mechanisms, such as vertical variations in horizontal transport, can also cause such structures, and both demographic and physical mechanisms can act to disperse layers. It is difficult to understand or predict fine-scale patch dynamics without quantifying these mechanisms. To better assess conditions under which active movements might strongly impact thin layer dynamics, we quantified protist swimming in natural water samples, using laboratory-based observations of water samples with intact vertical structures and also using an in situ protist behavior observation platform. We used motion analysis to quantify swimming characteristics at the level of individual cells. Finally, we applied population-level modeling techniques and scaling analysis to assess impacts of cell-level movements. Our analyses suggest a delineation between regions of parameter space in which active swimming is, or is not, a significant contributor to thin layer dynamics.

TIDAL EFFECT ON THE DENSE WATER DISCHARGE: A MODELLING STUDY

Numerical studies are carried out to validate our hypothesis, that the tide-induced shear disturbance will not only augment the benthic layer thickness, but also greatly enhance the descent of dense water over the continental slope, based on our previous analytical studies. A primitive-equation, free-surface, coastal ocean model is employed to demonstrate the sharp contrast in the density distribution in model runs with and without tidal components. Results of control runs are consistent with Ekman dynamics theory and lab experiments, which predict dense water does not descend beyond the upper slope. Hence Ekman dynamics is not sufficient for its descent, as dense water would be quickly neutralized through strong diapycnal mixing. Once tides are included, dense water discharge process is rectified in two major ways: 1) the dense benthic layer depth spans several times of the Ekman layer; 2) it descends all the way into the deep basin, far beyond tidal excursion. The separation of benthic layer and shear layer restricts the dilution of the benthic property, and greatly propels the descent process. The model output also agrees well with the observations from ANSlope.

MODELING OF SEDIMENT TRANSPORT MODES DURING CROSSTEX EXPERIMENT

During the CROSSTEX experiment, various cycles of shoewear and offshore sandbar movement in a large wave flume were documented. Throughout these phases of bed evolution, hydrodynamic information related to waves and currents, as well as bathymetric and suspended sediment concentrations were collected. The present study evaluates occurrences of bedload and suspended load transport during onshore and offshore sediment transport events. Bedload will be estimated via an adaptation of the Meyer-Peter Muller formulation (Meyer-Peter and Muller, 1948). Suspended load will be evaluated with an advection/diffusion model (Fredsoe and Deigaard,1992). To drive these models, wave hydrodynamics are modeled using an extended Boussinesq equations model (Teran Cobo, 2007) and a phase resolving eddy-diffusive boundary layer model (Henderson et al., 2004). Undertow will be computed either from a circulation model like POM, or from recorded data. Comparisons between observed and modeled results for sediment concentration, sediment flux, and bathymetric change, but also wave height and water velocity, will be conducted systematically. Special consideration will be paid to identifying the dominant modes of sediment transport during the different phases of the experiment.

PSEUDOCALANUS IN SVALSWARD WATERS; DISTRIBUTION PATTERNS OF TWO SIBLING COPEPOD SPECIES

Marine copepods of the genus Pseudocalanus are very common throughout the northern hemisphere. They contribute considerably to plankton biomass and are important in the marine food web as a link between microalgae and planktonivores. Pseudocalanus consists of several sibling species, and two of them (P. minutus and P. acuspes) are known to inhabit the Svalbard area. These two species are hard to discriminate morphologically and are therefore often referred to as Pseudocalanus spp., ignoring potential differences in biogeochemistry and population dynamics. In order to discriminate between these species, we used a combination of molecular analyses, morphology and morphometrics and mapped the distribution of the two species in waters around Svalbard (78 degrees N); an archipelago surrounded by warm Atlantic waters on its western side and by cold Arctic waters on the east side.

A WATERSHED APPROACH TO MERCURY CYCLING AND TRANSPORT IN SOUTH CAROLINA

Concentrations of total Hg in water were determined from sites along a geographical gradient within South Carolina. Sites with differing watershed characteristics were chosen to identify potential factors governing the spatial variability of Hg levels throughout the state. Overall, there is a spatial west to east gradient in the state, with water column concentrations of fish and organic Hg (10-55 mg) and sediment Hg (0.1-5 mg). The river Q1 moves from the uppermost estuarine region to the eastern coastal floodplain region (Q2: 0.70; p<0.001). Correspondingly, 89% of the SC fish consumption advisories are located within these coastal flood plain regions. There is a significant correlation between increasing fish Hg concentrations and increasing percent wetland area across the state (Q2 = R2: p<0.001). A time series study of mercury speciation within a coastal flood plain river (25% wetland area) indicates that 70-90% of the total and methyl Hg are found in the <0.45 micron size class and dissolved methyl Hg concentrations range from 3-26% of the total Hg in the river and from 4-7% in the seawater end member.

CIRCULATION AND FLUX OF SUSPENDED-PARTICULATE MATTER (SPM) THROUGH THE CENTRAL CHANNEL, ILHA GRANDE BAY, SE BRAZIL

Ilha Grande Bay (IGB) is located in the southern tip of Rio de Janeiro state, SE Brazil. It is freely connected to the Atlantic ocean. In its central area lies a large, east-west trending island, which is separated from the continent by a narrow and deep feature, the Central Channel. IGBs eastern end is connected to Sepetiba Bay, a shallow, highly polluted environment and a potential source offine-grained, contaminated sediment. The chief motivation of the present study was to identify scenarios conducive to the advection of SPM from Sepetiba Bay into IGB through the Central Channel. A 24 m deep monitoring station was occupied by anchored boats in December 2005, September 2006 and March, April and July 2007 for 25 hours. Instrumentation included a 600 kHz Teledyne RD Stracp and a Seabird CTD integrated with a turbidity sensor (D&A Instrument OBS-3). Water samples were collected at several depths and filtered in the laboratory to determine concentration of SPM in mg/l; these values were then used to convert turbidity (OBS) and echo intensity (ADCP) into water column concentration of SPM.

HIGH ENERGY, WAVE-INDUCED TURBULENCE AND SLOPE FAILURE ALONG THE MISSISSIPPI RIVER DELTA FRONT

Seafloor sediment instability and slope failure adjacent the Mississippi River Delta Front (MRDF) has gained renewed attention with the passage of several recent tropical cyclones. Hurricanes Ivan (2004) and Katrina (2005) exacerbated prior MRDF shelf failures previously linked to (1) differential loading near river mouths; (2) sediment instability exacerbated by pore water and methane gas; or (3) wave action that weakened unstable sediments, all resulting in failure. This paper focuses on the seafloor morphology impact initiated by five major hurricanes to strike the MRDF from 1965-2005. A 26-km deep monitoring station was occupied by anchored boats in December 2005, September 2006 and March, April and July 2007 for 25 hours. Instrumentation included a 600 kHz Teledyne RD Stracp and a Seabird CTD integrated with a turbidity sensor (D&A Instrument OBS-3). Water samples were collected at several depths and filtered in the laboratory to determine concentration of SPM in mg/l; these values were then used to convert turbidity (OBS) and echo intensity (ADCP) into water column concentration of SPM.
From the river sources to the open sea, the European WFD constitutes one of the most

CORAL REEF ECOSYSTEM ASSESSMENT USING NASA AIRBORNE AVIRIS AND DCS IMAGERY

To adequately image through a water column and to delineate variation in coral reef ecosystem benthic types, sensors having high spatial, e.g., a Cirus digital camera system (DCS), and spectral, e.g., the Airborne Visible Infrared Imaging Spectrometer (AVIRIS), resolution and high signal to noise are needed. Further, there is a need to better understand the optical properties of coral reefs, seagrass, other benthic types, and water column constituents from field-collected data so current and future satellite and airborne remote sensing can be optimized for coastal zone ecosystem research and management. In August 2004, we flew the AVIRIS and DCS on a NASA ER-2 over the Florida Keys and Puerto Rico. In March 2005, we flew AVIRIS/DCS on the Twin Otter over Kaneohe Bay, Oahu. Also, in December 2005, we flew AVIRIS/DCS on the Twin Otter over Puerto Rico and the US Virgin Islands for assessment of the 2005 Caribbean coral reef bleaching event. For each of these deployments, we collected coincident spectral data from dominant bottom types and coral under various health conditions using a handheld spectroradiometer. These spectral data will be used to classify the benthic types within the AVIRIS imagery. An overview of the airborne missions and coincident field data collection will be presented along with preliminary image and field-collected spectral data products.

TAXONOMY OF OCEAN OBSERVATORIES BASED ON THEIR CAPACITY OF PARTICIPATION IN A VIRTUAL OBSERVATORY

Over the next few years, ocean observatories such as the NEPTUNE regional observatory will start generating a massive amount of data available to scientists, students, educators and the public at large. In order for the scientific community to perform studies at the global level on topics such as ocean temperature variances, they need to access transparently data and the associated tools from multiple observatories, using a virtual observatory model similar to the one in place for astronomy. This paper proposes a taxonomy of ocean observatories, based on their capacity of participation in a virtual observatory using criteria such as the level and type of services offered, the availability of data and the processing capabilities.

WAVE HEIGHTS FROM A 3-M DISCUS BUOY IN THE MISSISSIPPI SOUND - DURING HURRICANE KATRINA

In August 2005 the eye of hurricane Katrina passed 49 nm to the west of a 3-m discus buoy, in 20 m water depth, operated by the Central Gulf of Mexico Ocean Observing System (CenGOS). Buoy wave heights were measured with an onboard 6-axis accelerometer and from the displacement of a GPS antenna as measured by Real-Time Kinematic (RTK) GPS. The computed wave heights are compared to the nearby NDBC 42007 buoy and show reasonable agreement for wave heights less than 2-3 m. At higher wave heights there is a potential bias in the wave heights if the buoy’s heel is not accounted for. This is believed to be the result of swell in shallow water, a heel in the buoy caused by wind and currents, and the failure to tilt-correct the accelerometer data.

THE EUROPEAN WATER FRAMEWORK DIRECTIVE AS AN INTEGRATIVE APPROACH TO THE MANAGEMENT OF THE WHOLE AQUATIC ECOSYSTEMS.

From the river sources to the open sea, the European WFD constitutes one of the most ambitious acts for the integral management of the whole European aquatic environments, specially considering that it’s being carried out from an ecosystem perspective. The ecos-
carbon (DOC), colloidal organic carbon (COC), dissolved inorganic carbon (DIC), and total dissolved nitrogen (TDN). Column chromatography of DOC was lowest in February (344 µM) and highest in July-2007 (344 µM) with a yearly average of 301.3±2 µM. Percentage of COC (1 kDa-0.45 µm) was 61.3% based on the measurements of permeate time series samples and ultrafiltration permeation model. Average DIC concentration was 2460±280 µM with highest concentration (2975 µM) during low-dissolution (September) and lowest (1926 µM) during high-dissolution (January). TDN concentrations varied from 67 to 222 µM, with a mean concentration of 132446 µM. A general increase with increasing discharge. However, there is no correlation between DOC and discharge. Based on the correlation between instantaneous flux and corresponding discharge, annual export fluxes of DOC, DIC and TDN during 2006-2007 were estimated to be 1.45±E+15 gCyr, 9.11±E+15 gCyr and 1.01±E+15 gN/yr, respectively, compared to 2.13±E+15, 13.5E+15 gC/yr and 1.94±E+15 gN/yr using a long-term discharge of 18,280 m³/s between 1981-2005.

DIRECT NUMERICAL SIMULATION OF TURBULENT INTERACTING WITH AIR-SEA INTERFACE AT SMALL SCALES

The problem of turbulence interacting with an air-water interface is important to atmosphere-ocean momentum transport, gas transfer, and many other mixing and transport processes in air-sea interactions. In order to understand the fundamental dynamics of turbulence near the sea surface at small scales, we perform a mechanistic study using direct numerical simulation. We simulate the unsteady, three-dimensional Navier-Stokes equations subject to air-water free surface boundary conditions. Spatial scales are discretized with pseudo-spectral and finite-difference methods. Time integration is realized through second-order fractional step scheme. From the simulation data, substantial information on the statistics and the structures of the flow field has been obtained. In particular, coherent structures in the flow field are identified. Turbulent kinetic energy and enstrophy budgets are quantified. Finally, effects of turbulence structures on scalar transport near the air sea interface are illustrated and quantified.

SPATIAL AND TEMPORAL VARIABILITY OF THREE DISTINCT SATELLITE OCEAN COLOR ALGORITHMS TO IDENTIFY HARMFUL ALGAL BLOOMS OFF THE WEST FLORIDA COAST

Near real-time remote sensing imagery has been widely used to identify ocean surface features such as oil slicks, eddies, upwelling, river plumes and harmful algal blooms (HABs). Since toxic blooms of Karenia brevis are observed yearly in the west Florida coast, an accurate technique to remotely detect HABs is highly desired. A NOAA monitoring system identifies areas likely to be classified as HABs, but field samples are still required for confirmation. Two other recent approaches, also based on visible space-borne measurements, have shown promising results for HAB detection. The spatial and temporal variability of these three satellite products are examined to address two questions: 1) How effectively are HABs detected along the entire shoreline, from Key West to Cape San Blas? and 2) Are these algorithms successful year-round? The predictive success of these three satellite-based methodologies is evaluated by comparing with an in situ database of cell counts. Quantifying the uncertainties associated with these algorithms is important to provide guidance for resource management decisions to better plan mitigation actions.

DYNAMICS OF DISSOLVED NEUTRAL AND ACIDIC SUGARS IN SEAWATER

Carbohydrates are an important component of organic matter in the ocean. Originating from primary production, they are hydrolyzed by the phytoplankton cell as structural components and for energy storage, or released to the dissolved organic matter by exudation, leakage, grazing or cell lysis. It is generally accepted that dissolved carbohydrates (dCHO) are an important food source for heterotrophic organisms, especially bacteria. More recently, it was demonstrated that dCR, and particularly acidic sugars, are also involved in abiotic processes, such as the activation of carbohydrate colloids and their subsequent aggregation into gel particles, or trace metal scavenging. Understanding these processes is prerequisite to better estimate upper ocean particle dynamics and organic matter export. To ascertain dCHO-dynamics and their partitioning into gel particles, we measured the abundances of neutral and acidic sugars and transport-exchange vector (TEP) particles and their subsequent aggregation into gel particles, and field studies. Analysis of dCHO in seawater was performed using High Performance Anion Exchange Chromatography after desalination by dialysis and acid hydrolysis. Here, we show preliminary results on the composition and abundance of dCHO and TEP during phytoplankton blooms dominated by either diatoms or coccolithophores.

OBSERVED AND SIMULATED DAILY VARIABILITY OF THE MERIDIONAL OCEAN CIRCULATION CAYMAN - ASHES IN THE ATLANTIC

We compare a daily timeseries of the meridional overturning circulation (MOC) estimated from the UK/US RAPID/MOCHA array at 26N to two global circulation models: (i) the coupled climate model ECHAM5/MPI-OM, and (ii) the ECCO-GODAE state estimate. In ECHAM5/MPI-OM, the waters are up to 4C warmer and up to 0.5 more saline than the observations, depending on the depth. In ECCO-GODAE, the waters span the observed temperatures and salinities at all depths below 200m within the range of uncertainties estimated by Forster and Wunsch (2007). A decomposition of the MOC into Florida Current, Ekman and upper mid-ocean geostrophic transports yields a similar level of variability among all estimates: ECHAM5/MPI-OM reproduces the magnitude of the observed variability, standard deviations for the eight ensemble members differ by 1 by at most. ECCO-GODAE shows a smaller variability, but a correlation of 0.9 for the Ekman transport, and 0.6 for the MOC. In both models, the upper mid-ocean transport is closely approximated by the residual of the MOC minus Florida Current and Ekman transport. For future comparisons, we suggest to compare the upper mid-ocean transport from the observations to the residual transport in the models.

THREE-DIMENSIONAL MODELING OF NEARSHORE HYDRODYNAMICS DURING THE PASSAGE OF WEATHER FRONTS

A five day nearshore field experiment was conducted in December 2003 near Myrtle Beach, South Carolina, providing measurements of waves, currents and bathymetry concurrently with offshore data collection around a shoal. The present work uses two numerical models for simulations of nearshore hydrodynamics to study the comparison between large scale and nearshore flows during the passage of weather fronts. This study uses a Q3D nearshore model (SHORECIRC) and a 3D model (ROMS) with grids resolving the nearshore, using the results of larger scale models as boundary conditions. The wave model SWAN is used for wave transformation and ROMS also simulates large scale flows driven by tidal and wind forcing in Long Bay. Various conditions are simulated, including two frontal passages. The first storm generated waves from the south driving a moderate longshore current. The second front generated waves with a large angle of incidence from the north, driving longshore currents approaching 2m/s. Results from the models are compared with the measurements as well as inter-comparisons between the models to understand the differences between the three-dimensional and the quasi-three-dimensional models.

PREDICTING OYSTER LARVAE DISPERSAL IN PAMLICO SOUND FROM SURFACE DRIFT BUOYS AND CURRENT PROFILE OBSERVATIONS

Oyster restoration efforts in Pamlico Sound, NC are based on a network of oyster broodstock sanctuaries. The success of these efforts depends on the larval connectivity between these sanctuaries. We can predict oyster larval dispersal envelopes using both eulerian and lagrangian current measurements. Forward integration of the near-surface currents measured by an ADCP allows us to predict paths followed by passive particles. We compare the predicted paths to the actual paths taken by GPS tracked surface drift buoys. Because wind-driven currents are generally stronger near the surface, paths taken by these passive buoys represent the farthest distance oyster larva can travel within the estuary. Dispersal envelopes generated from the current profile data form a range of all possible locations oyster larvae might travel from a fixed location and assess connectivity among oyster sanctuaries constructed by the North Carolina Department of Marine Fisheries.

SALINITY BIAS IN LEVEL AND LAYER DATA ASSIMILATION RESULTS FOR THE TROPICAL PACIFIC

ENSO has a significant impact on climate variability throughout the world and so has been the key focus to improving coupled forecasts for the tropical Pacific. In previous work, we have shown that assimilation of salinity along with other key variables allow a temporary improvement in the initial state for ENSO prediction (eg. Hackert et al., 2007). Yet, biases in the salinity field and hence the subsurface density field in the ocean still exist. Therefore, we will perform a systematic evaluation of model salinity biases for the period 2002-present using OI (Carton and Hackert, 1989) of all available surface and subsurface salinity data (eg. Argo, XBT, TAO etc.). The assimilation biases that are included in this study are the NCEP Global Ocean Data Assimilation System (GDAS) and our Ensemble Reduced-Order Kalman Filter (ERKOF) results. GDAS is a level model (MOMS) which
assimilates Tz and synthetic salinity profiles from a local climatological T-S relationship using the OI technique of Drizler and Rosati, 1989, whereas EROF utilizes a sigma-coordinate model (Gent and Cane, 1989) which assimilates all available subsurface observations (along with SL and SST) using the Kalman Filter technique. Differences in model and assimilation methodologies will be discussed.

EFFECT OF SPATIAL AVERAGING ON SPECTRAL CHARACTERISTICS IN THE FREQUENCY DOMAIN OF IN-SITU VELOCITY DATA

Oceanographic velocity point sensors inherently average over some volume to obtain magnitude and direction while acquiring data at a prescribed sampling rate. Spectral analysis is subsequently performed on such data to derive turbulent parameters. Using measurements from the Atlantic continental shelf obtained using a submerged particle image velocimetry (PIV) system, whose data provides a spatial distribution of velocity at a specified sampling rate, permits investigation of the impact on the energy spectrum in the frequency domain due to spatially averaging the data. PIV data were spatially averaged at various scales, and energy spectra in the frequency domain were computed. Spatial averaging has a clear frequency-dependent impact on the energy level at frequencies lower than expected from a simple conversion of the space-to-time scales using Taylor’s Hypothesis. The non-local effect of spatial filtering in the frequency domain is the primary contributor to this result. This has important implications for spectrally derived turbulent quantities, especially for data collected at high frequencies using techniques employing large spatial averaging.

HIGH-FREQUENCY FLUCTUATIONS IN DENMARK STRAIT OVERFLOW TRANSPORT

The transport of Denmark Strait Overflow Water (DSOW) exhibits quasi-periodic fluctuations immediately south of Denmark Strait with periods of 2-4 days. These fluctuations are visible in satellite imagery of surface temperature which typically shows a train of cold tongues found southwest of Denmark Strait. They have also been observed as DSOW transport fluctuations by moored current meter arrays which show that the transport variability is similar in magnitude to the mean transport itself. Using 2-km resolution, 97-level regional circulation models we explore the kinematics of these fluctuations. The model solutions show realistic variability and clearly reveal how DSOW descends from the Denmark Strait sill in balanced flow in the core of the northerly high-salinity eddies. Lateral engulfment of ambient Fram water is also clear and seems to be the initial process that eventually leads to entrainment and mixing of ambient water into the DSOW plume. The model cyclones are associated with unambiguous signals in sea level and surface temperature. We discuss the prospects for processing the historical record of remote-sensing data at Denmark Strait to construct a time-series of daily DSOW fluctuations. The main challenge is to overcome the instrument noise in the altimetric sea level, but the satellite coverage is adequate to give a useful signal.

FURTHER IMPROVEMENT OF CLIMATE PREDICTION USING HADC3M

Changing ocean heat content is a key metric for global warming studies but its assessment is made difficult by variable ocean sampling and large advective changes in basin scale heat content on decadal timescales. We present an analysis of ocean heat content change based on isothermal depths and mean temperature above isotherms. We show that we can assess separate contributions to total heat content in this way and furthermore that these quantities have different spatial and temporal characteristics which allows upper ocean heat content to be assessed with reduced errors. We make comparisons of assessments from data with long runs of the HadCM3 coupled model under varying greenhouse forcing.

SHIFTING SURFACE CURRENTS IN THE NORTHERN NORTHEAST ATLANTIC OCEAN

Analysis of surface drifter tracks in the North Atlantic Ocean from the time period 1990 to 2006 provides the first evidence that the Gulf Stream waters can have direct paths to the Nordic Seas. Prior to 2000, the drifters entering the channels leading to the Nordic Seas originated in the western and central subpolar region. Since 2001 several paths have been present in the drifter tracks leading to the Rockall Trough through which the most saline North Atlantic Waters pass to the Nordic Seas. Eddy kinetic energy from altimetry shows also the increased energy along the same paths as the drifters since 2000. These near-surface changes have taken effect while the altimeter shows a continual weakening of the subpolar gyre. These findings highlight the changes in the vertical structure of the northern North Atlantic Ocean, its dynamics and exchanges with the higher latitudes.

PHYSIOLOGICAL AND MARINE CONNECTIVITY OF ANTARCTIC SHELF INVERTEBRATE FAUNA

Establishment of the Antarctic Circumpolar Current (ACC) and the Antarctic Polar Front (APF) are hypothesized to be barriers to gene flow into and out of Antarctic waters. Using a multidisciplinary approach that examines both larval distribution as well as the genetic
structure of marine invertebrate populations in Southern Ocean regions, the relationship between gene flow, potential barriers such as the ACC and APE, larval dispersal and geographic history were assessed. Results indicate that isolation has occurred in the past between the South American and the Antarctic continental shelves, but much more recently than dogma contends. Additionally, mtDNA sequence data reveal cryptic speciation in several species, implying that connectivity of populations of ancestral taxa was intermittent since the formation of the ACC and APE. Genetic characterization and temporal distribution of larvae have allowed further insights into the life history of Antarctic benthic forms. The assumptions commonly made about Southern Ocean oceanographic processes and their influence of biodiversity and historical connectivity will be revisited.

UNSUPervised THRESHOLDING AND Morphological PROCESSing FOR AUTOMATIC OUTLINE EXTRACTION
At least two software packages— DARWIN, Ecker College, and FinScan, Texas A&M exist to facilitate the identification of cetaceans—whales, dolphins, porpoises—based upon the naturally occurring features along the edges of their dorsal fins. Such identification is useful for biological studies of population, social interaction, migration, etc. The process whereby fin outlines are extracted in current fin-recognition software packages is manually intensive and represents a major user input bottleneck: it is both time consuming and visually fatiguing. This research aims to provide automated methods (employing unsupervised thresholding and morphological processing techniques) to extract cetacean dorsal fin outlines from digital photographs thereby reducing manual user input. Ideally, the automatic outline determination will improve the overall user experience and improve the ability of the software to correctly identify cetaceans. To assist with unsupervised thresholding, a new metric was developed to evaluate the

MECHANISMS CONTROLLING SEASONAL-TO-INTRAANNUAL MIXED-LAYER TEMPERATURE VARIABILITY IN THE EASTERN TROPICAL INDIAN OCEAN
Processes controlling seasonal- to intraannual-mixed-layer temperature (MLT) variability in the eastern tropical Indian Ocean are climatically important, but not well understood. We examined the regional MLT balance using an ECCO ocean data assimilation product, which satisfies heat conservation. We compare two sectors (90°-95°E, 0-5°S and 91°-94°E, 7°-10°S) within the traditionally defined eastern Indian Ocean Zonal Dipole Mode (IOZDM) anti-node (Saji et al, 1999), focusing on dominant mechanisms during the 1994, 1997 and 2006 IOZDM events. These two sectors differ due to local circulation characteristics and must be examined separately: if budget components are averaged over the entire anti-node, effects of regional processes that are important to IOZDM variability are obscured. On the seasonal time scale, surface heat flux assists and dominates MLT changes over the inner shelf, but subsurface processes play secondary roles. On intraseasonal scales, subsurface processes dominate cooling at (90°-95°E, 0-5°S), whereas surface heat flux counteracts cooling; both effects are larger in 1997 than in 1994 and 2006. Horizontal advection opposes interannual cooling at (90°-95°E, 0-5°S), but is the dominant mode of cooling at (98°-101°E, 7°-10°S) for all three events

CAN REMOTELY SENSE PARAMETERS, COUPLED WITH IN SITU MEASUREMENTS, BE USED TO ESTIMATE THE SIZE AND LOCATION OF HYPOXIA IN THE NORTHERN GULF OF MEXICO
The hypoxic area located west of the Mississippi River outflow in the northern Gulf of Mexico spans 12,000 to 22,000 km² annually. Since 1985, this hypoxic zone doubled in size (Rabalais et al, 2002). Management options to reduce the size of Gulf hypoxia focus on reductions in Mississippi River nitrogen loads (CENR 2000). Riverine nutrient input, chiefly nitrogen, stimulates primary production in the coastal ocean, and the resultant organic matter sinks below the pycnocline, formed from the summer stratification in summer months. Hypoxia occurs when respiration below the pycnocline, in the absence of surface mixing, exceeds oxygen replenishment. Current models for predicting the size and location of the Gulf hypoxic zone focus on riverine nitrogen as the primary input parameter and succeed in explaining up to 88% of hypoxic zone size (Turner et al. 2006; Scavia et al. 2004). Remote sensing data coupled with in situ measurements have been explored previously in the correlation of satellite-derived chlorophyll concentration with river discharge, nitrate load, and hypoxia (Walker and Rabalais 2006). Our focus is to investigate if hypoxia formation is associated with additional remotely sensed parameters such as sea surface temperature, sea surface height anomaly, and ocean color data products. We will employ time-series analysis of sea surface temperature changes, phytoplankton blooms, and other phenomena are correlated with the formation of the Gulf hypoxic zone.

MIXING AND DISSIPATION OF INTERNAL Mens WAV EMON ON A SHELF SLOPE
On the shelf slope north of Scotland the rate of turbulent kinetic energy (TKE) dissipation, calculated from density overturns, is 6±10^-4 W/kg. Using a standard mixing efficiency, this dissipation rate is equivalent to a diapycnal diffusivity of 10^-3 m^2/s, two orders of magnitude larger than typical open ocean background levels. The rate of TKE dissipation cannot be fully explained by local shear and strain measurements so we invoke a far-field source of energy, supplied in the form of internal waves, to drive mixing over the slope. The across-slope internal wave energy flux is 130 W/m^2 at semi-diurnal frequencies with 180 W/m^2 at diurnal frequencies. This can be reconciled with the TKE dissipation rate by assuming all the internal wave energy is dissipated in the ~4.5 km that the pycnocline intersects the slope. The rate of TKE dissipation inferred from this assumption is between 3 and 6×10^-4 W/kg ; comparable to the dissipation rate calculated from density overturns, and emphasizes the role of internal waves in the transfer of tidal energy, not just into the abyssal ocean, but around complex topography.

AN UPWELLING BESTIARY: OFFSHORE FLOW STRUCTURES REVEALED BY LONG-RANGE, HIGH FREQUENCY RADARS IN CALIFORNIA
As part of the Coastal Ocean Currents Monitoring Program (COCMP), two long-range High Frequency Radar (HF-Radar) units have been installed near Point Arena, California. Combined with standard-range systems, these units provide hourly estimates of surface currents from nearshore to 200km offshore. This radar installation provides one of the largest spatial footprints yet to observe ongoing, real-time maps of shelf and slope surface currents for this major upwelling center. Initial observations reveal a spatial complexity strongly hinted at during previous field programs (CODE, NCCCS, WEST). Coastal currents are not simply related to alongshore wind stress, as suggested by the canonical model of wind-driven upwelling circulation. Filaments from Point Arena, instabilities in the California Current, and mesoscale eddies all influence the currents. These flows impact shelf and coastal waters, leading to large currents even in the absence of strong winds. The relative contribution of such "ermote forcing" to surface currents varies with spatial location, season and year, but can be a substantial fraction of the momentum budget over much of the region.

SENSITIVITY OF WEST FLORIDA SHELF SIMULATIONS TO INITIAL AND BOUNDARY CONDITIONS PROVIDED BY HYCOM DATA ASSIMILATIVE OCEAN HINDCASTS
The influence of initial and boundary conditions on free-running West Florida Shelf (WFS) simulations is evaluated by nesting HYCOM within three data-assimilative ocean hindcasts and a free-running ocean simulation. The hindcasts were produced as part of the ongoing development of the Navy’s next-generation HYCOM ocean nowcast-forecast system. The evaluation is being performed by conducting nested free-running WFS simulations for 2004 and 2005 and comparing model fields to high-quality observations including ADCP moorings and coastal HF radar measurements. The WFS simulations were run from 2000 to 2005, run on the University of South Florida curvilinear coordinate system, but the nesting boundary was too far offshore to constrain simulated variability over the shelfbreak and continental slope. Another set of experiments was therefore conducted in a smaller domain to perform the evaluation. Initial analysis of 2004 results demonstrates that nesting boundary conditions have little influence on the dominant wind-drive currents over the inner shelf, but do have a modest impact over the middle and outer shelf. At several ADCP mooring sites, nesting within the presumably more advanced NCODA hindcasts slightly degraded the simulated velocity. This surprising result will be further explored, and full analysis of the 2004-2005 experiments will be presented, at the meeting.
SURFACE TROPICAL CALCAREOUS GREEN ALGAE RESPONDING TO OCEAN ACIDIFICATION?

Atmospheric CO₂ concentrations are increasing faster than expected on Earth for the last 650,000 years. Within this century, atmospheric CO₂ will be double pre-industrial levels. Because the oceans are the largest natural reservoir for CO₂, ocean chemistry will change more dramatically in the last 20 million years. Indeed, pH values of the open ocean have decreased by 0.1 since 1980 and are predicted to decrease 0.5-0.6 in the next 80 years. Ocean acidification will likely affect fundamental geochemical and biological processes including calcification and carbonate sediment production. The east and west Florida shelves provide natural gradients from temperate to tropical carbonate sedimentation; these gradients provide natural laboratories to examine the effects of ocean acidification on aragonite production by calcareous green algae. Scanning electron microscopy can reveal ultrastructural details of calcification. Comparison of Halimeda spp. from archived samples collected more than 40 years ago, with specimens collected in ongoing studies, are indicating the influence of declining carbonate saturation over this time span; both sets of samples will provide data for future comparisons.

SHORT-TERM SEDIMENT DEPOSITION IN A DELAWARE ESTUARY SALT MARSH

The purpose of this study was to determine the relative influences of suspended-sediment concentration (SSC), settling velocity (from particle size) and hydroperiod on tidal deposition rates during a spring tide in a section of the S. Jones River marsh (Delaware). Wind samplers, sediment traps, water-level recorders and a LISST-100 particle-size analyzer were deployed on Spartina alterniflora marsh for five days with samples recovered daily. SSC decreased exponentially from the river levee to marsh interior; and a similar trend was observed for tidal depositional fluxes of sediment. Hydroperiod ranged from 4 to 10 hours. The median grain size of in-situ particle aggregates measured by the LISST (66-170 microns) was about seven times larger than the median of disaggregated samples collected at the same site, and the disaggregated grain size of freshly deposited sediment (10-27 microns) did not vary significantly within the study area during the experimental period. Given the limited spatial variation in particle settling velocity (size) and hydroperiod, it is concluded that the across-marsh SSC gradient was the primary control on observed patterns of sediment depositional flux during the experimental period.

REDUCING BARRIERS TO ACADEMIC ACHIEVEMENT AND MARINE GEOSCIENCES CAREERS: A MODEL MIDDLE SCHOOL PROGRAM INTEGRATING GEOSCIENCES AND LITERACY

Concurrent with the growing sense of urgency to improve geosciences education, high stakes accountability systems have led to a decline in K-8 science teaching and learning, especially for underrepresented minorities. Poor literacy skills serve as a barrier to participation in science even though science has great potential to improve students'literacy skills. Our presentation describes an NSF-funded project to improve academic achievement of underrepresented middle school students through exposure to marine geosciences integrated with strategic literacy instruction to improve their comprehension and deep conceptual understanding. The project involves students in a super-enriched summer school academy taught by teachers engaged in intensive professional development, then guides these students into carefully articulated work and research internships, after-school programs, field trips and college counseling experiences. Teachers from the professional development effort continue providing enhanced science instruction throughout the academic year. This project will evaluate and document a model program comprised of a variety of critical elements that can be flexibly utilized by scientists and educators in myriad contexts to enhance diversity in the geosciences by improving students'capacity in literacy and science.

TIDES AND SALINITY IN THE FRASER RIVER PLUME

We utilize a unique dataset to assess the tidal effects on the mean salinity of a highly seasonal river plume. The dataset was obtained by an instrumented ferry which crosses the plume of the Fraser River, British Columbia, eight times per day over the years 2002-2008. Tidal effects for this time series were investigated by applying the Lomb-Scargle periodogram to plume average salinity. The spectrum showed strong lines in diurnal and semi-diurnal bands suggesting that tidally-driven mixing and advective processes are important in determining the character of the plume. The strength of the diurnal lines relative to the semi-diurnal lines is not proportional to their respective strength in currents. In addition, strong sidebands of the main tidal lines appear at 1/4 to 1 year, reflecting the strong seasonality of the flow of the unformed river. Finally, unlike many river plumes, little correlation was found with the wind. Using the ferry record, we estimate the fresh-water residence time in the plume to be about one day, leaving little time for substantial wind mixing.

OBSERVATIONS OF FINE-PARTICLE TRANSPORT AND DEPOSITION

We summarize results of flume experiments examining the transport behavior of dilute suspensions of non-cohesive silt, flocculating gelatin particles, and bedload. Smooth and rough-granular beds and a highly-permeable bed comprising layered-screen mesh. Considered in terms of a simple model incorporating simultaneous deposition and entrainment, fine-particle transport in suspension is well described by a dimensionless parameter S which reflects the ratio of flow-induced lift (Saffman 1968; J. Fluid Mechanics) acting on the submerged weight of individual particles. Gross rates of fine-particle deposition or arrival at the bed are similar for permeable and impermeable beds alike, scaling with Stokes settling in relatively slow flows but otherwise diminishing linearly with S. In the case of an impermeable bed, all newly-deposited particles reside on the bed surface and the rate of re-entrainment increases exponentially with S. In contrast, particles newly-deposited to a flat, permeable bed find significant refuge and thus show no discernible re-entrainment into suspension.

EDDY PARAMETERIZATION IN A WIND-DRIVEN CHANNEL WITH TOPOGRAPHY

The extent to which eddy parameterizations can help coarse-resolution ocean models approximate eddy-resolving dynamics is explored in the context of a wind-driven two-layer channel configuration. The model includes a meridional rim and mimics water mass conversion through interface damping at the northern and southern boundaries. It is found that in the presence of topography, the practice of diffusing layer interface heights degrades the coarse-resolution model solution due to its adverse effect on standing eddies. Diffusion coefficients that result in meridional and zonal transports comparable to those of eddy-resolving solutions need to be unreasonably high and alter the horizontal path of the current drastically. Instead of improving results through varying diffusion in space, we attempt to implement a machine-learning-based approach whereby the differences between the fields in fine and coarse-resolution versions of our model are interpreted as eddy fluxes. These fluxes are then related to the coarse-resolution fields through a statistical learning method.

SEDIMENT-WATER EXCHANGE OF METHYLMERCURY IN NEW YORK HARBOR DETERMINED FROM SHIPBOARD BENTHIC FLUX CHAMBERS

Benthic mobilization is an important pathway by which organisms are exposed to methylmercury (MMHg) produced in sediments. We have developed shipboard benthic flux chambers (SBFCs) to measure MMHg efflux from sediment cores, and used this method at locations in NY Harbor under summer and winter conditions. Fluxes determined with the SBFCs were compared with diffusion-based fluxes estimated from gradients of dissolved MMHg in the same sediments (SBFC:diffusional flux ratio). SBFC: diffusional flux ratios ranged from 0.9 to 1.4 in August and 2.3-4.3 in February. SBFC: diffusional flux ratios were correlated positively with dissolved oxygen (DO) in bottom waters, suggesting that MMHg mobilization is largely diffusional when DO is less than about 80% saturation and enhanced at greater levels. This is consistent with the observed positive relationship between macrofauna abundance and DO. Thus, benthic MMHg mobilization fluxes, which are enhanced relative to diffusion when DO in bottom waters is near saturation, may be linked to increased abundance and/or activity of infauna that irrigate sediment. Improving oxygen conditions, therefore, could increase sediment-water effluxes of MMHg in NY Harbor and comparable coastal marine systems.

WHAT MAINTAINS THE SILICIC ACID PLUME AT 2.5 KM DEPTH IN THE NORTH PACIFIC?

Deep North Pacific waters contain a plume of high Si near 2.5 km depth. Although this plume was characterized by Talley and Joyce (1992), its dynamics remain incompletely understood. We have recently shown that sources in Cascadia Basin do not supply more than 3% of the input required to maintain the maximum. Sediment traps deployed across the N. Pacific indicate that BiS (biogenic Si) sinking below 1 km depth could dissolve to provide a sufficient flux, but that little dissolution occurs as they sink; dissolution must...
largely occur on the sea floor at depths >4 km. We propose that the plume at 2.5 km is maintained by dissolution of Fe on the seafloor, coupled with near bottom flow and local vertical transport near the Juan de Fuca Ridge. Localized transport should be driven by buoyancy added from below through geothermal heating, and from above by enhanced vertical mixing stimulated by topography. Transport lifts solutes added at depths exceeding 4 km, to the ridge crest near 2.5 km, where they subsequently spread throughout the North Pacific on isopycnals, forming the plume.

LEVERAGING UNIVERSITY UNDERGRADUATES TO DISSEMINATE OCEAN SCIENCES THROUGH ONLINE DISTANCE LEARNING

Ocean sciences can be disseminated widely via online instruction and distance-learning. COSEE-West and the College of Exploration provided an online workshop on coral reefs for K-12 science teachers, informal educators and the public that leveraged the manpower of undergraduate science majors enrolled in an upper division course, Tropical Oceans and Tropical Reefs, taught by Hanmer. The online workshop presented two research lectures by coral reef scientists and one lecture on the importance of their work to ocean science. Undergraduates who had earned high grades in Hanmer’s course were assigned K-12 teachers to mentor online, adding excitement and verve to discussions of the content. Hanmer added only one new lecture to the workshop; the students from his class provided most of the online mentoring. Subsequently these undergraduates gave talks in local schools for the two days and were role models for future ocean researchers to widely disseminate new discoveries beyond the scientific community, but if our impact is multiplied by our undergraduate and graduate students, we will reach many more K-12 teachers and students.

ESTIMATION OF HYDRAULIC PARAMETERS AND DISCHARGE OF THE GANGES AND BRAHMAPUTRA RIVERS FROM SHUTTLE RADAR TOPOGRAPHY MISSION DIGITAL ELEVATION MODELS

In this study, the potential of utilizing Shuttle Radar Topography Mission (SRTM) Digital Elevation Model (DEM) data to study the hydraulics of lowland, braided rivers of the Ganges-Brahmaputra basins was evaluated. Landsat TM images at 30m resolution were first classified to identify the water body from braided land areas for the estimation of hydraulic parameters. Water surface elevations measured from the SRTM DEM was found to have standard deviations of 5.59 m and 5.77 m for the Ganges and Brahmaputra rivers, respectively. The minimum reach length required for a reasonable estimate of water surface slope was found to be 131 km for the Ganges and 137 km for the Brahmaputra river. The water surface slope was estimated from a linear fit to the 8.45 cm/km for both rivers. Channel width was computed at each classified Landsat pixel along a center line obtained by threshold holding the Laplacian of an image containing the distance from each channel pixel to the nearest bank pixel. The hydraulic radius was then derived from the channel width, water surface elevation and in-situ bathymetry data. Using an estimate of Manning’s roughness coefficient n, the discharges for the braided rivers were derived and compared with measurements from calibrated rating curves during the low-flow (pre-monsoon) season of 2000.

DISPERSSION OF EGGS, LARVAE AND PELAGIC JUVENILES OF GRAND BANKS WHITE HAKE IN RELATION TO OCEAN CURRENT VARIABILITY

White hake (Urophycis tenuis, Mitchell 1815) on the southern Grand Banks are found at bottom depths from 50-800 m, associated with 4-8°C ambient temperatures. They are restricted to a narrow band along the southwest edge and into the Laurentian and Hermitage Channels where local bottom temperatures are warmest (> 4°C). We have investigated potential dispersion patterns of eggs, larval and juveniles under climatological monthly-mean circulation fields, M2 tidal currents and associated turbulent mixing, which were computed from a three-dimensional regional ocean circulation model. On the interannual scale, the teachers and were role models for future ocean researchers to widely disseminate new discoveries beyond the scientific community, but if our impact is multiplied by our undergraduate and graduate students, we will reach many more K-12 teachers and students.

THE BAMBOO WORM INVASION OF SAMISH BAY: ECOLOGY AND CONTROL OF CYLMENELLA TORQUATA IN A NORTHEASTERN PACIFIC ESTUARY

The bamboo worm, Clymenella torquata, is a tube-building polychaete native to the northwestern Atlantic. While not generally known for strong interactions, invasive C. torquata in the northeastern Pacific have impacted salt marsh culture operations. In Samish Bay, Washington, bioturbating worms destabilize sediments, thereby indirectly increasing mortality of oysters that subside under consolidated mud. The present study investigated the ecology of invasive C. torquata along beaches adjacent to an estzned shellfish farm to determine factors affecting worm distribution. At each survey station physical and biologi cal data were collected and compared to worm biomass and tube mass. Survey results corroborate previous observations that a significant negative relationship exists between C. torquata and sediment compaction/firmness; worms also also alter grain composition of the substrate. Biomass of C. torquata increases seaward perpendicular to shore, with highest worm activity at about +30 cm MLLW. In laboratory experiments, temperature affected burial speed and tube contraction rate, and worms produced highest-quality tubes in sediment ranging between 250-500 µm. Our work suggests that the distribution of C. torquata may be limited and physical and control measures might mitigate impacts on aquaculture.

SANDBAR FORMATION UNDER SURFACE WAVES - THEORY AND EXPERIMENTS

We report a combined theoretical and experimental study of sandbar formation under simple–harmonic surface waves. For coarse grains and weak waves, an established empirical rule of bedload transport is used with an asymptotic theory for the fluid flow. The surface waves are governed by potential theory and a depth-linear eddy viscosity is employed in the turbulent boundary layer at the seabed. The derived bed stress is used to predict the sand–bed evolution. Laboratory experiments and corresponding numerical simulations for both high and low beach reflection are discussed. For weak reflection, the shear stress associated with the return current is found to be important. Partial simulation of a field record in Cape Cod Bay is also described. The dependence of bar morphology on sediment grain size is examined experimentally. In particular, new quantitative data on sandbar formation and sediment sorting on a bed of mixed colored sands of significantly different grain sizes under standing waves is presented to motivate future study.

EVALUATION OF THE SAN FRANCISCO EBB TIDAL DELTA OVER THE PAST HALF CENTURY

The San Francisco River, situated in the central part of California, USA, is an extremely dynamic environment subjected to large waves and strong tidal currents that are amplified by the large tidal prism of San Francisco Bay and its narrow 1 km wide inlet beneath the Golden Gate Bridge. Wave heights commonly top 5 m during winter storms and peak tidal flows exceed 2 m/s at the Golden Gate. A multi-beam sonar survey recently mapped the bottom morphology in the region of the ebb tidal delta. The new survey enabled the calcu lated of seabed change that has occurred in the past 50 years, since the last comprehensive
survey of the area was completed. This comparison indicates that the delta contracted radially with an average vertical erosion of 60 centimeters equivalent to a total volume change of approximately 92 million cubic meters. Delft3D, a process-based numerical model, was applied to investigate the shape and evolution of the ebb tidal delta, and to explore the mechanisms behind the recent contraction of the delta. The quasi-equilibrium delta shape was determined given the tidal forcing, a simplified wave climate, and variable net sediment flux through the Golden Gate. The effects of changes in the tidal prism of San Francisco Bay are explored, as well as the relative contribution of wave energy and tidal currents to the shape and presence of the ebb tidal shalow and potential effects of rising sea level.

WATER QUALITY IN INDIAN RIVER LAGOON, FLORIDA: “WET” VS. “DRY” YEARS

Water quality in Indian River Lagoon (IRL) has changed significantly over the past eight decades due to watershed alteration and land drainage patterns. High-frequency water quality monitoring was conducted for two years at four sites. Year 1 had rainfall higher than the historical mean and related high runoff, due to tropical storms and hurricanes, while Year 2 had a severe drought (35% lower rainfall than historical mean). Reduced freshwater inputs during the “dry” year, relative to the “wet” year, resulted in an increased mean salinity from 25 to 32 psu and improvements in the three main attenuators of PAR (chlorophyll, suspended particulate matter, and sediment). These findings demonstrate the tremendous climate-related interannual variability in water quality and can be used in models of expected positive improvements in estuarine health following the reduction of freshwater inputs, which are recognized as the most significant human impacts on this estuary.

TEMPORAL VARIATION IN FOOD-WEB NITROGEN SOURCE IN THE NORTH PACIFIC SUBTROPICAL GYRE AS DETERMINED FROM COMPOUND-SPECIFIC STABLE NITROGEN ISOTOPE ANALYSES

Mesozooplankton biomass and abundance in the North Pacific Subtropical Gyre (NPSG), as measured by the Hawaii Ocean Time-series program at Station ALOHA (22.4°N, 158°W), has increased significantly from 1994 to 2005. We used amino acid- and species-specific stable nitrogen isotope analyses to determine if the increase in NPSG zooplankton populations was driven by changes in nitrogen source. Our analyses suggest that both biological fixation of atmospheric nitrogen and entrainment of nitrate from the main thermocline supported NPSG zooplankton food webs. However, nitrogen isotopic compositions of the copepod species Euchaeta rima, Pleuroeomorpha xiphias and Neocalanus robustus increased significantly from 1997 through the winter of 2000, indicating that entrainment of nitrate from the main thermocline was enhanced over this time period. Based on the zooplankton nitrogen isotope time-series and the concurrent changes in plankton community structure, we conclude that enhanced nutrient entrainment initiated a NPSG ecosystem shift in 1998.

SUPEROXIDE SOURCES AND SINKS IN THE GULF OF ALASKA

Superoxide radical can be produced in seawater by biological and photochemical mechanisms, and may play important roles in the redox or oxidation of trace seawater constituents. During a 2007 cruise to the Gulf of Alaska, we measured superoxide concentrations along with rates of production and decay, in surface seawater samples (0-50 m) using the MCLA chemiluminescence technique. Our study area included high-nutrient low-chlorophyll regions, coastal-offshore transects, and offshore regions influenced by transport of coastal water via mesoscale eddies. Sample were collected from GO-FLO bottles and a towed fish sampler. Superoxide concentrations and first-order decay coefficients were on the order of 40 to 500 pM and 0.002 to 0.02 s \(^{-1}\), respectively. Factors governing spatial and temporal variations in the production and decay of superoxide, and the resulting effect on trace metal cycling will be discussed.

EXCESS NITRATE IN THE UPPER THERMOCLINE WATERS OF THE SUBTROPICAL NORTH ATLANTIC: UNCERTAINTIES AND CONUNDRUMS

A well observed phenomenon found in the upper thermocline of the subtropical North Atlantic is an excess of nitrate relative to phosphate (given Redfield expectations). What is uncertain are the sources of this excess N. Moreover, the mechanisms for introducing it to the thermocline and the rates of input are also not well established. Analyses of various data sets suggest that the sources may be multiple (N fixation, DOM export via subduction, atmospheric deposition) and the rates of similar magnitude (10 \(^{-11}\) mol N yr \(^{-1}\)). Unfortunately, since the mechanisms allowing these distinct processes to similarly accumulate excess N in the thermocline are not known, we cannot be sure that our present understanding of the system is correct. In this presentation, we will assess the likely inputs, and consider the conundrums that remain in understanding excess N accumulation in the subtropical North Atlantic.

MASS TRANSFER IN CANOPY FLOW: AN INVESTIGATION OF THE EFFECT OF HYDROZOAN COLONIZATION ON THE GIANT KELP MACROCYSTIS PYRIFERA

Hydrozoan colonies on giant kelp form a sparse canopy that modifies boundary layer characteristics and mass transfer dynamics at the blade surface. This has important implications for kelp nutrient uptake, waste removal, and suitability of the blade as a microbial habitat. Controlled lab experiments were conducted in a recirculating flume on individual, bare and colonized kelp blades, under conditions of varying Reynolds number and colony density. Lab measurements included profiles of oxygen concentrations and velocity distributions. Field velocity was also measured within the kelp bed. Dimensionless canopy density (ad) values were 0.011 or less. Concentration boundary layer thickness (CBLT) was calculated using similarity groupings and a hyperbolic tangent fit. Results indicate that CBLT did not significantly depend on average bulk velocity, but CBLT is significantly greater with hydrozoan colonies that within a universal scaling relationship which describes concentration distribution as a function of distance from the blade surface is proposed.

INTERANNUAL DIFFERENCES IN SIMULATED PRIMARY PRODUCTION IN THE NORWEGIAN SEA CONNECTED TO VARIATIONS IN NAO

Along the Norwegian coast, from 60N to 70N, the primary production in 1995 and 1996 has been simulated using a primary production model coupled to a hybrid coordinate ocean model with horizontal grid resolution of 4.5 km. Over two years (1995/1996) was chosen, because the North Atlantic Oscillation (NAO) changed from positive value in 1995 to negative in 1996. Westerlies (which are strong during positive NAO years) introduces more arctic waters into the Norwegian sea, and limit the extension of atlantic waters. The NAO also influences the volume transport in the North Atlantic Current and therefore changes the distribution of nutrients. Preliminary model results show an earlier spring bloom in 1996 compared to 1995, this is not consistent with the observed values at station MIKE. The differences between observed and modeled results will be explained. The inconsistencies between modeled and observed results are probably caused by the depth of the mixed layer in the model, and runs with different mixed layer formulations will be performed to evaluate this.

WAVE FORCED SUB-AERIAL BEACH VARIABILITY, OCEAN BEACH, SAN FRANCISCO, CA

Sub-aerial beach surveys were conducted with differential GPS at Ocean Beach, San Francisco, CA, during 2005 and 2006 to determine the impact of various wave conditions at five morphologically unique reaches. The shoreline-normalized volume change was calculated from the survey data, as well as the change of the Mean High Water (MHW) line. An attempt was made to correlate sub-aerial beach response with the measured offshore wave conditions as well as numerical model derived nearshore wave heights. Direct correlations between either the volume or MHW line change between surveys with any of the offshore wave parameters (significant wave height, peak period, and peak direction) or the numerical model data yielded low R2 values. Multiple regression analysis on the most northerly reach of Ocean Beach gave an R2 value of 0.79 when the average wave height and average wave period between surveys is considered. The reason for the low correlation values on the rest of the beach is unknown, but is likely related to rapid beach recovery following storms and the temporal spacing of the sub-aerial surveys.

THE ROLE OF NUTRIENT GRADIENTS IN THE EPISODIC FORMATION OF THIN PLANKTON LAYERS IN MONTEREY BAY, CA.

Thin plankton layers are often embedded within steep nutrient gradients or associated with transient chemical plumes. However little is known about the mechanistic roles that chemical gradients play in the episodic formation and maintenance of productive, thin plankton layers in coastal waters. What are the critical temporal and spatial scales for the interaction of chemical gradients and such plankton patches? In order to answer these questions it is necessary to make high-resolution measurements of biological, physical and chemical data on comparable scales. Two multi-week summer-time field experiments were conducted during 2005 and 2006 in Monterey Bay as part of ONR's "Layered Organization in the Coastal Ocean (LOC0)" program. The objective was to monitor the vertical and horizontal gradients of nutrients associated with thin plankton layers that develop episodically in Monterey Bay. Multi-channel profiling nutrient analyzers were deployed on high resolution ship-board and autonomous moored profilers. The nutrient profiles were recorded simultaneously with bio-optical, chemical and physical parameters. The comparative observations on the variability of nutrient gradients and plankton patchiness during the two LOC0 field experiments harbor some interesting results.

AN INSTRUMENTED MODEL TEST BED FOR THE CAROLINAS COAST

An instrumented model test bed has been set along the Carolinas coast to evaluate coastal process modeling technologies. Initially developed to support modeling applications for the US Army Corps of Engineers (USACE) Morphos program, the test bed includes an extensive ground truth data archive, populated by wave, wind, water level and current observing assets operated by the USACE Field Research Facility (FRF) and various governmental and academic partners. Assessment and quantification of numerical model performance is accomplished with the Automated Model Evaluation and Diagnostics System (AutoMEDS). For any predicted quantity, AutoMEDS matches model predictions with observations, performs temporal correlation and quantile-quantile regressions, computes a variety of error statistics and evaluates overall model performance. The test bed has been used to assess the performance of an experimental SWAN forecasting system that is under development for the National Weather Service (NWS) and the North Carolina Floodplain Mapping Program. Model sensitivity runs have been initiated to identify prediction strengths and weaknesses and facilitate parameter selections for final model implementation.

LARGE EDDY SIMULATION OF UPPER OCEAN MIXING WITHIN A FRONT

Large Eddy Simulations (LES) techniques are used to study upper-ocean mixing in a well-sampled front off Monterey measured during the summer of 2006 as part of the AEOS experiment. A period of driven mixing was followed by rapid restratification of the wind layer. Representative horizontal stratification due to gradients of temperature and salinity within the front are incorporated as a background in otherwise periodic realizations of the dynamics between O(1) and O(1000) m length scales. During the mixing phase, cross frontal turbulent horizontal fluxes induced by wind-driven vertical mixing are shown to be significant, relative to what the fluxes would be in a regional-scale model where horizontal eddy diffusivities are as low as 1 to 10 m/s. Turbulent horizontal fluxes of similar in magnitude are also induced in the along-front direction (i.e. they do not down-gradient). These lateral turbulent fluxes are found to increase with LES domain size, consistent with the expectation that subgrid fluxes in a regional model should decrease with increasing grid resolution.

HARBOR SEAL MOVEMENTS AND HOT-SPOTS IN THE GEORGIA BASIN REVEALED THROUGH THE USE OF SATELLITE-TELEMETRY

Research in the Georgia Basin, Pacific Northwest, previously suggested that male harbor seals (Phoca vitulina) more <28km from their haul-out site during breeding. However, no data exist on movements of males or females at other times of the year. We employed satellite-telemetry to describe movements of harbor seals in the region during spring and summer. Twenty harbor seals were equipped with SPOTOS and SPLASH tags (Wildlife Computers) during April and May 2007 at three sites: one rocky site (n=5,1M,F) and one mudflat bay (n=3,2M,1F) in northern Puget Sound, and one rocky site in SE British Columbia (N=8M). Preliminary results indicate an average transmission length of 110 days (sd=32, n=30). Seals from rocky sites traveled distances >125km (n=6), with 78% of seals traveling farther than 28km. Additionally, they were found to excursion to the outer coast, an unexpected behavior as the inland and coastal seals are genetically distinct stocks. Conversely, all but one seal from the mudflat site moved <22km from the tagging site. Data suggest that regional seal movements are highly variable and long-term monitoring is needed to accurately assess hot-spots.

MEASURING BIOAVAILABLE HYDROCARBONS IN THE NEARSHORE BEAUFORT SEA: COMPARISON OF CAGED MUSSELS (MYTILUS TROSSULUS) AND SEMIPERMEABLE MEMBRANE DEVICES (SPMDs)

Measuring dissolved, bioavailable contaminants in seawater is a challenging task in any environment, but is even more problematic in the Arctic. As part of the U.S. Minerals Management Service (MMS) Continuation of Arctic Nearshore Impact Monitoring in Development Area (CANNIDA) multidisciplinary monitoring program, MMS undertook an investigation to compare bivalve (Mytilus trossulus) tissue uptake to passive non-biological Semi Permeable Membrane Devices (SPMDs). The primary objective of the comparisons were to determine which method best characterized bioavailable PAH assemblages in the nearshore Alaskan Beaufort Sea and to estimate relative contributions from offshore oil and gas development activities and other petrogenic (e.g. boat fuel) and biogenic (e.g. combustion PAH deposited from arctic aerosol into coastal soil) PAH sources. Exposure systems were deployed at locations proximate to an active oil production site and several reference areas with varying levels of human activity. Method comparison studies were conducted in 2002 and 2004. Subsequent mussel only deployments were performed in 2005 and 2006. Both systems provided data useful in assessing environmental impacts of oil and gas development activities.

LONG-TERM TRENDS OF PHYTOPLANKTON IN CHESAPEAKE BAY FROM IN-SITU AND REMOTE OBSERVATIONS

We draw on historical and recent data on floral composition, biomass, and primary productivity in Chesapeake Bay to quantify long-term trends against a backdrop of strong climatic forcing that evokes a high degree of interannual variability in this dynamic estuarine ecosystem. Data sources include historical observations (1950-1983), monitoring cruises (1984-present), individual research programs (1982-2005), and aircraft remote sensing of chlorophyll biomass (1989-present). Decadal patterns of chlorophyll in the Bay are described, reflecting variability of freshwater flow and the effects on nutrient loading and light availability; seasonal to interannual variability of primary productivity; statistical methods to classify regional climate; coincident forcing of floral composition, biomass, and primary productivity by flow/climate; applications of historical and recent data in developing chlorophyll criteria to assess ecosystem responses to mandated reductions of nutrients. Data from these sources are combined with climate analyses and biogeochemical modeling to support our current understanding of phytoplankton dynamics in Chesapeake Bay, leading to predictive capabilities heretofore unrealized for this complex ecosystem.

DOMIC ACID ASSISTED COPPER UPTAKE BY A NATURAL COMMUNITY FROM HNLC WATERS

Domoic acid (DA), a marine algal toxin responsible for the symptoms of amnesic shellfish poisoning, is produced by various species within the genus Pseudo-nitzchia. While we recognize the toxic nature of this molecule, the physiological reason for its production is unclear but may be linked to its iron- and copper-binding capacity. At Ocean Station PAPA, a known high nitrate, low chlorophyll (HNLC) area, we tested the hypothesis that DA production in non-biological Semi-Porous Membrane Devices (SPMDs) was due to the presence of DA/copper complex and we analyzed the change in the community structure and activity in the uptake of copper. Using shipboard incubations, seawater was amended with DA and a DA/copper complex and we analyzed the change in the community structure and activity in the uptake of copper. Using shipboard incubations, seawater was amended with DA and a DA/copper complex and we analyzed the change in the community structure and activity in the uptake of copper.
Pseudo-nitzschia, suggesting that other organisms incorporated DA from the DA-copper complex. pDA was not found in the DA only treatments, lending support to the current hypothesis that DA is produced primarily as a means of sequestering copper.

CHARACTERIZATION OF VOLCANISM ALONG THE SOUTHEAST INDIAN RIDGE

With a constant intermediate spreading rate of 7.2 cm/yr, the SEIR allows for us to better isolate other determining factors of its diverse morphology. Increasing gravity anomalies, seismological evidence of a decrease in crustal thickness and geochemical data suggesting a constant mantle source have been used to estimate a 15°C decrease in mantle temperature from 100°C to 110°C. Seismic evidence also shows shallow magma chambers under portions of the ridge from about 100°C to 104°C. With this information, it has been argued that magma chamber presence in the SEIR changes at threshold mantle temperatures. Characterization of its volcanism supports previous claims of threshold changes in the intermediate spreading rate ridge processes and structure, provides further evidence for the importance of magma chamber presence and suggests that the Australian Antarctic Discordance extend 700 km farther west than previously thought.

COUPLING CLIMATE AND FISH POPULATION MODELS: AN EXAMPLE BASED ON A MECHANISTIC RECRUITMENT HYPOTHESIS FOR ATLANTIC CROAKER

Forecasts of the effect of climate change on fisheries resources are needed to ensure sus- tainable management in the future. Prior work with Atlantic croaker has hypothesized a simple mechanistic chain between recruitment, environmental variability, and population dynamics. Here, this mechanistic chain is incorporated into a population model based on an environmentally explicit stock recruitment function and then linked to global climate models to forecast population abundance and distribution under different scenarios of cli- mate forcing. The coupled population-climate model indicates that even though climate-driven environmental effects result in increases in spawning stock biomass, fishing mor- tality remains the primary driver of population abundance. Further, the model indicates that although croaker have been rarely caught in the northern Mid-Atlantic and southern New England waters in the past 100 years, that under high CO2 emission scenarios, they would become a more regular component of the region’s fisheries. The links between climate and population models developed here can be used as a framework for develop- ing climate forecasts for other species and in other ecosystems and thus contribute to the quantitative understanding of the effects of climate change on living marine resources.

Hare, M. P., Cornell University, Ithaca, USA, mhp7@cornell.edu

THE OYSTER AS BIONICINDICATOR OF POPULATION CONNECTIVITY AMONG SOUTHEASTERN FLORIDA LAGOONS

The eastern oyster (Crassostrea virginica) is a keystone species occupying estuarine habi- tats throughout the eastern and Gulf of Mexico coasts of the United States. The oyster’s pivotal role in these ecosystems stems from its reef-forming habit, providing habitat for diverse fauna, and the water clarifying accomplished by the enormous filter feeding capaci- ty of the oyster populations. In the semi-enclosed lagoons of the Indian River and south- eastern Florida, alterations to freshwater flow have had dramatic effects on habitat quality for oysters. Remnant and disjunct oyster populations now exist with an unknown degree of connectivity via larval dispersal. To map oyster population sources and sinks, genetic analyses were conducted on adult and newly-settled oysters collected within lagoons and near ocean inlets in 2007. Genetic differentiation among reproductive adult populations enabled the inference of source populations and migration routes for juvenile oysters dur- ing one recruitment season. Contemporary patterns of connectivity among lagoon oyster populations will inform oyster restoration efforts, help forecast the consequences of fresh- water drainage alterations, and provide testable hypotheses for general larval dispersal patterns among southeastern Florida lagoons.

UPDATE ON A SCALEABLE, REALTIME NETWORK FOR HF RADAR

Local, state, regional, and federal discussions directed towards the establishment of an Integrated Ocean Observing System (IOOS) continue to emphasize a desire for the in- stallation, development, and operation of a network of surface current mapping systems for use by a broad range of end users. Central to the operational success of a large scale network will be a scalable data management, storage, access, and delivery system. Staff at the Coastal Observing R&D Center at Scripps Institution of Oceanography are research- ing, developing, and implementing a prototype data management system for ocean current information derived from HF radar. The architecture of the HF-Radar Network lends itself well to a distributed and service-oriented networking approach for networking sensors on a global level. This joint university-NOAA partnership is focused on defining and meeting the expressed needs for an IT architecture supporting a national network of surface current mapping data systems, and takes advantage of the existing systems deployed in the U.S., including the California-wide Coastal Ocean Currents Monitoring Program. An update on the capabilities of the system, and opportunities for interna- tional involvement will be presented.

A MODELING STUDY OF RETRIEVAL BIASES

Comprehensive modeling studies have been carried out to simulate the expected clear-sky SST retrieval error in the AVHRR Pathfinder dataset. The simulations have used the full high-resolution (~1.25 x 1.25) ECMWF Reanalysis data (ERA-40), the JCSIA Community Radiative Transfer Model and the Pathfinder matchup dataset (1985 - 1999) to replicate the sampling and algorithm development methodology as closely as possible. The resul- tant retrieval coefficients have then been applied to the entire ERA-40 for the same time span, using the approximate overpass time for cloud-free grid cells. The resultant SST retrieval bias estimates, derived from over 150 million atmospheric simulations, are eval- uated. The retrieval biases are investigated to determine the underlying physical causes, including the effects of air-sea temperature difference and atmospheric absorption. The annual signal in bias is likely to have an impact on the determination of EOIs for historical SST reconstruction techniques.

BATHYMETRIC INVERSION FROM SHORE-BASED VIDEO IMAGERY

Models that predict nearshore behavior require as input boundary conditions the bottom profile. Traditionally, beach profiles are measured with differential GPS receivers mounted on amphibious vehicles or small boats. Logistical difficulties in obtaining frequent beach profiles over large nearshore areas have limited their acquisition to a few sites or inten- sive study periods. In this work, we evaluate the ability of remote imaging techniques to measure the beach profile using land-based video cameras. Such techniques have been developed for video systems on airplanes (Dugan et al., JGR, v.106 2001), from which the methodology used in this project is based. The airborne techniques will be adapted for use with a fixed, highly oblique video camera mounted on a 20 m high tower erected on the dune at the USACE Field Research Facility (FRF). Water depths are determined by estimating linear wave theory dispersion curves from image intensity energy surfaces in wavenumber-frequency space. Approximately 30 minute video time series over successive, overlapping square sections of the nearshore (100 m on a side) are obtained from a 6 m depth to near the shoreline. Comparison with bathymetry measured using traditional in situ survey methods by the FRF will be presented and a quantitative assessment of the accuracies and limitations of the video techniques discussed.

ESTIMATED RATES OF FORMATION OF SUBANTARCTIC MODE WATER AND ANTARCTIC INTERMEDIATE WATER IN THE SOUTHEAST PACIFIC

Large volume cold, fresh water masses of Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW) are formed inustral winter in the Southeast Pacific. SAMW forms at outcropping isopycnals within deep mixed layers (>400m) north of the Subantarctic front, and AAIW forms between the Polar and Subantarctic Fronts. These water masses fill the lower thermocline and intermediate oceans of the South Pacific extending to depths of 800-1000 m, ventilating the subtropical gyres. Analysis of physical properties from an August-September 2005 cruise found SAMW and AAIW deepening to 27.4 σθ and 27.06-27.20 σθ, respectively, with AAIW particularly near 27σθ across the gyre. CFC-11 and CFC-12 saturations at the source for both AAIW and SAMW were observed to be in close equilibrium (~95%) with the present atmosphere. Recent CFCs and WOCE Pacific data are used to estimate formation rates for SAMW and AAIW, which are proportional to the CFC inventories divided by the CFC concentrations as a function of time and equilibrium values.

GIS-BASED ANALYSIS OF NUTRIENTS AND MICROALGAL BIOMASS IN LITTLE LAGOON, ALABAMA, A POORLY-FLOUshed COASTAL LAGOON
We used a combination of flow-through and discrete sampling to map water quality and microbial abundance of three organisms in Littleton, AL. The measured parameters were temperature, salinity, and the concentrations of total phosphorus, total nitrogen and chlorophyll a. All data were matched with the appropriate coordinates and interpolated in ArcGIS 9.2 using Geostatistical Analyst. Interpolations and supporting plots show consistent trends between all parameters. There were strong gradients of salinity and temperature between the ends of the lagoon and the narrow neck that connects it to the Gulf of Mexico. High nutrient and chlorophyll levels were also found at both ends. This indicates freshwater inputs at both ends, which is inconsistent with surface maps. Chlorophyll was highly correlated with both TN and TP and increased significantly per unit N or P between the first and second sampling trips, indicating poor flushing. If the strong relationship between nutrients and microagal biomass (as chlorophyll) persists it may result in adverse effects such as blooms and hypoxia in the lagoon, given the very rapid population growth in the watershed.

PROTEINS AS BIOMARKERS: USING SHOTGUN PROTEOMIC MASS SPECTROMETRY TO TRACK THE FATE OF ALGAL PROTEINS IN MARINE SYSTEMS

Protein comprises the largest compartment of nitrogen in phytoplankton and thus the largest potential contributor of nitrogen to marine systems. Despite rapid recycling of protein in ocean waters, proteinaceous remnants have been recognised in particles and sediments. We have applied detailed peptide mapping and newly constructed proteomic databases to examine the suite of individual proteins present in the marine diatom Thalassiosira pseudonana, and their fate during degradation by natural microbial communities. The 23 day incubation was analyzed by tandem mass spectrometry followed by computational analyses with SEQUEST search engines specified to follow the fate of several hundred proteins and their potential for preservation. These results provide insight into the mechanisms by which intact proteins are transformed and the potential for identified protein sequences to be identified in the marine environment.

CONTROLS ON FLOW VELOCITY AND FLOW RESISTANCE IN THE PATTERED FLOODPLAIN LANDSCAPE OF THE EVERGLADES

Surface-water flow characteristics and vegetation density were measured in the Everglades at a location with a landscape pattern that was once common: flow parallel and topographically and vegetationally distinct ridges and sloughs. The purpose was to determine controls on velocity and flow resistance in a way that is generally relevant to floodplain wetlands with laminar to transitional flow conditions, and also to characterize Everglades flow in support of restoration. Continuous measurements over two wet seasons demonstrated that depth-averaged velocity through sloughs is approximately a third greater than on ridges and that unit-width slough discharge is approximately twice that on ridges. The difference relates to interactions between water energy slope, vegetation drag, and water depth, and also to differences in ground-surface elevation and vegetation architecture between the ridges and sloughs. These findings have general implications for predicting hydrological flows on heterogeneous, vegetated floodplains and also specific implications for wetland water managers seeking to manipulate flow velocity to optimize sediment entrainment, sediment redistribution, and other processes contributing to self-sustaining topographical variability and biodiversity in the Everglades.

TROPHIC CONNECTIONS IN COMPLEX FOOD WEBS: INSIGHTS FROM TERRESTRIAL ECOSYSTEMS

The cryptic behavior, feeding patterns and small size of terrestrial arthropods has led to the development of alternative techniques to study their interactions. Historically, observational, laboratory-based experimentation and visualization of gut or fecal content provided information pertaining to the foraging behavior of these organisms. However, over the last 60 years significant advances in biochemical and molecular technology have led to the integration of allozyme electrophoresis, stable-isotope analysis, radio-labeling and the use of polychlorinated biota in field ecology. Today, two approaches dominate: immunological detection of prey proteins using monoclonal antibodies and PCR-based detection of species-specific gene sequences. The use of these approaches is reviewed in the context of arthropod predation, and comparisons made to studies employing these techniques within marine and freshwater food webs. Furthermore, the ongoing use of antibody-based immunological approaches to study terrestrial trophic linkages will be examined and reasons for their use considered and contrasted to approaches employed in marine biology. Ultimately, although a multitude of approaches are available to ecologists, it appears likely that unless stage-specific interactions are being examined, specific PCR will dominate field research for the foreseeable future.

REAL AND APPARENT PHYTOPLANKTON BLOOM DUE TO ISLAND MASS EFFECTS

We recently reported a new aspect of Island Mass Effects: the Apparent Phytoplankton Bloom (APB) caused by phytoplankton growth (Deep Chlorophyll Maximum, DCM) as a result of advection to an island wake (Hasegawa et al., JMS in press). In addition to this, nutrients introduced by the vertical exchange stimulate phytoplankton growth; thus both the regular bloom and the APB contribute to the development of enhanced concentrations of phytoplankton downstream from islands. This is expected to influence the Princeton Ocean Model with a passive tracer and an embedded ecosystem model to investigate downstream dynamics given a geostrophically balanced incident flow with the DCM and a relatively small (~10km) island in a 1000m deep flat-bottom channel. Model results showed high tracer concentration in the lee of the island and in the generated cyclonic eddies as the APB. The cyclogeostrophic balance sustained the upwelled nutrient-rich deep water at the surface in the cyclonic eddies then resulted the "real" phytoplankton bloom which proceeded with time as the eddies flowing toward the downstream.

PREDICTED IMPACTS OF GLOBAL WARMING ON MARINE ECOSYSTEM WITH A 3-D HIGH-RESOLUTION ECOSYSTEM MODEL

To clarify the effect of global warming on marine ecosystems, we have been developing and improving a 3-D ecosystem model, COCO-NEMURO, which consists of NEMURO (North Pacific Ecosystem Model for Understanding Regional Oceanography) of PICES (North Pacific Marine Science Organization) coupled with COCO (CCSR Ocean Component Model). Hashioka and Yamazaki (2007) conducted a global warming experiment using a medium resolution version (1 x 1 degree) of COCO-NEMURO in the western North Pacific, and they showed a significant change on seasonal variation of the lower-trophic level ecosystem. As a next step, we developed a new high-resolution version (1/4 x 1/6 degrees) of COCO-NEMURO as an offline model in collaboration with climate modelers. We are currently conducting a 20th century experiment and a global warming experiment using physical forcing from a high-resolution climate model (the CCSR/NIES/FRCCG coupled Ocean-Atmosphere GCM: K-1 model, which contributed to the IPCC-AR4). Our model well reproduced the seasonal and regional variations of Chl-a concentration associated with meso-scale features in the present-day simulation. We will present the preliminary results of our global warming experiment.

TEMPERATURE EFFECTS ON DIETARY CHOLESTEROL DEMAND AND CHOLESTEROL CONTENT OF ZOOPLANKTON

Animals require cholesterol for growth, but many taxa are unable to synthesize cholesterol. Cholesterol stabilizes plasma membranes by countering fluidizing effects of elevated temperature and therefore dietary sterol demands and membrane cholesterol content may be affected by temperature. To assess temperature effects on cholesterol requirements, the copepod Eurytemora affinis was raised at 6° and 25°C on Synecococcus baijiensis supplemented with varying cholesterol levels. E. affinis achieves maximum growth rates at higher cholesterol concentrations at 25°C (+0.2 ug/l) than at 6°C (+0.05), indicating greater cholesterol demands at warm temperatures. We also investigated effects of acclimation temperature on cholesterol contents of zooplankton. Cholesterol levels vary over 3-fold (6 to 20 ug cholesterol/ug protein) among the tested species, and are positively correlated with maximum habitat temperature. Individual species responses to temperature acclimation, however, are variable. C. finmarchicus (CV and eggs) has 1.2-fold higher cholesterol levels following acclimation to high temperatures while Acartia tonsa and A. hudsonica have higher cholesterol contents at low temperature. It is not clear whether these results are due to habitat (neritic vs oceanic) or phylogenetic differences.

FORENSIC MODELING OF MARINE INVASIONS OF AN INLAND SEA USING ECOCLOGICAL CONNECTIVITY ANALYSIS

Range expansions of marine species are associated with natural and anthropogenic environmental change, as well as introductions. When the pace of invasion is rapid relative to ecological time a species is often judged to be introduced, even if the vector is not definitive. The cost of countering marine ecological invasions a posteriori is prohibitive,
so it is important to understand the epidemiology of the invasion before attempting intervention. We use marine ecological connectivity modeling to support such decisions.

Two marine species (Green crab and the MSX haplosporidian parasite) have appeared in a large, inland sea of eastern Canada during the past decade. The vectors are unknown, but the crab is thought to have arrived by larval transport from populations to the SW, while the oyster parasite is thought to have been introduced via ballast water. The distributions of both species in the 1200km2 area is in space-time, with environmental and recruitment limitations invoked but unproven. We use an advanced 3D numerical model of hydrodynamic connectivity and hydrology over a benthic habitat map to predict the vector of invasion and pattern and pace of post invasion dispersion through a heterogeneous ecosystem of variable exchange rates to test hypotheses about mechanisms of arrival and spread of these species through the Bras d’Or Lighthouse. Results of this forensic ecological modeling analysis are amenable to validation by population genetic methods.

CHEMICAL CHARACTERIZATION OF MUC (MOLECULARLY UNCHARACTERIZED CARBON) IN MARINE AND LACUSTRIINE SYSTEMS: A NEW ANALYTICAL APPROACH

We employ multidimensional NMR spectroscopy with High Resolution Magic Angle Spinning (HRMAS) and Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR-MS) of extracts to examine the molecular composition of MUC in marine and lacustrine sediments. HRMAS swells the organic matter by addition of a solvent (i.e., D2O, D6O-6) to the sample. We then analyze the extract by FT-ICR-MS to obtain highly resolved and accurately calibrated masses from which elemental formulas can be calculated. Elemental compositions of the peaks allow us to propose structures for the multitude of molecules present in the extract, thus providing molecular-level information that reflects the soluble extracts but also the insoluble components.

IRON FLUXES FROM THE SHELF REGIONS NEAR ELEPHANT ISLAND IN THE Drake Passage DURING AUSTRAL-WINTER 2006

Spatial distributions of dissolved iron, manganese and aluminium in the upper 500m near Elephant Island in the Drake Passage during the 2006 austral-winter are consistent with diagnostically-produced sedimentary sources and data obtained during the 2004 austral-summer. Near Elephant Island elevated levels of dissolved Fe (~5nM) and Mn (~30nM) above the shelf regions are well mixed down to the sediment-water interface. This contrasts with the Antarctic Circumpolar Current (ACC) where very low concentrations of Fe occur with high nutrients and low chlorophyll (HNLC). Phytoplankton abundance is greater offshore than on the shelf, the opposite of the austral summer; and suggestive of a system transitioning from light limitation on the shelf in winter to Fe limitation in the ACC during summer. High productivity downstream, east of the Antarctic Peninsula, is hypothesized to be the result of iron-replete water from the shelf regions being entrained into the HNLC and ACC water, a consequence of hydrographic forcing at the Shackleton Transverse Ridge. Calculations suggest that up to 28.5x10^3 moles Fe yr^-1 could be delivered to the iron-depleted ACC by this route.

SPRING BLOOM IN THE NORTHEASTERN LABORADOR SEA

A pronounced spring bloom occurs in the Northeastern Labrador Sea between March and May every year. The timing and intensity of this bloom may have a significant impact on the recruitment of zooplankton, and thereby for the ecosystem in the region. The near-surface stratification, required for the spring bloom, can be explained by a large influx of low-salinity water from the West Greenland Current into the bloom region. We find that this plume has a linear structure, for this influx to be the shedding of large anticyclonic eddies (Innringur Rings), which grab the low-salinity water of the Greenland shelf. The link between the biological production and the freshwater stratification opens a new window for monitoring the resistance-to-convection in the Labrador Sea, which is of significant climatic importance.

OBSERVATIONS OF THE SPATIAL VARIABILITY OF WAVE DIRECTIONAL SPECTRA IN A REGION OF HIGH SURFACE CURRENT VORTICITY USING WERA HF RADARS

A pair of WERA HF Radar (WERA) systems have been observing near-surface currents and archiving echo-Doppler spectra over the Southeast Florida shelf since June 2004 as a part of the Southeast Atlantic Coastal Ocean Observing System (SEACOOS). Wave parameters and directional spectra were extracted over the high surface current vorticity region adjacent to the western edge of the Florida Current. WERA observations were compared with in-situ directional spectral measurements. Additional comparisons with the SWAN directional shallow water wave model exploited the capability of the phased-array HF radar to provide spatial fields of both surface currents and waves. The directional spectra retrievals in the region of the in-situ observations were at large angles to both radar directions and therefore were sensitive to noise contamination. The temporal averaging of the signals was also relatively short (1024 samples, ~5 minutes). This necessitated the development of approaches to eliminate noisy Doppler spectra from processing before averaging multiple sample periods. Longer sampling intervals (2048 samples) and radio frequency interference reduction techniques were tested and their effect on data quality was assessed.

SEA STATE BIAS IN SATELLITE RADAR ALTIMETRY - REVISED

Sea state bias (SSB) is an effect in radar altimetry that arises both from the fact that wave troughs are better reflectors than wave crests, and from instrumental properties (tracker bias) with similar wavelength dependence, which results in a lower instantaneous sea surface height (SSH) measurement than what is actually there. Typically, SSB is estimated from altimetrically measured SSH, waveheight (SWH), and wind speed (U), differentiated over short times at the same geographic location. We investigate whether this commonly used approach may introduce a spurious value in the estimates of SSB. We use H1 not from any radar altimeter but from a simulation by the ECO2-2 high-resolution ocean general circulation (numerical) model. Therefore, our SSH should have zero SSB, except for random noise. We check this by using a simple parametric dependence on SWH and U, as measured by Jason-1 data during 2003, and consecutive cycle differences. Our preliminary estimates indicate that the factor multiplying the cross term on SWH and U is remarkably stable for any pair of cycles, and overall there is a spurious effect of the order of a fraction of a percent of SWH.

DECadal predictability of the Atlantic Meridional Overturning Circulation: Estimation of optimal perturbations for a coupled GCM

Future decadal climate forecasts are likely to rely on ensembles initialised using small perturbations to ocean and atmosphere conditions. In order to design efficient ensembles there is a need to identify those perturbations that grow most rapidly. Such perturbations may also be useful to identify where new ocean observations could improve forecast skill. We have employed two different methods to estimate such optimal perturbations for decadal forecasts of the Atlantic Ocean in the HadCM3 GCM. Firstly, we use linear inverse modelling (LIM) to find the initial condition anomalies which grow most rapidly under a particular norm of interest. Significant non-normal amplification is found in the GCM, which distinguishes this model from classical numerical experiments. We also demonstrate that optimal perturbations are sensitive to the forcing, and that basin-scale temperature and salinity fields. Secondly, we are using an ensemble based technique which, unlike the LIM approach, enables optimal perturbations to be estimated for specific initial conditions, e.g. a high or low overturning strength. The latest results will be discussed.

INTERNAL GRAY WAVES: ANALYSIS USING THE FOURIER, SCATTERING, AND CONTINUOUS WAVELET TRANSFORMS WITH APPLICATIONS TO LONG TIME SIMULATIONS

Analysis of tides and internal waves (IW) from model studies in the South China Sea is done using three techniques. We summarize results from standard Fourier techniques (the FFT), wavelet analysis with the wavelet continuous wavelet transform (WT) and the direct scattering approach (DSCA). IW success in elucidating underlying nonlinear dynamics. We apply these techniques to inverse modelling (LIM) to find the initial condition anomalies which grow most rapidly under a particular norm of interest. Significant non-normal amplification is found in the GCM, which distinguishes this model from classical numerical experiments. We also demonstrate multi-decadal predictability of the overturning strength, and of basin-wide temperature and salinity fields. Secondly, we are using an ensemble based technique which, unlike the LIM approach, enables optimal perturbations to be estimated for specific initial conditions, e.g. a high or low overturning strength. The latest results will be discussed.

SEDIMENT TRANSPORT PROCESSES IN LAKE ERIE

Time series observations of water temperature, turbidity, current velocity, and wave action were made at sites in the central (max depth ~25 m) and eastern (max depth ~55 m) basins of Lake Erie from September 2004 through October 2005. During the fall and early winter (Oct.-Jan.) increased turbidity in the central basin is correlated with wave and current activity, so most of the increases were due to local resuspension of bottom material. There
no evidence that resuspension occurred in deeper parts of the eastern basin. Instead, increased turbidity was due primarily to advection of material resuspended elsewhere. Wave action stopped after the lake became covered by ice in early February and did not recur until the ice melted. No sediment resuspension, and little advection of suspended material, was recorded during this interval. After the ice melted, smaller resuspension events were observed in the central basin until the water became stratified in mid June. After that time, no resuspension was observed until the lake re-mixed in late September.

TIDAL CURRENT SCOURING IN INDIAN RIVER INLET, DELAWARE
Swift tidal currents in the Indian River Inlet have generated conspicuous scour holes in dangerous proximity to bridge piers supporting a major coastal highway. It has been suggested that the presence of bridge piers developed the initial conditions causing scour and facilitated the subsequent deepening (to over 30 m) and migration of the holes to their present locations. Recently, current profile data was collected in the inlet using a boat-mounted ADCP over one complete tidal cycle in order to investigate hydrodynamic variability - specifically in the vicinity of the scour holes. Preliminary analysis of the data reveals significant three dimensional irregularities in the horizontal and vertical velocities that appear to be associated with flow constrictions and separations over and near the scour holes. Spatial velocity maps averaged over short time blocks will be presented and used to quantify flow variability in relation to tidal phase and bathymetry.

CIGUATERA POISONING: INCREASED INCIDENCE ASSOCIATED WITH CORAL REEF DECLINE?
Ciguatera toxins are produced by the dinoflagellate Gambierdiscus toxicus that is typically associated with benthic macroalgae in coral reef environments of the Caribbean and Pacific. These toxins accumulate in the tissues of herbivores that feed on these algae, and biomagnify through the food chain within tissues of larger predatory fish. Consumption of contaminated fish causes considerable morbidity in humans with incidence rates varying according to geographic location. G. toxicus distribution patterns have been linked to temperature, light and coral bleaching events, and continued degradation of coral reef environments. Global warming may favor its growth and lead to more frequent or larger outbreaks. This paper will examine the relationship between ciguatera outbreaks and various measures of coral reef health (e.g. bleaching history, percent coral cover) as well as other environmental measures such as sea surface temperature.

SEASONAL VARIATIONS IN PHYTOPLANKTON GROWTH AND MICROZOOPLANKTON GRAZING IN A EUTROPHIC COASTAL LAGOONAL SYSTEM IN SOUTH CAROLINA
Coastal S.C. is one of the fastest growing areas in the country. A byproduct of this growth is the construction of over 8,000 stormwater ponds, many of which are highly eutrophic and have large blooms of harmful algae (primarily dinoflagellates and raphidophytes). To determine the importance of microzooplankton grazing as a potential controlling factor of bloom formation/decline, we conducted dilution experiments in 2006 to 2007 in two detention ponds. Pond K1 is the end pond in a series of ponds and Pond K2 is a lone pond. Phytoplankton growth varied seasonally, ranging from 0.78 to 2.14 d−1 and from 0.83 to 1.59 d−1, respectively. Microzooplankton grazing ranged from 0.46 to 2.67 d−1 and from 0.23 to 0.99 d−1, respectively, and on average microzooplankton consumed ~80% of production. Our results suggest that microzooplankton grazing is an important loss process for phytoplankton in ponds that are dominated by harmful algae. Assuming that benthic consumers and mesozooplankton also remove a fraction of the production, then grazing may limit the overall availability of phytoplankton productivity for export to adjacent coastal water bodies from these ponds.

RELATIVE DISPERSION FROM A HIGH-RESOLUTION COASTAL AND OCEAN MODELS
Synthetic drifter trajectories computed from velocity data produced by a high-resolution models are used to investigate the scaling of relative dispersion and the distribution of Finite-Scale Lysapovun Exponent fields in the Adriatic Sea and the Gulf Stream region. It is shown that the relative dispersion model used in the Adriatic circulation is well conservative, and that the large-scale dispersion is dominated by persistent separation regions and the controlling influence of the Western Adriatic Current. The effects of varying degrees of spatial and temporal filtering of the input Eulerian velocity fields on the Lagrangian statistics are investigated in order to assess the sensitivity of such statistics to model error. While no clear exponential regime is observed in the full data set, a distinct flattening of the FSE curves are observed for larger-scale spatial smoothing. The role of chaotic advection in determining the small-scale relative dispersion in such cases is examined.

REGIONAL CABLE OBSERVATORY SOLUTIONS
The North East Pacific Time-series Undersea Networked Experiments (NEPTUNE) is a world premiere for a large scale Regional Cable Observatory (RCO). The Canadian part of NEPTUNE is being installed off Vancouver Island in 2007 and 2008. This new technology concept applied to oceanography enables the Internet under the ocean, along with power distribution. The proven high reliability and long life of the subsea communications equipment offers the opportunity to install permanent observatories for operation for at least 25 years. The paper will provide an overview of the key network & system features and will present progress in the development, construction, and installation of this pioneering system. Alcatel-Lucent are installing the backbone cable system for NEPTUNE, comprising land station equipment, the subsea cable repeaters and branching units and the subsea nodes. The subsea nodes, providing subsea connection points provisioning data and power will provide a gateway between the permanent observatory infrastructure and the instrumentation. This system will provide a robust pioneering infrastructure for long term monitoring and investigation of the Oceans.

UNDERSTANDING COASTAL CIRCULATION IN THE GULF OF MAINE AND MID- ATLANTIC BIGHT: A REGIONAL MODEL HINDCAST EXPERIMENT
Regional Ocean Modeling System (ROMS) is configured to provide circulation hindcast for the coastal region of the Northeastern United States, encompassing the Gulf of Maine (GOM) and the Middle Atlantic Bight (MAB). Coastal circulation in this region is strongly affected by both local momentum and buoyancy fluxes and a wide range of remote, offshore processes such as Gulf Stream meanders, meso-scale and submeso-scale eddies, and other basin-scale seasonal and inter-annual variability. The hindcast experiment therefore considers realistic surface forcing conditions. To effectively represent the impact of offshore variability, the data assimilative Hybrid Coordinate Ocean Model (HYCOM) solutions are also utilized to provide ROMS open boundary conditions via one-way nesting. Validations of this regional hindcast model and synthesis for coastal circulation during 4-year time period from 2003 to 2007 will be presented. Based on realistic, space and time continuous circulation realizations, we will also report findings/understandings of seasonal and inter-annual variability of circulation and shelf/deep- ocean exchange processes in this coastal region.
Photodegradation of ciprofloxacin and metolachlor in natural and constructed wetlands

Photodegradation of ciprofloxacin and metolachlor was carried out in one natural and three constructed wetlands (Old Woman Creek (OWC), Olentangy River Research Park, Waterman Farm Wetland, and Defiance County Wetland) to examine the effects of natural photolysis and photo-degradation (DPD) on the photolytic organic constituents. Ciprofloxacin underwent rapid degradation through direct photolysis (33.71 and 0.9533 hr⁻¹ at pH8 and pH4, respectively), whereas the degradation of metolachlor was relatively slow (0.01 and 0.0108 hr⁻¹ at pH8 and pH4, respectively). Compared to direct photolysis, wetland waters reduced the rate of ciprofloxacin degradation, especially at pH8, due to light screening by wetland waters. Metolachlor degradation was enhanced 2-15 times in wetland waters, with OWC water acting the most effectively. The addition of a strong iron complexing ligand, fluoride, significantly decreased metolachlor degradation, indicating iron played an important role in photosensitized degradation. The addition of 2.20 µM of iron promoted metolachlor degradation in OWC water by 50-100% at pH4, while no significant enhancements were observed for other wetland waters. Current studies are optimizing the photodegradation through altering the concentrations of different photosensitizers.

COMPARATIVE ANALYSIS OF THE ECOLOGY OF CALANUS FINMARCHICUS IN CANADIAN AND NORWEGIAN SUB-ARTIC SEAS

The Labrador and Norwegian Seas are both important overwintering areas and distribution centres for Calanus finmarchicus. Both provide springtime source populations to the adjacent shelves and/or shelf seas, which are seasonally ice covered and which are home to commercially important fish and invertebrate stocks. In the Norwegian and Barents Seas there is a greater annual variability in C. finmarchicus abundance, which is linked to the NAO index. A high NAO index is accompanied by strong south-westly winds leading to enhanced influx of Atlantic water, warm temperatures and higher C. finmarchicus abundances. By contrast, in the Labrador Sea between 1994 and 2004 there were no discernible changes in the abundances of overwintered C. finmarchicus in spring, or of juveniles in summer, despite large variations in the NAO and a sustained annual warming trend of >1°C. In both the Labrador and Norwegian Seas areal egg production rates are higher in the pre-bloom period and in both there are spatial differences in the magnitude and timing of recruitment. These latter differences will be discussed in relation to local spring bloom dynamics. The depth of C. finmarchicus from the surface to the overwintering depths appears to be earlier in the Norwegian Sea than the Labrador Sea, perhaps because it is farther north and has an earlier cessation of phytoplankton growth.

PROJECT INSTAR: LESSONS LEARNED OVER 10 YEARS OF PROVIDING SCIENCE EDUCATION TO K-12 TEACHERS

For ten years, Project INSTAR has engaged over 400 teachers from Miami-Dade County Public Schools in authentic research and field activities with real scientists focusing on coastal, marine and atmospheric environments. The two-week Institute introduces teachers to a wealth of current science topics that enhances their knowledge of scientific content, and exposes them to hands-on field and laboratory research, as well as state-of-the-art equipment and technology that they can use in the classroom. Participants receive 3 graduate credits, as well as, educational materials and classroom equipment that they can use back in the classroom with their students. These teachers have potentially impacted over 60,000 students about the importance and enjoyment in understanding the science, nature, and beauty of the South Florida ecosystems and positively influenced our future workforce and scientifically literate leaders. This presentation will highlight the lessons learned and modifications made over the years that have made this program a success. Examples such as marketing and recruitment strategies, funding avenues, graduate credit issues, collaborations between university departments, and school year follow-up will be emphasized.

MODELING PROPOSED HABITAT RESTORATION IN SEMI-TROPICAL SHALLOW COASTAL TIDAL WETLANDS

A modeling study of a coastal tidal wetland in Florida is reported which considers the influence of proposed dredged ponds on geomorphology and freshwater habitat. The ponds would connect to the main tidal creek, that runs through the wetland, and be upstream of the existing fresh to salt water interface. The central question is whether the ponds could accelerate past anthropogenic reductions in freshwater habitat without causing other negative environmental impacts. Extensive topographic/bathymetric and habitat surveys of the wetland were made together with a two year monitoring program of water flow parameters. Hydrodynamic modeling in very shallow coastal wetlands faces significant challenges from both the complex topography, and small spatial scales, that control water flow, as well as from the spatially inhomogeneous roughness created by submerged vegetation. The extremely non-linear tidal excursions are found to influence both vertebrate habitat and advective/ diffusive transport in the wetland. The simulated wetland ponds are predicted to cause changes in tidal elevation and deposition which could affect wetland geomorphology especially in the lower reaches, and mouth, of the tidal creek.
centrations at depth during the dark period may be invalid for certain dinoflagellates such as K. brevis, which does not actively migrate downward at night and blooms in coastal areas not characterized by a nitrocline.

APPLICATION OF ADJOINT METHODS IN OCEAN MODELING

Ocean models have become an ubiquitous tool for investigating key aspects of oceanic circulation and variability. The progress in this area is impressive, and has, at times, left some complementary aspects of modeling out of focus. Whenever gradient information from models is sought, it be to minimize model vs. observation misfits in state estimation, to investigate sensitivities of key oceanic quantities to a very large number of parameters, or to determine normal or non-normal stability, the adjoint method presents itself as a natural tool for efficiently computing such gradients. We provide an overview of adjoint modeling with the MIT general circulation model (MITgcm). The context of automatic differentiation has enabled us to extend our applications in various directions from coupled ocean-biogeochemical to ocean-sea ice modeling, and using various configurations from global coarse-resolution to regional eddy-permitting scales. New developments are discussed, mainly driven by the requirement of a new-generation EICO ocean state estimation system.

GLACIAL/INTERGLACIAL CARBON CYCLE CHANGES AS DERIVED FROM GLOBAL MODELING OF MARINE SEDIMENT CORES

Marine sediment core data and the ice core record provide the foundation for an understanding of past changes in the global carbon cycle. But how to derive changes in governing parameters of the carbon cycle from these tracer data? In our approach, we carry out a series of forward simulations of the ocean carbon cycle over the last climatic cycle using a coarse resolution global biogeochemical ocean circulation model. The model includes basic parameterizations of the carbon, oxygen, phosphorus, and silicon cycles. The atmospheric carbon dioxide concentration is a prognostic model variable. Early diagnosis is simulated through a sediment module which is interactively coupled to the water column. The sediment model includes the four weight fractions calcium carbonate, organic carbon, opal, and clay. A time transport model was developed which allows proper synchronization of the various sediment weight fractions when leaving the sediment mixed layer down. From the forward simulations, synthetic sediment cores are recovered out of the model sediment for comparison with sediment core data from the real world. A method for deriving best estimates for changes in governing ocean carbon cycle parameters by combining the information from simulated and observed sediment core data is presented. The results will deliver best estimates for changes in ocean carbon cycle parameters due to climate change and a more alkaline glacial ocean as compared to today’s ocean.

LABORATORY STUDY ON THE RECOVERY OF A STORM PERTURBED UPPER OCEAN LAYER

The effects on the ocean water column due to a storm passage can be characterized as three sequential processes: mixing of the upper layer due to momentum and heat transfer, propagation of energy into the thermocline, and recovery back to the pre-storm state. Recent field observations show that the ocean responds rapidly to a storm, in a matter of hours, while recovery to the initial state takes several days or more. To gain a better understanding of processes governing the recovery, a series of laboratory experiments have been performed. These experiments consider equilibration of the mixed water mass with the adjacent non-mixed water (i.e. region not affected by the storm) by wave propagation and water mass intrusions. A preliminary conceptual model has been developed to describe the recovery of a storm perturbed upper ocean layer that characterizes the recovery process in terms of temporal and spatial scales, including BV frequency and the nature of the forcing mechanism. Laboratory experimental results as well as recent field observations of storm induced water column alteration/recovery will be presented.

EVALUATING THE SONIC LAYER DEPTH RELATIVE TO THE MIXED LAYER DEPTH

Sound speed within the ocean surface mixed layer increases with depth until (typically) a decrease in temperature occurs, resulting in a local maximum. The depth of this sound speed maximum is referred to as the sonic layer depth (SLD) and characterizes the ability of the upper ocean to trap acoustic energy in a surface duct. A closely related parameter that characterizes upper ocean mixing is the mixed layer depth (MLD). While SLD and MLD often coincide, they are not always the same because of the differences in the sensitivities of density and sound speed to temperature, salinity, and pressure. This analysis evaluates the SLD/MLD differences in space and time for a global set of in situ profiles observations. It is shown that in the northern hemispheric spring when fresh re-stratification events occur, the SLD is 10% deeper (shallower) than the MLD in 39% (7%) of the observed profiles. A parabolic equation acoustic transmission model is used to evaluate the relative skill of the SLD and MLD estimates to predict surface acoustic trapping as measured by a simple metric.

RAPID GRADUATIONAL ADJUSTMENT OF A HORIZONTAL SHEAR LAYER

Shallow coastal ocean flows frequently involve strong horizontal shear layers in combination with a horizontal density gradient. Examples include estuarine outflows and separating flows around headlands and islands. The stability and evolution of the shear layer formed from the initial state of two co-flowing streams with laterally-varying, but depth independent, velocity and density is explored through three-dimensional non-hydrostatic numerical calculations. In the absence of the density contrast, the shear layer undergoes the classic instability including roll-up of the vertical vorticity into well-defined vortices. The addition of the density gradient results in a lateral gravity-driven flow resembling a lock-exchange. The lateral adjustment leads to tilting (from vertical) and stretching of the emerging shear layer vortices, greatly amplifying vorticity in the vortex cores. This converts horizontal shear into vertical shear and ultimately the rapid break-down of the vortices, large density overturns, and vertical mixing. The work is guided by a simple scaling argument that compares the timescale for growth of the linearly most unstable wave on a pure shear layer to the timescale for the transverse gravitational adjustment. For large values of this ratio the gravitational adjustment dominates and inhibits the shear instability. As this ratio decreases, the shear and gravity-driven flows become increasingly coupled, producing strong mixing.

THE PHOTOCHEMICAL INTERFERENCE IN OXYGEN-BASED MEASUREMENTS OF PRIMARY PRODUCTIVITY

Measuring oxygen to determine primary production (PP) is the oldest method still in common usage. However, the photochemical reaction of molecular oxygen with chromophoric dissolved organic matter (CDOM) represents a sink that can exceed microbial respiration in highly colored surface waters. This interference can be minimized by using colorimetric photochemical filters that block light at 440 nm or correcting for the interference using abiotic oxygen consumption rates in sterile filtered controls. We utilized oxygen-based measurements of PP with photochemical (filtered) controls in three distinct ecosystems. The Delaware Estuary, mid-Atlantic Bight, and Barra Bonita (a hyper-eutrophic, tropical reservoir) showed photochemical oxygen consumption rates ranging from 0% to 50% of total PP depending on both CDOM concentration and type of container materials used. This correction was of a magnitude similar to (and often greater than) dark respiration. Our results indicate that oxygen-based PP measurements, without proper controls or light filtration, are likely to significantly underestimate environmental PP rates.

FROM MODES TO MUSSELS: ECOLOGICAL FORECASTING OF COASTAL ECOSYSTEM RESPONSES TO CLIMATE CHANGE

We developed a biophysical-based model that predicts the body temperatures of coastal invertebrates using NOAA and NASA weather station and remote sensing data as inputs. We explored the body temperatures of ecologically important species over a broad range of temporal and spatial scales. Because body temperature is so important to the physiological health of these animals, by comparing predictions of temperature against known physiological tolerances, we could then forecast (and, using historical data) hindcast levels of mortality and thus shifts in geographic ranges of several species. Tests of this approach show that we can hindcast historical range shifts in species distributions with considerable accuracy, suggesting that future range shifts may be predictable. However, the accuracy of the prediction changes with the time scale over which the forecast is made. This result emphasizes the importance of coupling the output from deterministic models within a probabilistic framework that is usable by resource managers.

TRINITY RIVER, CALIFORNIA: EVALUATING EFFECTIVENESS OF MANAGEMENT ACTIONS ON MIGRATORY SALMON USING AN ECOSYSTEM APPROACH

The Trinity River Restoration Program in Northern California is rehabilitating the river and restoring flows after 40 years of channel simplification. Since the Program manages flow, we are interested in whether increases in flow are beneficial to our salmonids. We forecasted the body temperatures of ecologically important species over a broad range of invertebrates using NOAA and NASA weather station and remote sensing data as inputs. We developed a biophysics-based model that predicts the body temperatures of coastal invertebrates using NOAA and NASA weather station and remote sensing data as inputs. We explored the body temperatures of ecologically important species over a broad range of temporal and spatial scales. Because body temperature is so important to the physiological health of these animals, by comparing predictions of temperature against known physiological tolerances, we could then forecast (and, using historical data) hindcast levels of mortality and thus shifts in geographic ranges of several species. Tests of this approach show that we can hindcast historical range shifts in species distributions with considerable accuracy, suggesting that future range shifts may be predictable. This result emphasizes the importance of coupling the output from deterministic models within a probabilistic framework that is usable by resource managers.
lene was to separate out variation in both natural and hatchery runs due to ocean or climatic factors from variation due to river management using adult estimates for each species. The approach was to use ENSO indices: primary production, chlorophyll a and sea surface temperatures in the ocean off the north Coast of California (remote sensing data), ocean temperatures near shore (Buoy), in-river temperatures, and flows. Natural Trinity River coho and fall chinook respond to long term changes in ocean conditions and in-river flows. In the case of coho, the runs have positively responded to increased flows in base flows in late summer/fall since 1991. Understanding climatic and regional ocean conditions allowed us to evaluate the effects, over time, of in-river flow management and rehabilitation on our runs.

**MOUMENTUM BALANCES ACROSS A WAVE-DOMINATED CORAL REEF**

For many coral reefs, circulation is dominated by waves breaking over the reef crest that drive a strong circulation over back reef habitats. Unlike classical work on beaches, where the primary momentum balance is between radiation stress gradients and set-up of the free surface, flows over coral reefs typically have mean flows into a lagoon, and thus friction can also be important in the momentum balance. Unfortunately friction on coral reefs is difficult to estimate a priori due to the remarkably high rugosity. Here we studied a nearly tideless system in Moorea, French Polynesia to isolate the effect of wave force on coral reef circulation. An array of 7 stations spanning the forereef, reefcrest and backreef areas was instrumented with pressure sensors and velocity profilers. The resulting data were used to estimate the contribution of each term in the cross-reef momentum balance, as well as corresponding bottom friction coefficients. Initial results show that the momentum balance varies markedly with distance from reefcrest and transitions from a radiation stress and set-up balance, to a friction and set-up balance.

**A NEAR REAL-TIME MARINE ENVIRONMENTAL MONITORING NETWORK FOR THE CARIBBEAN**

The National Oceanic and Atmospheric Administration's (NOAA) Integrated Coral Observation Network (ICON), has been operational in the Caribbean since 2000 and has marine environmental monitoring stations for the purpose of understanding coral ecosystem dynamics in the Bahamas, St. Croix, Puerto Rico and Jamaica, with plans for new station installations in Little Cayman, and Antigua in the near future. These stations collect hourly data on all the standard meteorological parameters, as well as sea temperature, salinity, light and (on some stations), partial pressure of CO2 and Pulse Amplitude Modulating fluorescence. The ICON program collects these data and integrates them with satellite data for research-oriented ecological forecasts for marine behavioral events. Through collaborative work with intergovernmental and academic partners, the ICON program hopes to expand its research platforms throughout the Caribbean and enhance its ecological forecasting capabilities.

**HAVE CLIMATE REGIME SHIFTS ALTERED OCCURRENCE PATTERNS OF MARINE MAMMALS IN THE CALIFORNIA CURRENT SYSTEM?**

Climate variability in the California Current System (CCS) impacts many ecological processes, which can influence top predators such as marine mammals. Climate regime shifts, such as ENSO, PDO or NPGO, have been described as intermittent and decadal fluctuations between cold and warm water regimes with related vacillations in physical and biological properties. A closer examination of sighting records of marine mammals, along with a concurrent assessment of climate record, may elucidate a pattern of shifting marine mammal distributions that correlate with climate shifts. Data from a variety of sources, including NMFS surveys in the CCS in 1979, CalCOFI surveys from 2004-2007, and published occurrence data dating from 1950, was utilized to create a time series of relative abundance of a variety of marine mammal species in the CCS. This time series was then compared to climate records from the CCS (such as in-river flows, along with a concurrent assessment of climate record, may elucidate a pattern of shifting marine mammal occurrence patterns across the CCS (such as in-river flows, along with a concurrent assessment of climate record, may elucidate a pattern of shifting marine mammal occurrence patterns across the CCS). An attempt to test the hypothesis that marine mammal occurrence patterns could be linked to climate regime shifts is underway. An understanding of this relationship could be used to examine top-down forcing on food webs impacted by regime shifts.

**COMPARISON OF OBSERVED AND MODELED ALONGSHORE-VARIABLE SURFACE CURRENTS**

Surfzone currents observed along 2 km of coastline, onshore of a large submarine canyon, were compared with the predictions of a depth-integrated nonlinear shallow water circulation model. To estimate the radiation stresses that drive mean flows, the wave field observed 12 km offshore in 550 m water depth was shoaled across the inner shelf using a linear refraction model, and dissipated across the surfzone using a standard breaking parameterization. The steep canopy bathymetry produced alongshore variations in the wave field, and corresponding alongshore variations in both observed and predicted currents. Onshore of the canyon, both observed and predicted alongshore currents often were as strong as 0.4 m/s toward the north, while 1 km north of the canyon observed and predicted alongshore currents were as strong as 0.2 m/s to the south. Every half hour, mean alongshore currents observed at 26 locations were regressed against corresponding predictions. Correlations between predicted and observed alongshore currents usually were positive (0.20 of 162 half-hour time series), indicating that the model had some skill in predicting the spatial variability of the alongshore current. However, correlations often were low or moderate (0 < r < 0.85, with mean r = 0.41), possibly owing to errors in the predicted wave forcing, or the presence of low-frequency eddies in observations.

**RESIDENCE TIME EFFECTS ON INTERNAL ORGANIC CARBON AND NITROGEN LOAD IN A SOUTHEAST U.S. COASTAL PRAIRIE**

Reductions in water turnover rates brought about by increased consumptive use of surface water and changes in broad-scale meteorological patterns can alter nutrient enrichment effects in river eutrophies. Phytotplankton biomass and internal nitrogen loading associated with changes in discharge and residence time in the tidal freshwater reach of the St. Johns, a low-head, blackwater river of the humid subtropical SE U.S. Atlantic Coastal Plain, were examined in simulations with the eutrophication model E-Qual/JCM. Observed data indicate significant positive relationships between seasonal mean algal biomass and increased internal N loading with increased spring and summer residence time. Model simulations indicated that while reduced flow and increased residence time maximized algal biomass and internal N concentration, reduced nutrient input and restricted fresh-water reach area tended to minimize organic carbon and N load to the estuary. Greatest “effective” N and OC loads to the estuary were achieved at moderate low flow that optimized both nutrient supply and residence time. This modeling study concludes that discharge reductions that shift average flow conditions to moderate-low flow will have the greatest potential whole-estuary detrimental effects on water quality.

**TURBULENT RELATIONSHIPS: IS THERE A RULE OF THUMB PREDICTING THE INFLUENCE OF EPIBENTHIC ORGANISMS ON HYDRODYNAMICS BASED ON THEIR STRUCTURAL PARAMETERS?**

Epibenthic species with structures protruding into the water column modify near bed velocity fields by exerting mechanical resistance to fluid flow. This modification changes the habitat providing benefits but also imposing costs on the organisms. Here we studied the trade-off can be an important evolutionary constraint on the physical structures of such species. We related fluxes through the turbulent cross-reef relationships: is there a rule of thumb predicting the influence of epibenthic organisms on hydrodynamics based on their structural parameters?
A METHOD TO DETERMINE INDIVIDUAL WATER MASS CARBON UPTAKES USING AN INVERSE MIXING ANALYSIS

An inverse mixing analysis is used to calculate anthropogenic carbon uptake in water mass formation regions using the output from two general ocean circulation models. The TROMP method uses a weakly non-linear under-determined system of mixing equations to estimate relative water mass contributions and variations in selected source water properties, namely the DIC. The analysis relies on pre-defined definitions of pre-industrial DIC water mass concentrations. A relation between the delta pCO2 disequilibrium at the mixed-layer base and the atmospheric CO2 content is used as a substitute for a static DIC definition. The anthropogenic carbon uptake in a source water region as well as mean water mass transit times are calculated.

GEODETIC AND TIDAL DATUMS: TYING WETLAND SURFACE ELEVATION CHANGE TO LOCAL WATER LEVELS

Tying geodetic, tidal, and Surface Elevation Table (SET) datums within coastal wetlands provides a framework for evaluating the sustainability of Mid-Atlantic brackish marshes. A strategic partnership between NOAA, FWS, USGS, and the National Aquarium in Baltimore has developed a high-accuracy vertical reference frame within Blackwater National Wildlife Refuge (Chesapeake Bay) to track surface elevations and water levels over time. Tide stations are used to estimate regional mean sea level trends with respect to upland bench marks. SETs measure localized wetland elevation change with respect to a wetland bench mark. Tying these two components together enables us to monitor millimeter-level changes in wetland surface elevation with respect to both local sea levels and upland elevation. Over time, accurate heights of SET benchmarks also allow us to measure deep subsidence. Initial results at Blackwater are producing high precision, vertically referenced elevation change data and digital elevation models coupled to hydrodynamic models. These data are providing both valuable insights into the sustainability of Blackwater brackish marshes facing local sea level rise, and critical information for future large-scale restoration of this essential coastal habitat.

INTERANNUAL VARIABILITY OF MESOSCALE EDDY ACTIVITY IN THE GULF OF ALASKA

Mesoscale eddies provide a key pathway for the transport of momentum, heat and nutrients, and strongly influence the time and space distribution of ocean biology. However, quantification, in an objective way, the distribution of eddies, their characteristics and how they change interannually remains a challenge. A novel method for identifying and tracking eddies in satellite sea level anomaly data is applied to the Gulf of Alaska region. The method allows the spatial and temporal variability in eddy activity to be defined, providing the first systematic census of anticyclonic eddies in the region. The Haida and Alaskan Stream eddy corridors are clearly defined, as is an ‘eddy desert’ in the southwest of the basin, where the probability of an eddy occurring is zero. Maps of eddy trajectories for each year show substantial interannual variability in number and propagation paths. Periods of increased eddy activity do not necessarily correspond to El Niño events, but are associated with anomalous downwelling wind conditions along the continental margin. The complex biological response to the anticyclonic eddies will also be discussed.

SHORT-TERM FOOD VARIABILITY DURING MEROPLANKTONIC LARVAL DEVELOPMENT: EFFECTS ON THE SIZE AND AGE OF METAMORPHIC COMPETENCE

As the larvae of many benthos develop in the plankton, they encounter environmental variability on a range of spatial and temporal scales. To measure the effects of food variability on a scale of days, we performed a food-switching experiment on larvae of the sabellariid polychaete Phragmatopoma. We manipulated phytoplankton concentrations and tested five feeding regimes: a high-food treatment that remained constant throughout larval development, constant low food, and three treatments in which larvae initially fed low food were switched to high food on either day 8, 16, or 20 after hatching. Larvae raised on constant high food became competent to metamorphose 11 days faster than larvae fed constant low food (day 14 vs. 25) and were significantly larger at competence.

Larvae switched from low to high on day 8, 16, or 20 reached competency on day 20, 24, and 28, respectively. The growth of larvae switched from low to high reached competency at the same size as larvae fed constant high food, suggesting a larva’s size at competency is strongly influenced by its recent feeding history.

SENSITIVITY OF SUBANTARCTIC CORALLINE MACROALGAE TO ELEVATED CO2

The effects of ocean acidification are predicted to occur first and be most severe in calcifying organisms from coldwater environments. However, assessing the impact of altered seawater chemistry on coldwater ecosystems is presently difficult, and requires a comparison of predicted carbonate saturation states, for the next 100 years, with the physiologic effects of calcification in marine organisms. This study is a collaboration between carbonate chemists and marine ecologists and utilizes an inexpensive system that allows realistic modification of seawater carbon chemistry. Most importantly, this system allows for independence among replicates essential for statistical tests and lacking in many studies conducted on ocean acidification to date. In our experiments we exposed the widely distributed coralline Arthrocardia to conditions that mimic the carbon chemistry of seawater today and that predicted for 2050, 2100 at 10°C over 50 years. Corallines are important in many marine habitats at all latitudes, and are likely to be particularly vulnerable if they precipitate soluble high-Mg calcite. Here, we present data on growth and calcification rates, and investigations into dissolution and physiological acclimation to lower pH.

A COMPARISON OF LOWER TROPHIC LEVEL MODELS FOR THE COASTAL GULF OF ALASKA

As part of the Global ecosystem dynamics program (GLOBEC), we have been examining the coupled physical-biological dynamics of the Coastal Gulf of Alaska (CGOA) using the Regional Ocean Modeling System (ROMS). ROMS now includes several lower trophic level models, e.g. the 4-box NPZD model of Powell et al., the 11-box, multi-size-class NEMURO model of Kishi et al., and the 11-box, multi-size-class NPZ model with iron limitation of Hinckley et al. These models range from the general to the specific; in particular, the Hinckley et al. model has been designed and tuned specifically for use in the CGOA. Here, we compare results among these three models in 3D simulations of the CGOA at 3-km resolution. This comparison of regionally-specific vs. general model performance on the same grid, and their covariance, is intended to inform future model comparisons among GLOBEC study regions (e.g. CGOA vs. Southern Ocean) using globally-relevant NPZ model.

DIFFUSE LIGHT ATTENUATION COEFFICIENT VS. TURBIDITY TO DETERMINE WATER QUALITY IN RIVERS, ESTUARIES AND OCEANS

Worldwide aquatic ecosystems are being affected by an increased loading of nutrients and pollutants causing environmental and economic damage. The impacts on water quality are usually measured in terms of suspended solids concentration. Currently, the most common field sampling measurement for water quality is nephelometric turbidity (NTU). However, turbidity is not an absolute scientific quantity and is dependant upon most common field sampling measurement for water quality are usually measured in terms of suspended solids concentration. GROSS BIOLOGICAL PRODUCTION OF DIMETHYLSULFIDE (DMS) AT TWO COASTAL SITES WEST OF THE ANTARCTIC PENINSULA. Upper ocean DMS variability is driven by coupled physical, chemical, and biological processes involved in the marine sulfur cycle. Robust approaches exist for constraining photochemical and biological DMS losses, but direct measurement of gross DMS production is difficult. We used a diagnostic modeling approach to estimate gross biological DMS production at two stations along the Antarctic Peninsula near Palmer Station. The biogeochemical model was constrained with measured values of DMS concentrations and DMS photolysis and microbial consumption - the loss rates were determined in incubations using the 35S tracer method. A well-tested one-dimensional physical model forced with meteorological measurements was used to construct vertical mixing. At each time step, we restored model DMS distribution to match the observations and diagnosed gross biological production from the difference between modeled and observed DMS concentrations. Herrero, S. E., University of South Carolina, Columbia, USA, herrons@mailbox.sc.edu; Benitez-Nelson, C., University of South Carolina, Columbia, USA, cbnelson@geol.sc.edu; Thurnherr, L., University of South Carolina, Columbia, USA, lthurnherr@geol.sc.edu. INSIGHTS INTO SEDIMENT TRAP FLUXES: POSSIBLE UNDERESTIMATION OF OPAL FLUX IN THE SANTA BARBARA AND CARIACO BASINS. In marine systems, the flux of particulate biogenic silica (opal) to depth reflects the biological production of diatoms in overlying waters. This flux may be measured using automated sediment traps, but recent questions regarding trap integrity have arised due to solubilization of particulate matter within trap cups. Our study measured dissolved silicate and particulate biogenic opal concentrations in sediment trap samples collected from the Santa Barbara and Cariaco Basins. Dissolved silicate found within trap samples was compared to trap particulate biogenic silica to calculate a percent loss of 0.6 ± 1.1% for Santa Barbara and 3.1 and 2.9% for Cariaco Basin. Relatively consistent concentrations of dissolved silicate (305 ± 109 μM for Santa Barbara, 273 ± 136 μM for Carico) within the trap samples, independent of flux or deposition period suggest a solubility control, i.e., maximum dissolution is achieved. It remains to be seen whether this is due to saturation or the regularity of super- natant exposed particle surface area. Regardless, this dissolution factor varies spatially and therefore must be taken into consideration for determining opal fluxes to the seafloor. Herrufeld, L. L., University of Hawaii, Honolulu, USA, mvermeij@hawaii.edu. DIURNAL DISSOLVED INORGANIC CARBON, PHOSPHORUS, NITROGEN, AND IRON DYNAMICS IN PERMEABLE BACK-REEF SEDIMENTS OF THE SOUTH SHORE OF MAUI, HAWAII. Nutrient and iron dynamics were examined in a coastal backreef environment on south Maui where chronic eutrophication via terrestrial sedimentation and non-point nutrient inputs via submarine groundwater discharge occur. Because of the high permeability of the sediments, physical factors can greatly affect porewater water column exchange and, hence, porewater concentrations. We examined the diurnal concentration changes in inorganic carbon, phosphorus, nitrogen, and iron in the sediment porewater and the water column, and explored the covariance between solute concentrations and physical forcing (e.g., temperature, wind, current). Preliminary results suggest that both submarine groundwater discharge and sediment biogeochemical processes, coupled with physical forcing, can largely account for concentration changes observed in sediments and the water-column. This study emphasizes the challenge managers and scientists face while assessing nearshore water bodies based on the collection of sporadic discrete water quality samples. Hesser, T. J., University of Florida, Gainesville, USA, hesser@coastal.ufl.edu; Slinn, D. N., University of Florida, Gainesville, USA, slinn@coastal.ufl.edu. MODELING BOUNDARY LAYER DYNAMICS OF SHEET FLOW USING A MIXTURE APPROACH.
Due to the existence of sheet flow during storm events, numerically quantifying sediment transport during sheet flow conditions is an important step in understanding coastal dynamics. Traditional methods for modeling sediment transport requires solving separate equations for fluid and particle motion. We have chosen an alternate approach that assumes a system containing sediment particles can be approximated as a mixture having variable density and viscosity that depend on the local sediment concentration. Here, the interactions are expressed through the mixture viscosity and a stress-induced diffusion term. There are five governing equations that describe the flow field - the mixture continuity and momentum equations and a species continuity equation for the sediment. The addition of a bed-stiffness coefficient to simulate particle pressures in the bed has increased the consistency of the model results. This model which was developed for Crosshox has shown promising comparisons to laboratory data demonstrating the effectiveness of the model mixture in simulating sediment transport in the sheet flow layer.

SPREADING IN THE NEAR-FIELD MERIMACK RIVER PLUME

A numerical simulation of the near-field Merrimack River plume is used to investigate how buoyant plumes spread within a few kilometers of an estuary mouth. There are three principal findings of this study. First, many properties of the plume are primarily a function of radial distance from the estuary mouth, and are uniform across the arc of the plume. Second, the percent change of plume width (in the cross-flow direction) is proportional to the percent change in radial distance from the mouth; the percent change in width is shown to be about 1.2 times the percent change in radial distance, resulting in a plume with spreading streamlines strongly influencing the core of the plume. Third, plume spreading is related to the local internal gravity wave speed. These finding allow the width of the plume to be estimated as a function of distance from the estuary mouth. These principle findings from the numerical model compare favorably to observations.

METATRANSCRIPTOMIC ANALYSES OF BACTERIOPLANKTON IN SURFACE WATERS OF THE OLGOTROPHIC NORTH ATLANTIC AND SOUTH PACIFIC OCEANS

Recent metagenomic analyses of bacterioplankton in the open ocean have revealed a wide suite of genomic potential activities, yet there have been few in situ studies of bacterio-plankton assemblage gene transcripts. We conducted bacterioplankton metatranscriptomic analyses of surface waters at several locations in the oligotrophic North Atlantic and South Pacific Oceans during the day and night in an attempt to identify dominant gene transcripts and putative dominant biochemical processes. Separation of RNA from mRNA using commercial mRNA enrichment protocols was in all cases incomplete, and influenced by environmental sample preparation and composition of assemblages. Phylogeny of mRNAs retrieved was congruent with PCR-amplified rRNA phylogeny, and demonstrated dominant expression of nucleic acid metabolic and energy metabolic genes. Furthermore, our results indicate common types of assemblage gene transcripts between locations in both the light and dark phases. Comparison of gene transcript libraries to available metagenomes suggests that dominant gene expression may be used to characterize the physiochemical conditions in which assemblages exist. Moreover, our results demonstrate the potential for metatranscriptomics to elucidate dominant active metabolic processes within oceanic bacterioplankton assemblages.

HIGH-LATITUDE ATMOSPHERE-OCEAN COUPLING IN SEA-LEVEL RECORDS

Sea-level measurements from bottom pressure recorders and tide gauges in the Southern and Arctic Oceans are used to investigate the existence in the ocean, of counterparts to atmospheric modes of variability, such as the Southern Annular Mode and the Arctic Oscillation. In the Southern Ocean, 19 relatively short time series (c.<15years) of high temporal resolution are detided by band-pass filtering and then subjected to statistical and empirical orthogonal function (EOF) analysis in order to identify recurring and propagating sea-level patterns upon seasonal to interannual timescales. Correlations of these patterns are then made with climate indices, to determine the extent to which they correspond and thereby help to identify the driving mechanisms for sea-level fluctuations. A similar technique is applied to Arctic Ocean sea-level measurements, which, given the greater length and lower temporal resolution of the time series, lend themselves to the study of atmosphere-ocean analogues upon seasonal to decadal timescales.

ECOHAB PACIFIC NORTHWEST: TOXIC PSEUDO-NITZSCHEA IN THE NORTHERN CALIFORNIA CURRENT

ECOHAB PNW studies have improved our understanding of physical, chemical, and biological processes required to produce toxic conditions in razor clams on the coastal beaches of Washington State. Observations have confirmed that the Juan de Fuca Eddy is a chronic source of particulate domoic acid. As shown by model studies and observations this is due in part to the fact that under downwelling-favorable or weakly fluctuating wind conditions, the eddy is retentive and well supplied with macronutrients, thus allowing cells to become highly concentrated. Toxicity appears related to Cu and Fe limitation, but not to macronutrient concentrations, including silicate. Results confirm that cells can maintain their population and toxicity well past the time that they have escaped from the eddy and been transported southward parallel to coastal beaches, as occurs under upwelling-favorable wind conditions. The cells are thus positioned for subsequent onshore transport to coastal beaches that occur during storms. The role of the plume from the Columbia River has been identified as critical to understanding the specific mechanisms and timing of toxin and cell delivery to coastal beaches.

TAXONOMIC AND PHYSIOLOGICAL GRADIENTS WITHIN THE PHYTOPLANKTON COMMUNITY OF A STABLE SHELF SEA THERMOCLINE

A deep chlorophyll maximum (DCM) occurs within the seasonal thermocline of many shelf sea regions including the North West European Celtic Sea. Tidal mixing maintains the thermocline (and therefore DCM) at + 9 °C surface irradiance whilst the dissipation of tidally generated turbulence provides the DCM with a supply of nitrate from the bottom mixed layer. The narrow thermocline is subsequently a region of marked gradients in light and nutrient availability. Turbulence profiles obtained with a FLY shear probe across the Celtic Sea confirmed the thermocline to be a region of high stability, with mixing length scales in the centimeter range (c.10m in the surface mixed layer). Vertical gradients in phytoplankton community composition were observed within this stable region. The taxon-specific biomass maxima were decoupled from pigment maxima which occurred at the base of the DCM. Vertical gradients in taxonomy and photophysiology are discussed in terms of mixing timescales. Spectral absorption characteristics and effective absorption cross sections of PSI appear to be possible taxonomic traits that may contribute to the observed gradients.

MJO-INDUCED RAINFALL VARIABILITY OVER THE MARITIME CONTINENT OBSERVED BY TRMM

The Madden-Julian Oscillation (MJO) is known to be a dominant component of intraseasonal rainfall variability over the tropics on higher latitudes. But the influence of the MJO on the rainfall variability over the maritime continent had not been documented in detail. Our previous work found that significant part of the rainfall variability in Indonesia is...
Our aim was to study patterns of primary productivity in the Arctic Ocean using the 10 year satellite record available from SeaWiFS. A relationship between surface chlorophyll and productivity was developed from in situ data from all Arctic regions, and applied to average monthly chlorophyll retrieved from satellite imagery. Monthly anomalies from the 10 year median are most apparent in April and May, which coincides with the timing of ice retreat, no clear trend towards positive or negative anomalies was observed. The Siberian shelf seas show great interannual variation in anomalies during the summer months compared to the Barents, Chukchi and Beaufort Seas. The annual productivity for the Arctic calculated from satellite imagery ranged from 504 to 570 Tg C yr⁻¹, this is approximately one order of magnitude lower than that quoted in the literature. This could be because the satellite imagery misses the subsurface maximum that dominates summer productivity. Since 2005, summertime ice retreat has been increasing dramatically, however, using the current satellite record no significant difference was observed in the magnitude of total annual Arctic productivity.

VALIDATING OCEAN SURFACE CURRENT INPUTS FOR SEARCH AND RESCUE

This presentation covers the evaluation of surface current inputs from operational ocean models used for Search and Rescue Applications. The Canadian Coast Guard is routinely in need of adapting to improvements in available surface currents for operational oceanography systems. As a result, there is a need to evaluate the impact of each new available source of ocean current forecast on the success and Rescue drift calculations (CANSARP) with ocean model current input using a defined database of surface current drifters will be presented. A protocol for evaluating the impact of new ocean currents on reproducing observed drift is proposed and results discussed from an inter-comparison of drift methodologies.

CALCITE SATURATION STATE EFFECTS ON THE MG AND SR DISTRIBUTION COEFFICIENTS OF CULTURED BENTHIC FORAMINIFERA

Field studies suggest that calcite saturation states near and below saturation alter element distribution coefficients in benthic foraminifera. Two separate 8-month benthic foraminiferal culture experiments investigated the response of proxy signatures to three different calcite saturation seawater environments. Total alkalinity was manipulated to modify the culture carbonate chemistry (TA = 2380, 1910, 1320 μeq kg⁻¹). Mixed-species foraminiferal assemblages, labeled with calcine, were inoculated into culture chambers distributed evenly among the control and treatment seawater reservoirs. These cultures were maintained at 7.0±0.2 °C temperature and 36.5±0.3 ‰ salinity. Total alkalinity and dissolved inorganic carbon, measured biweekly, characterized the carbonate system and verified that the calcite saturation state did not vary substantially. Foraminiferal reproduction was observed in each seawater chamber. Terminal calcite chambers precipitated in culture were identified by the appearance of the pre-culture calcine label and were separated by laser microdissection. Separated chambers and seawater samples were analyzed for Mg/Ca and Sr/Ca. Results from the 2005 experiment identified a significant negative correlation between alkalinity and the magnesium distribution coefficient (D_Mg, p-value = 0.095). This research was funded by National Science Foundation grants OCE-0351029, OCE-0350794, OCE-0437366, and OCE-0647891.

TURBULENT EDDY DIFFUSIVITY ESTIMATED FROM OVERTURNING SCALE OFF ADELIE LAND, ANTARCTICA

Recently, a region off Adelie Land has drawn attention as a source of Antarctic Bottom Water (AABW). In order to understand the formation mechanism of AABW, it is necessary to evaluate turbulent eddy diffusivity K, throughout the water column near the shelf break. To clarify the strength of turbulent mixing near the shelf break, we conducted hydrographic observations off Adelie Land with Sea-Bird Electronics SBE911 plus in austral summer of 2003 and 2005. It is preferable to measure turbulence with a turbulent

PRIMARY PRODUCTIVITY PATTERNS IN THE ARCTIC: THE 10 YEAR SEAWIFS RECORD

Associated with the MJO and that the influence of MJO is not spatially uniform, by using rain gauge data. However, insufficient coverage of the station data limited our analysis to only small portion of the territory. Therefore, we use pentad-mean gridded TRMM rainfall data from 1998 to 2006. The phase and amplitude of the MJO are defined according to the MJO index based on Wheeler and Hendon (2004), and a composite mean of rainfall anomalies (deviations from mean seasonal change) for each MJO phase is calculated. The MJO signals are clearly identified in most part of the maritime continent. Positive rainfall anomalies are dominant during wet phase and negative anomalies in dry phase of the MJO. This result ensures our previous conclusion that the rainfall variation of this region is significantly influenced by the MJO and that the impact of the MJO is not spatially uniform. Rainfall over the ocean is dependent more clearly on the MJO phase than over the large islands. Such a pattern suggests different rain causing mechanisms between ocean and land.

DISSOLUTION OF BIOTIC: SILICA IN PERMEABLE COASTAL SANDS

In the shallow shelf, a large fraction of the diatom production is decomposed in the sediment, and large areas of the sea bed in this environment are covered by permeable sands. We conducted flume and column experiments to determine how pore-water flows affect the degradation of diatoms embedded in permeable Gulf of Mexico sands and the distribution of silicic acid within the sediment. Our results show that pore-water flows increase the distribution rate of diatoms in the sediment and the subsequent release of silicic acid to the water column. These findings emphasize the importance of coastal permeable sediments in the cycling of marine silica.

CHARACTERISTIC LENGTH IN MARINE POPULATIONS: THE INTERPLAY OF LARVAL DISPERSAL AND ADULT POPULATION SUCCESS IN DETERMINING DISTRIBUTION

The ratio of variance in dispersal to the strength of selection is termed the characteristic length (lc) and is proportional to the width of genetic lines. Several properties of clines can be related to lc including the fact that populations cannot respond to changes in selection on co-dominant loci across the entire length of the cline. We apply the concept of characteristic length to explore the interplay of larval dispersal and reproductive success in determining the distribution of adult populations. Geographic gaps in reproductive success must exceed the lc to be reflected in the distribution of the population. Gaps that exceed the lc may lead to abrupt changes in abundance and may result in the coincident geographic limits of species with dissimilar relationships to environmental gradients. This limits attempts to predict changes in distribution in response to changes in the environment, including global warming. Ecologically relevant components of lc are possible to estimate empirically. We illustrate the potential utility of this concept with several examples.

CLOSING THE WATER CYCLE OVER THE OCEAN USING A CONSTELLATION OF SATELLITES

We are in the final stages of completing our Passive Microwave Water Cycle (PMWC) product for the NASA Energy and Water Cycle Study (NEWS). The purpose of this product is a full characterization of the atmospheric branch of the water cycle over the global oceans using accurately intercalibrated passive microwave data. The product uses data from nine different satellites: SSM/I (on F08, F10, F11, F13, F14, F15), AMSR (on AquA and Mopor-I), TMI (on TRMM); and will add additional passive microwave sensors as their data become available. The product is a monthly, 0.25-degree product currently spanning the last 20 years: 1987-2007. The product contains six maps: water vapor transport divergence, precipitation, and water vapor transport divergence, evaporation (D), precipitation (P), and water vapor (WV). The development of this product has generated many science questions. We will discuss the differences between passive microwave rainfall retrievals and what the hydrological cycle implies about precipitation, with particular emphasis on mid- and high-latitudes. We will discuss the water cycle balance and trends in the water cycle. We will examine these trends in terms of the global energy budget and against climate model predictions. We will explain our technique for calculating water vapor transport divergence, show some results, and explain what it implies for ocean–land exchanges.

CONTRIBUTION OF COMMERCIAL FISHING TO THE DECLINE IN HAWAIIAN MONOCHASUS SCHAUINSLANDI.

Recorded declines of Hawaiian monk seals (Monachus schauinslandi) have occurred over the past half century in the Leeward Chain of the Hawaiian Islands. Preliminary evidence from stable carbon (13C/12C) and nitrogen (15N/14N) isotope ratios in bone collagen from the seals (n=20) shows a shift in both isotopes between the 1910s and 1970, indicative of a diet switch, possibly from a benthic diet (crustaceans, mollusks) to a more pelagic diet (fish), as well as a potential environmental change. We surmise the advent of commercial fishing of potential prey items post-World War II led to the decline of preferential prey items and forced the seals to utilize prey species potentially less nutritious and/or which require more energy to capture. Less nutritious prey could be at least partially responsible for the reproductive failure and overall decline of Monachus throughout its range. These historic isotopic values are compared to modern seals and potential prey from the main Hawaiian Islands with the current assumption that the isotope signatures are similar with the Leeward Islands of the chain.

MEAN SEA SURFACE HEIGHT FIELD IN THE NORTH PACIFIC.

Altimeter data observed by TOPEX/Poseidon are provided as sea surface height (SSH) anomalies from mean SSH field averaged for a certain period, since the geoid of the earth cannot be specified at present. On the other hand, using hydrographic data, we can calculate sea surface dynamic height (SSDH). If both observation time and location are matched each other, then we can obtain mean SSH averaged for the period by subtracting SSH anomaly from SSDH. This method proposed by previous study was so unique. But they could not help depending on statistical method with not being interpolated or extrapolated data. So in the present study, we use Argo float data as hydrographic data, distributed densely in time-space domain in the world’s oceans. In order to determine the match-up conditions, time-space decorrelation scales are estimated from the along track data. With these conditions, 44/135 match-up data are found in the North Pacific. The locations are distributed in almost the whole North Pacific. We estimated on each point estimation term. This field seems to be similar to World Ocean Atlas 2005, although we used the Argo profile data only for 6 years. It is expected from our results that more realistic and finer mean SSH field will be available when the Argo floats provide more hydrographic profiles in the future.

OBSERVATIONS OF OCEAN SURFACE CURRENTS IN THE WEST OF OKINAWA.

We conducted the observation of the surface currents in the west of the Okinawa Island by high-frequency (HF) radars in 1999 and 2000. The observation area is the east of the Kuroshio in the East China Sea. We found that the time-averaged surface currents were almost southward. We confirmed the observation result by HF radars using the assimilation data of Japan Coastal Ocean Predictability Experiment (ICOPE) from 2003 to 2005. The currents west of Okinawa are also southward in the ICOPE data. We inferred the beginning of the southward current from the ICOPE data. It is inferred that currents in the east most eastern part of the Kuroshio are bifurcated southward, and flow into the west of Okinawa Island. The currents are controlled by the bottom topography. The wind stress curl in the area, where the bifurcated current can be seen in ICOPE data, is negative because of lesser SST, while the curl is positive in the eastern part of the Kuroshio because of higher SST. The Kuroshio recirculation southward currents are sometimes enhanced. The currents are enhanced when positive and negative wind stress curls are also enhanced.

FLOW SYSTEM AND DENITRIFICATION OF SHALLOW GROUNDWATER IN THE DOZEN PLAIN, SAJOI, JAPAN.

Major ion concentrations, nutrients and stable isotopes in shallow groundwater have been measured to understand the groundwater flow system, and characteristics of the denitrification process with groundwater flow and salt water intrusions processes. These measurements were made in the Dozen plain, which is a major part of Sajio city, located in the north of the Shihoku Island, southwestern Japan. The main feature of the groundwater systems in this area is that is an artesian in the coastal area, where there are tidal flats, have existed at least 400 yrs. The artesian flow system in these area may be the past submarine groundwater discharge system. The groundwater in the plain may be recharged by either precipitation over the plain or by four river waters from the east to the west (R. Uzui, R. Kam, R. Nakaizaya and R. Daimyoujin). Even in the eastern part of the plain, the contribution of the Daimyoujin river water (high silicate concentrations), which flows from a granite mountain, influenced by denitrification (low oxygen and nitrate concentrations), is relatively larger than local precipitation or water from the other rivers.

PRODUCTION AND RESPIRATION RATES IN KARENIA BREVIS.

Kareния brevis is the dinoflagellate responsible for harmful algal blooms in Florida coastal waters. Field and laboratory rates of photosynthetic carbon uptake have been measured in this species, but few reports exist of its respiration or net production rates; these are essential to refine models to predict development and maintenance of coastal blooms. We are conducting a study of the carbon physiology and genomic signatures of K. brevis in cultures and natural populations. Net community production and respiration rates from light-dark bottle incubations of K. brevis populations from a coastal site in Sarasota Bay reinforced this conclusion. Enhanced respiration rates at dusk were attributed to a close coupling between Karedia and the microbial loop, and the potential for light-enhanced dark respiration. Culture studies are underway to verify production and respiration rates, and the genomic signatures, of a Sarasota Bay clone where growth is regulated by light.

DYNAMICS OF NUTRIENTS AND PHYTOPLANKTON BIOMASS IN HONG KONG WATERS BEFORE AND AFTER SEWAGE ABATEMENT.

There are two anthropogenic N sources for Hong Kong waters, the summer Pearl River discharge and the year round sewage discharge in Victoria Harbor. In the summer wet season, the Pearl River discharge increased N03 and Si04 in western waters (105 and 75 uM, respectively) and the highest phytoplankton biomass (20-30 g/UL) was observed in southern waters. In Victoria Harbor, sewage effluent discharge resulted in high NH4 and PO4 (to 20 and 1.3 uM, respectively) and bottom dissolved oxygen (DO) was generally ~3.5 mg/L. In contrast, in eastern waters with nutrient-poor coastal water, total inorganic nitrogen and PO4 was generally <10 and <0.5 uM, respectively. However, after sewage treatment, NH4 and PO4 decreased by 40-83% and 30-48%, respectively, particularly in Victoria Harbor.

IMPACTS OF IRON-INDUCED ELEVATION OF MAXIMUM QUANTUM YIELD AND CHLOROPHYLL TO CARBON RATIO ON THE NUTRITION UTILIZATION OF THE SOUTHERN OCEAN.

Iron fertilization in the Southern Ocean, whether natural or intentional, has vast biogeochemical consequences including increased primary productivity, elevated phytoplankton biomass and more efficient nutrient utilization. During the Southern Ocean Iron Experiments (SOFeX) some of the phytoplankton physiological responses to iron addition were 1. chlorophyll to carbon ratio tripled, 2. maximum quantum yield of photosynthesis (Φ_P), a measure of light-limited primary productivity, doubled, and 3. P_(max), a measure of light-saturated primary productivity, was statistically unchanged. Here we use these phytoplankton physiological responses to iron addition to model how iron, grazing, export, mixing and mixed layer depth determine the potential nitrate utilization and potential biological pump during the Southern Ocean growing season. This model uses climatological physical data as a baseline and explores the biological response using very simple ecosystem dynamic assumptions. With our current knowledge of the light environment and iron regulation of the Southern Ocean we aim to diagnose what is ecologically possible if phytoplankton are relieved from iron limitation and if the light limitation of the Southern Ocean is less pronounced.

THE TRACE METAL FLUXES IN THE WATER COLUMN OF THE SOUTH CHINA SEA: BIOTIC VS ABIOTIC SOURCES

Our previous study found that the metal composition in the algae collected in the SouthEast-Asia-Time-Series (SEATS) offshore station in the South China Sea was mainly occupied by extracellular portion (Ho et al. &O, 52, 1776). The metals might be originally derived from the anthropogenic aerosols containing abundant dissolved trace metals. Here we determined the elemental composition and fluxes (P, S, Al, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Mo, Cd, Mg, Ca, Sr, Ba, Ag, and Au) by analyzing the sinking particles collected by sediment traps at the depths of 160, 620, and 3400 m at the SEATS from year 2000 to 2005 to examine their composition features. Strong vertical and seasonal variations were observed. The metal fluxes increased with the depths increased and the Fe:Al ratios were the same as the sediment, indicating that lateral lithogenic particle input was the dominant particulate metal source for the deep water. In contrast, principle component analysis showed that most of the metals at the top depth were correlated with P and S, which represented the biotic component.

UNDERSTANDING THE EFFECTS OF CHANGING HYDROLOGY ON NUTRIENT SOURCES AND COUPLING BETWEEN THE EVERGLADES AND FLORIDA BAY: AN ISOTOPIC BIOGEOCHEMICAL PERSPECTIVE

Stable isotopic analyses and abundance measurements of inorganic and organic nutrients provide a robust and effective approach to determining linkages between Everglades nutrient sources and dominant biogeochemical pathways observed in Florida Bay. Regionally distinct isotopic signatures of dissolved nutrients and biological sinks show that DON and DIN from the Everglades are transported, incorporated and cycled into biological materials of Florida Bay. Hydrologic conditions, wet vs. dry season, exhibit a strong control on the spatial gradient in δ15N within the Everglades-Florida Bay complex. Similarity in isotopic compositions and gradients of dissolved inorganic and organic nutrients, as well as biological materials, during the wet season show close linkages between the Everglades and Florida Bay, but these trends are dampened in the dry season when sheet flow decreases and in situ processes dominate. This approach can predict how regional changes in the distribution and composition of Everglades dissolved nutrients will direct Florida Bay nutrient cycling. Whether these changes are a result of seasonality or of anthropogenic restructuring of hydrologic flow.

MULTI-SPECTRAL SEISMIC IMAGES OF THE WATER STRUCTURE.

The European funded Geophysical Oceanography (GO) research programme together with additional research funded by the Deutsche Forschungs gemeinschaft is investigating the value of seismic methods to address key questions in physical oceanography. In April 2004, a three-dimensional array was deployed across the SEANTS (Southern European Ambient Time-series) and the area was monitored for a year. The primary aim of the project was to study the propagation of a thin layer through the water column, a process that is theoretically well understood but difficult to observe in practice. The project has been successful in terms of both scientific and educational goals. The project has also been successful in terms of collaboration between scientists from different countries and disciplines. The project has also been successful in terms of the dissemination of results.

PROPAGATION OF A THIN LAYER THROUGH A SYNTHETIC MOORING ARRAY

A dense phytoplankton layer, at times as thin as 1 meter, was observed at a depth of approximately 100 meters in the Philippine Sea. Five autonomous gliders, positioned in a 2-dimensional array with a horizontal scale of 100 km, held station for 10 days during May 2004, continuously profiling between the surface and 200 meters. Profiles of physical and optical properties at each station were completed every 3 hours. The phytoplankton layer propagated northward across the array, consistent with advection by a meso-scale eddy observed with satellite altimetry, and with vertically averaged current velocity measurements made by the gliders. The layer was coincident with small-scale vertical temperature and salinity structure. Both the phytoplankton layer and the TS signature made a gradual diapycnal shift from denser to lighter water, suggesting the layer was formed by vertical shear before being advected across the array.

FROM RIVER BASIN TO BARRIER REEF: AN INTEGRATED APPROACH TO LAND-SEA INTERACTION IN TROPICAL WATERS

The transfer of water and sediment from upland river catchments towards estuaries, coastal seas and offshore located reef systems is subject of an Indonesian-Dutch integrated study of a tropical river system on East Nias. Local sediment supply in river catchments is partly a function of the monsoonal climate, including ENSO events but is increasingly affected by human-induced changes in land-use patterns such as deforestation, open pit mining and palm plantations. Catchment modelling of soil erosion, in combination with hydrodynamical, sediment transport and ecological field and modeling studies provide clear evidence for the morphological and ecological impact of the (fluvial) sediment load. The estuaries trap part of the coarser sediment in the form of sandy (mouth)bars. Turbid, buoyant plumes carry a significant amount of the fine-grained suspended matter in a seaward direction and seafloor lines and current and particle analysis demonstrate an ongoing seaward extension of the Holocene delta platform and prodelta by deposition of silty and muddy sediments. Meanwhile turbidity patterns also affect coral reefs, as deduced from ecological parameters such as coral cover, partial mortality, coral colony size and degree of spatial competition.

The NSF-funded University of Oregon GK12 Learning About Where We Live Project places graduate students in 132 K - 6th grade classrooms in eleven schools in four school districts on the southern Oregon coast. The graduate students teach marine science to ~3300 students and provide embedded professional development to 132 teachers. Initially using the Marine Activities Resource Education curriculum, the program has expanded to a term or year-long program in which graduate students provide active-inquiry based sessions that integrate classroom inquiry and field activities designed to meet state science standards. Professional development activities for teachers provide marine science content, opportunities for curriculum development and planning for program sustainability. Evaluation results indicate that teachers view the program as adding valued expertise, scientific legitimacy, and materials to their curriculum. Graduate students described their participation as an enjoyable learning experience; felt they are generally successful in increasing elementary students scientific excitement, comfort, and awareness; view themselves as positive role models for students; and view their greatest contribution as making science accessible and exciting for teachers and students.

EFFECTS OF RETRETTING ARCTIC SEA ICE ON WALRUS AND OTHER MARINE MAMMALS

As the climate warms, Arctic ice extent decreases and food webs shift. Arctic marine mam-
mals will attempt to adapt. Many species will be negatively impacted by habitat loss while
others may benefit. Historically, some Arctic mammals, including walrus, inflated warmer,
more southerly ranges, using the Arctic as a refuge from hunting and commercial exploit-
ation. Their previous range may presage adaptations to warmer conditions. In this analysis, we
will model a projected ice cover, material fluxes and surface temperatures in a doubled CO2
scenario, while representative marine mammal species will be mapped using their full pre-
industrial ranges to gauge environmental tolerances. The impact on carrying capacity of
the shift of the marginal ice zone to deeper waters will be assessed. As ice-retreats and com-
mercial activities in the Arctic surge, it is hoped that such projections will facilitate environ-
mental policies that maximize the ecological potential of a warmer Arctic region.

DESIGN AND INITIAL TESTS OF A COASTAL OCEAN DATA ASSIMILATION SYSTEM

A coastal ocean data assimilation system is being developed. The goal is to combine
large and disparate datasets with ocean numerical models, producing accurate analyses, forecasts, and respective uncertainty estimates for any littoral region. A modular interface
combines the Estuarine and Coastal Ocean Model (ECOM) and the Local Ensemble
Transform Kalman Filter (LETKF) into a highly scalable, portable and efficient ocean data
assimilation system. LETKF, a recent adaptation of ensemble Kalman filtering techniques,
works particularly well for very large non-linear dynamical systems in both sparse and
dense data regimes, and provides efficient algorithms for error estimation and quality con-
trol. In simulation experiments involving the New York Harbor Observing and Prediction
System (NYHOPS) the filter quickly converges, eliminating bias and greatly reducing rms
erors. This behavior is robust to changes in ensemble size, data coverage, and data error. Future plans include data in operational environments and
the evaluation of the skill of analyses and forecasts under different flow regimes and boundary
conditions, with diverse data streams, and in various model configurations.

ANALYSIS OF THE BIOLOGICAL FUNCTION AND WATER QUALITY

ADEQUACY OF A CONSTRUCTED WETLAND

Bioassessment and chemical monitoring of the J.I. Case Wetland Wildlife Refuge, con-
structed for waterfowl in Vigo County, Indiana, reveals a distinct partitioning in habitat.
While the aquatic habitat is similar to that of other wetlands, shoreline fauna and vegeta-
tion are more characteristic of the upland areas. Low amphibian capture by the pitfall trap
method and high abundance of upland plant species indicate that the biological activity
of this wetland is not representative of a natural wetland. In an ideal wetland, seasonally
inundated shores limit the abundance of non-wetland species. In contrast, the algal and
chemical patterns in the water column mimic natural wetland functions. Chemical signa-
tures reveal periods of increased algal production, along with nutrient removal. Because
microbes act in nutrient cycling, bacterial population counts and genetic identification
of bacterial species is ongoing. Although water quality is adequate (characterized by low
nutrient levels and turbidity in wetland discharge), the physical design of this constructed
wetland differentiates it from natural wetlands in that a sharply sloping shoreline separates
an inadequate wetland buffer zone from a typically functioning water system.

QUANTIFYING THE INFLUENCES OF BIOGEOCHEMICAL PROCESSES ON THE PH OF NATURAL WATERS

An approach for modelling the pH of natural aquatic systems is presented. This approach
allows for quantification of the influences of kinetically modeled processes on the rate of
change of proton concentration. It can be applied to models containing multiple biogeo-
chemical processes, air-sea exchange, and advective-dispersive transport. The influences
of kinetic processes are calculated including the effect of re-equilibration of the system
due to a set of acid-base reactions in local equilibrium. Modelling pH in the described way
is used to shed light on the influences of different biogeochemical processes on the pH
of the Schelde estuary in the SW Netherlands and N Belgium. Generally, CO2 export to
the atmosphere is identified as the main process increasing the pH while nitrification is
found to be the main process decreasing it. The combined effect of advective-dispersive
transport of all modeled chemical species either increases or decreases the pH depending
on the respective circumstances.

A MODELING STUDY OF DEVELOPMENTAL STAGE AND ENVIRONMENTAL VARIABILITY EFFECTS ON COEPOD FORAGING

A stochastic, object-oriented Lagrangian model is used to study how behavior
contributes to copepod grazing success. This individual based model simulates distinct foraging
behaviors of Clausocalanus furcatus, Paracalanus aculeatus, and Oithona plumifera. Simulations
were performed to investigate the effects of: 1) prey size preference; 2) variation in prey size spectrum; and 3) turbulent intensity on these species grazing rates.
Size preference simulations show that compared to copepodes, cell ingestion rates for
mature females are an order of magnitude lower and carbon uptake is reduced by 35%. A prey spectrum skewed toward small cells promotes copepodite success since the
adult females basal metabolism requires a prey concentration exceeding 850 cells ml-1. Variations in turbulent intensity reveal distinct ecological niches with stronger mixing
favoring O. plumifera and stable conditions favoring C. furcatus. Differences in theoreti-
cally-derived and simulated prey encounter rates show that the hopping behavior of O.
plumifera significantly increases prey encounter while the feeding behavior of C. furcatus
can result in localized prey depletion. These simulations highlight the importance of spe-
cific feeding behavior in defining oceanic copepod distributions.

DOES ELEVATED CO2 AFFECT LARVAL SKELETAL DEVELOPMENT IN SEA URCHINS?: EXPLORING THE MECHANISMS WITH GENE EXPRESSION

ANALYSIS AND MORPHOMETRICS

Ocean acidification and the biological consequences of this altered seawater chemistry
have emerged as a significant environmental threat to healthy marine ecosystems. Because a
more acidic ocean interferes with calcium carbonate fixation to form shells or calci-
fed skeletons, future ocean chemistry may significantly alter the physiology of calcifying
marine organisms. Using manipulative experiments we are exploring mechanisms that
have emerged as a significant environmental threat to healthy marine ecosystems. Because
O. plumifera significantly increases prey encounter while the feeding behavior of C. furcatus
can result in localized prey depletion. These simulations highlight the importance of spe-
cific feeding behavior in defining oceanic copepod distributions.
The global geostrophic flow and horizontal kinetic energy are now well-instrumented at the sea surface and to satellite altimeter range on the GRACE ground, but how much of this horizontal kinetic energy extends to greater depths is much less well known. Understanding the vertical distribution of this energy is crucial to quantify the energy dissipated via bottom drag, and to explain the forward energy cascade observed in the altimetry data. This study updates and extends the previous work of Carl Wunsch (1997) by decomposing current meter velocity profiles into the barotropic and first few baroclinic modes, with the inclusion of many new current meter locations around the globe and the application of more stringent profile selection criteria. The role of surface quasi-geostrophic modes is also explored. An additional result will be a searchable interface to the current meter archive, available upon request.

HIGH-RESOLUTION COMPARISON OF NEARSHORE MODEL PREDICTIONS AND OBSERVATIONS

Observations of nearshore processes obtained using high-resolution video imagery are compared with multidimensional model predictions of shoaling wave energy transformation, breaking wave dissipation, and non-steady flows resulting from time-variant forcing. Daylight hourly video measurements have been collected at a site in the northern Gulf of Mexico, which was instrumented with an upward looking Acoustic Doppler Current Profiler (ADCP) deployed in 14 m depth. Data from this ADCP, when combined with surveyed bathymetry, was used to initialize shoaling wave conditions that also drove model estimates of surf zone currents. These predictions, computed for over 200 test cases spanning an approximately 1-year interval, were compared to temporally and spatially variant measurements of wave-number frequency spectra, Particle Image Velocimetry (PIV) estimates of current speed and direction, nearshore location of initial wave breaking, and shoreline development. Within the surf zone, when waves were energetic (significant wave heights > 0.5 m), observed and predicted wave directions and dissipation patterns agree well. Current estimates are less robust, likely due to the complex and potentially dynamic sand bar patterns in very shallow water, however the qualitative structure of the PIV observations is well modeled. These findings are being used to investigate the applicability of sediment transport and morphological modeling codes to bathymetry measurements at this site.

PATTERNS IN THE FINE-SCALE VERTICAL DISTRIBUTIONS OF ZOOPLANKTON

Up-looking acoustical zooplankton sensors were deployed for several weeks in northeastern Monterey Bay, CA during the late summer and early fall of 2005 and 2006. Volume scattering strength spectra measured at time intervals of 1 min and 12.5 cm in depth were converted to profiles of biovolume-size spectra for two distinct zooplankton shapes and small bubbles abundances, throughout a 20 m water column. At times layers of zooplankton dispersed and filled most of the water column, but at other times plankton was distributed in patches. Layers were tracked in depth as they responded to external physical stimuli, e.g., light, internal waves, Langmuir circulation, water column stratification. Plankton behavior was observed as the layer migrated vertically, presumable in pursuit of food (e.g., phytoplankton or microzooplankton). Both normal and reverse migration patterns were observed. Small pelagic fish tended to school during the day, responding when they encountered plankton, and when dispersed at night they appeared to aggregate in the layers and patches. Work sponsored by ONR Oceanic Biology, Code 322BC.

DISTRIBUTION AND TRENDS OF CAULERPA PROLIFERA IN THE INDIAN RIVER LAGOON, FL

Caulerpa prolifera is a commonly occurring, native, rhizophytic alga associated with seagrass beds in the Indian River Lagoon (IRL). FL. C. prolifera exhibits almost the same habitat enhancing traits as seagrass beds - stabilization of the substrate, reduced turbidity, and nutrient uptake. It is thought that a monoculture bed of C. prolifera can sustain a structured faunal community similar to that of a seagrass bed but the limitation of this alga in the IRL is largely unknown. It has been suggested that lower light requirements may allow C. prolifera to extend SAT habitat into deeper water than where the most common occurring seagrass in the IRL, Halodule wrightii, is typically found. In efforts to understand the spatial and temporal patterns of C. prolifera, St. Johns River Water Management District added C. prolifera monitoring to 85 established seagrass transects in 2007. The resulting data from 1998 to 2007 displays a very episomal pattern with greater abundances of C. prolifera found in the Northern IRL south to Eau Gallie River and in Banana River, including Successful Harbor.

DO CURRENT METERS REVEAL THE ARROW OF TIME IN OCEAN CIRCULATION?

Ocean dynamics involves interaction among vastly many degrees of freedom. Yet our understanding rests on classical, not statistical, mechanics. What may we be missing, and
The coastal ocean is characterized by high exchange rates of nutrients and particles between the sediment and the water column. To date, the rates and transfer processes at this interface, the benthic boundary layer (BBL), remain poorly understood. We show how the exchange of nutrients and particles is mediated by the benthic boundary layer (BBL). This approach is favorable as it is non-invasive and integrates over concentration profiles of oxygen and nutrients in the BBL. This approach is favorable as it is non-invasive and integrates over concentration profiles of oxygen and nutrients in the BBL. Thus a correlation is inferred between the isotopic fractionation of Fe and the oxidation of organic carbon in marine sediments. Does it show? Measures of model performance have turned to topography, tay-fivs, where tay = Coriolis vector, V is horizontal velocity and S is gradient of total depth. The BBL has revealed stunning differences among models, and a slight tendency for finer resolution eddying models to achieve more positive tau. But what are the observations? From more than 17000 current meter records over 84000 months, global statistics show markedly positive tau, increasingly so at higher latitudes and greater depths. Why? Tendency for flow along isobaths would be realized by tau of either sign. It is argued that the sign of tau follows the 2nd Law (entropy generation) and this ‘Arrow of Time’ points to possible advances for both theory and modeling of ocean circulation.

THE FUTURE OF NEARSHORE PROCESSES RESEARCH

In 1989, the nearshore researchers convened a first-ever community workshop to discuss the past, present and future of nearshore processes research. The result, either directly or indirectly, was a community vision and a decade of phased experiments aligned with an agreed-upon strategy. A second meeting, held a decade later, updated this vision and helped provide plans for the follow-up programs. In the subsequent span of time, much has changed. Under increasing proposal pressure and need for relevance, funding agencies have shifted priorities and expected time scale of relevance. The move toward observing and prediction systems has strengthened and the recognition of inherent behavior in nonlinear dynamical systems as the nearshore has changed our goals and priorities. In this talk, I will try to summarize the recent history of nearshore science and speculate of profitable future directions.

INTERCALIBRATION OF BIOCHEMICAL MARKERS AS INDICES FOR EGG PRODUCTION AND METABOLIC ACTIVITY IN A COMMON BALTIC SEA COPEPOD UNDER VARYING FOOD AVAILABILITY

There is growing evidence that biochemical indices can be used to infer growth and metabolic activity of zooplankton. In this study we used a Baltic copepod, Acartia bifilosa (Calanoida), to intercalibrate traditional measures (egg production rate; EPR, respiration, and ingestion) and biochemical indices (RNA, DNA, RNA:protein, and specific aminoacyl-tRNA synthetase; spARS) using animals incubated at varying food concentrations. The long-term observations indicate that ingestion and EPR were best described by RNA:protein ratios, while respiration was best described using RNA:protein ratios followed by RNA levels. These findings further contribute to the development of methods for zooplankton growth assessment in field and laboratory studies.

SAR IMAGING OF THE OCEAN SURFACE-AN OVERVIEW

The finely detailed imagery of the ocean's surface from a synthetic aperture radar (SAR) is one of the most complex and least understood data sets that are provided by a remote sensing instrument. What to make of the unprecedented two-dimensional views of waves, currents and eddies, slicks, surface manifestations of subsurface features, all brushed over by interactions with the boundary layer, have captivated and perplexed researchers for over three decades. Add to this mix the ocean's motion during the SAR imaging process and one has quite a challenge to derive quantitative information on what these image patterns uniquely provide on upper ocean processes and air-sea exchange. An overview will be provided of the basic concepts of SAR imaging of the ocean surface, characteristics of feature detection, what oceanographic information can be extracted including in combination with other sensors, the capabilities of current and past satellites, how to access data and products, and some thoughts on the future. Are you thinking about using SAR and wondering how to get started? This talk should help you get things going.

Redox cycling is a crucial mechanism for both the precipitation and solubilization of Fe in marine sediments. Fe cycling across shallow sedimentary redoxcline has been linked to processes of Fe delivery to the oceans in organic rich shell environments. Dissolved porewater Fe in sediments that undergo intense redox recycling have characteristic light Fe isotope compositions relative to the average weathering product. Here we present the isotope compositions of porewater Fe from three cores that were collected from deepsea (>3000 m) Southern Ocean sites off the Crozet Islands. Porewater Fe concentrations reach up to 300 μmol/l and show isotope compositions that are only slightly decreased (min -0.3%) relative to average weathering product. Implicit in these results is a variation between the isotopic fractionation found in marine shelf, and deep-sea derived, porewater Fe. The degree of redox-recycling is suggested to influence the amplitude of the Fe fractionation exhibited in shallower, organic rich shelf environments. From comparison of 0.2mm and 0.02mm porewater filters, we hypothesize that organic ligands and/ or colloids associated with the relatively high porewater Fe concentrations, and that redox cycling is less significant, in these deep-sea sediments compared to organic rich shelf environments. Thus a correlation is inferred between the isotopic fractionation of Fe and the oxidation of organic carbon in marine sediments.

RE-EVALUATING THE IMPACT OF REDOX CYCLING ON MARINE POREWATER FE ISOTOPES

Redox cycling is a crucial mechanism for both the precipitation and solubilization of Fe in marine sediments. Fe cycling across shallow sedimentary redoxclines has been linked to processes of Fe delivery to the oceans in organic rich shell environments. Dissolved porewater Fe in sediments that undergo intense redox recycling have characteristic light Fe isotope compositions relative to the average weathering product. Here we present the isotope compositions of porewater Fe from three cores that were collected from deepsea (>3000 m) Southern Ocean sites off the Crozet Islands. Porewater Fe concentrations reach up to 300 μmol/l and show isotope compositions that are only slightly decreased (min -0.3%) relative to average weathering product. Implicit in these results is a variation between the isotopic fractionation found in marine shelf, and deep-sea derived, porewater Fe. The degree of redox-recycling is suggested to influence the amplitude of the Fe fractionation exhibited in shallower, organic rich shelf environments. From comparison of 0.2mm and 0.02mm porewater filters, we hypothesize that organic ligands and/ or colloids associated with the relatively high porewater Fe concentrations, and that redox cycling is less significant, in these deep-sea sediments compared to organic rich shelf environments. Thus a correlation is inferred between the isotopic fractionation of Fe and the oxidation of organic carbon in marine sediments.
ESTIMATION OF PRIMARY PRODUCTIVITY WITH THE RATIO OF SPECTRAL IRRADIANCE AT A WAVELENGTH OF 555 NM TO THAT AT 443 NM AT SUBSURFACE WATER

Time-series observation of optical fields just below the euphotic layer has been made in the northwestern North Pacific. Downwelling spectral irradiances (Ed at four wavelengths of 412, 443, 490, and 555 nm) are observed with the Bio-optical Long-term Ocean Monitoring System package (BLOOMS). During more than one year, optical system is kept free of biofouling by use of copper shutters. The ratio of surface PAR to in situ quantum irradiance (in situ QI), which is index of turbidity, synchronizes well with the ratio of spectral irradiance at a wavelength of 555 nm to that at 443 nm (Ed(555)/Ed(443)), which is index of chlorophyll concentration. Using the Ed(555)/Ed(443) and an empirical equation, primary productivity for the experimental period can be estimated. During increases of ratio of surface PAR/in situ QI and Ed(555)/Ed(443), primary productivity and organic carbon flux also increases. Optical sensor deployed at sub-surface water becomes a powerful tool to estimate primary productivity and, in combination with data of nutrient and settling particles, to evaluate the biological pump.

THE STRUCTURE OF ESTUARY BOILS OBSERVED WITH A DIGITAL ECHOSOUNDER

Boils are ubiquitous in rivers, estuaries and energetic regions of the coastal ocean, and are responsible for redistributing momentum and suspended matter. As embedded features, they may also provide information about the speed, depth and other characteristics of the flow. As part of COHSTREX (Coherent Structures in Rivers and Estuaries Experiment), we are investigating the relationship between the surface and subsurface expression of boils in the Snohomish River estuary, WA. The subsurface structure of boils generated by strong tidal flow over a rocky sill was resolved with a digital echosounder (Biosonics), which was mounted alongside an upward-looking ADCP on a bottom tripod 5 m downstream of the sill. This combination allows the vertical profiles of acoustic backscatter to be shifted such that instantaneous images of the boil size and structure are obtained. Boils extend from below the height of the sill to the water surface, in a large field and modeling study. The observed boils are compared with simple vortex models to better understand their structure and propagation.

MODELING OF INTERNAL WAVES IN THE GULF OF OMAN AND THE PERSIAN GULF

A modeling system forecasting the circulation of the northern Arabian Sea and the Persian Gulf is used to study internal waves in the Gulf Oman and the Persian Gulf during the summer of 2007. Our modeling system is well suited for this study with a resolution of about 2 km in the horizontal and 66 levels in the vertical, and because it uses realistically steep bathymetry. In order to observe semidiurnal tides, three profiling floats were deployed in the Gulf Of Oman. In addition to providing deep profiles used for assimilation, these floats also provide additional information matched that predicted for vertically-sheared inertial oscillations generated by the horizontal density gradient due to a near-inertial wave of 100 m vertical wavelength. The phase and period of the wave ensured constructive interference with the isopycnal displacement achieved by advection during the diurnal cycle. The stratification by the sheared advection matched that predicted for vertically-sheared inertial oscillations generated by the geostrophic adjustment of a density front, ubiquitous in the ST. By further including the effects of unconfined thermaline inhomogeneity we can account for 100% of observed daytime retrastrification.

4-D OBSERVATIONS OF A RESTRATIFYING SURFACE MIXED LAYER WITH SUB-MESOSCALE LATERAL

Four-dimensional observations from within the Subtropical Front (STF) are presented of a restratifying surface mixed layer (SML) containing a sub-mesoscale lateral density. During a 33 hour period, 16 small-scale surveys were conducted around a drogued float. Insonation accounted for only 60% of observed restratification during daytime at 50 m. vertical scale following nighttime convection that extended throughout the entire SML. This proportion dropped to 25% at 10 m scales in the lower half of the SML. Additionally, restratification was caused by the vertically-sheared horizontal advection of the lateral density gradient due to a near-inertial wave of 100 m vertical wavelength. The phase and period of the wave ensured constructive interference with the isopycnal displacement achieved by advection during the diurnal cycle. The restratification by the sheared advection matched that predicted for vertically-sheared inertial oscillations generated by the geostrophic adjustment of a density front, ubiquitous in the ST. By further including the effects of unconfined thermaline inhomogeneity we can account for 100% of observed daytime retrastrification.

THE SSU COAST CAMP: A NOVEL APPROACH TO INCREASE DIVERSITY IN MARINE SCIENCE

The NOAA Living Marine Resources Cooperative Science Center implemented the Coast Camp for Youth at Savannah State University to expose youth aged 7-18 years old to the marine sciences. The half day camp was offered for the first time in June 2007 using a curriculum based on the seven principles of Ocean Literacy with particular emphasis on issues, features, and animals characteristic of coastal Georgia. Eighty-six campers received hands-on classroom instruction and field experiences ordered such that they began with the geological and physical nature of the ocean, continued to its biological and chemical nature, its susceptibility to man, and concluded with its importance to the planet and the lives we depend on. The curriculum was designed to encourage students from groups traditionally under-represented in the STEM disciplines. This presentation will provide a qualitative and quantitative overview of the challenges and successes observed in this program.

GLOBAL SURFACE SALINITY CHANGE DETECTED BY ARGO FLOATS

We investigate surface salinity distribution and characteristics of its spatial and temporal variation in the World Ocean. The recent development of the Argo float array has allowed researchers to document changes in global surface salinity. In the climatology, salinity is generally lower in the subpolar and tropical regions and higher in the subtropics. We compared the annual average surface salinity distribution in 2003-2006 with the climatology and found a general enhancement of lower and higher surface salinities, except in the North Atlantic Ocean. Further, we estimate enhancement of the global hydrological cycle from the surface salinity, suggest that the strength of the global hydrological cycle is enhanced by approximately 2.4% compared to that 25 years ago. Our results, based on changes in global surface salinity, provide an evidence of an enhanced global hydrological cycle probably caused by global warming.

COMMUNITY STRUCTURES OF ENTEROCOCCUS SPECIES IN LAKE PONTCHARTRAIN AND THE 17TH STREET CANAL WATERS FOLLOWING HURRICANE KATRINA

Polymerase chain reaction (PCR) primers to amplify partial 23S rRNA genes from genus Enterococcus were designed on the basis of the conserved regions of sequences retrieved from GenBank database. By using one primer combination, Enterococcus rRNA genes were successfully amplified from the water DNAs and isolates collected from Lake Pontchartrain and the 17th Street Canal during September and October, 2005 after Hurricane Katrina. The amplified DNAs were then used for the analysis of the community structure of enterococci in these Katrina-impacted waters. The sequence analysis following the RFLP screening illustrated the phylogenetic diversity of enterococci in the lake and canal water samples. The enterococci that have been considered as important fecal pollution indicators or clinically important ones such as E. faecalis and E. faecium were detected from both water DNAs and isolates while the dominant and novel groups were observed mainly in water DNAs. This study enabled inferring sources of these enterococci and associated ecological information. It also provided the enterococci community signatures in Katrina-impacted lake and canal waters.

WHAT CAN WE LEARN ABOUT THE WATER FROM THE SECCHI DISK DISAPPEARANCE?

The widely used and successful Secchi disk method has gained renewed interests recently despite its history of more than 140 years from initial introduction. It is interesting to revisit the issue from a different perspective than many have been accustomed to, namely, imaging instead of radiative transfer. It is understood that the scattering properties of the water are ultimately determined by the outcome of the image formation and transmission within, along with the attenuation caused by absorption. By examining the point spread function (PSF), which describes the system response to a point source in the medium or its Fourier transformed counterparts, we demonstrate that the traditional theory converges with imaging theory. Further, we show the relationship between Secchi disk depth and inherent optical properties of the water, which offers hints about the amount of information retrievable from Secchi depth.

SUCCESSIVE LARGE SCALE GENOME DUPLICATIONS IN DINOFLAGELLATE EVOLUTION: NEW INSIGHTS FROM PCNA AND SSU RNA GENE EVOLUTION

Dinoflagellates are the second most abundant phytoplankton in the oceans but “unusual” in their cytology, genetics, and evolution. Their possession of enormous genomes (nearly 1-100 fold that of the human haploid genome) is particularly puzzling. Literature shows that highly repeated sequences or genes exist in dinoflagellate nuclear genomes, leading us to hypothesize that the large genomes may be caused in part by rampant gene or genome duplications. In this study, we examined this hypothesis by analyzing the gene copy numbers (GCN) of PCNA (proliferating cell nuclear antigen) and SSU rRNA (small subunit rRNA) genes. Literature shows the genome sizes of representative species from major orders of dinoflagellates. The observed correlation between the GCN and genome sizes suggests that dinoflagellate genomes have undergone successive large scale duplication in the past. Phylogenetic analysis of PCNA homologs supports that the duplication events have taken place for multiple times and when they occurred was “predicted” by additional sequence analysis. Thus the varied GCN and genome sizes could be the snapshots representing how many different times dinoflagellate gene or genome duplications have occurred in the evolutionary history.

SALT MARSH GROUNDWATER DYNAMICS DELINEATED USING GROUNDWATER TEMPERATURE AS A TRACER

Knowledge of groundwater-driven exchange of water, solutes, and nutrients between salt marsh estuaries and shelf waters is important for understanding global solute budgets and such phenomena as acute salt marsh dieback. Here we investigated salt marsh ground-water dynamics, using heat as a tracer, as part of a larger field and modeling study. Seven piezometer nests were installed in two transects at an acute marsh dieback site within the North Inlet NERR, Georgetown, South Carolina. Each nest contains three piezometers screened at depths of 1 m, 2 m, and 4 m. Temperature was recorded at 10 minute intervals
in the piezometers beginning August 2006 and ranged from 9 – 30ºC over a one-year period. A comparison of observed temperatures and results of a 1-D conductivity–temperature–depth model indicates that groundwater temperatures were primarily conductive from January through September 2007. However, the piezometer temperature record from October 2006 suggests vertical advection and possible density-driven overturn. If occurring on a march-wide basin scale, such flow could provide a significant pulse of nutrients and solutes to coastal surface waters.

VERTICAL SALT FLUX IN A RIVER PLUME: LATTE OBSERVATIONS VS. GRADIENT-RICHARDSON NUMBER CALCULATIONS

The LADCP dye tracer experiments provided a direct measurement of the salt flux into the Hudson River plume along the New Jersey coast. These are compared with gradient-Richardson number (Bi) calculations using data from a 1200 kHz ADCP mounted over the side at 1 m depth and a CTD on an undulating profile 50 m behind the RV Hatteras. The vertical diffusivity, Kz, derived from Bi using the Lamont Ocean Atmosphere Model turbulent closure scheme, was combined with the vertical salinity gradient to calculate the vertical salt flux at 4 m depth, the base of the dye patch. The calculated and observed salt fluxes correspond to within a factor of 2. The greatest observed salt flux, 3 x 10^-4 m s^-1, occurred when the river plume was a southward flowing gravity current. Upwelling events produced salt fluxes up to 1.7x10^-4 m s^-1. For 7 dye experiments averaged over a range from 0.8 to 1.0 and 1 to 2 x 10^-4 m s^-1 respectively. But, within an experiment these varied by up to a factor of 5 suggesting considerable spatial and temporal variability.

PHYLOGENIES OF KEY TAXA FROM DEEP-SEA CHEMOSYNTHETIC COMMUNITIES IN THE GULF OF MEXICO AND RELATIONSHIPS WITH OTHER TAXA FROM AROUND THE WORLD

The discovery and exploration of deep-sea cold-seeps continues to be accompanied by the discovery of new species. These new species are often closely related to taxa from previously studied deep-sea reducing habitats. Molecular analyses were used to place the six species of vestimentiferan tubeworms, four species of mussels, and two species of shrimp from the Gulf of Mexico in the phylogenetic context of related taxa from around the world. Within the Gulf of Mexico, the distribution of each taxon is strongly correlated with depth. The phylogenies also show a strong connection among populations on either side of the Atlantic at similar depths, particularly among the GoM, Barbados Prism, and populations from seeps on the west coast of Africa. In addition to phylogenetic affinities to Atlantic species on the GoM, the deep-sea shrimp species on the GoM is closely related to a hydrothermal vent species found on the Mid-Atlantic Ridge. These data suggest either a relatively recent exchange of larvae across the Atlantic or a relatively slow mutation rate in the genes analyzed (predominantly COI).

THE LIVERPOOL BAY COASTAL OBSERVATORY

A Coastal Observatory has been operating since August 2002 in Liverpool Bay, Irish Sea. The bay has strong tidal mixing, receives fresh water from several estuaries and enhanced levels of nutrients. It stratifies intermittently. The Observatory’s rationale is to develop the science underpinning the ecosystem-based approach to marine management, including distinguishing between natural and man-made impacts. The Observatory has three components for each of which the goal is at least some (near) real time operation - measurements, modelling and the dissemination of the results via the web. The four measurements include: main strands, each on different space or time scales to test the numerical models, are fixed point time series (in situ and shore-based), regular spatial surveys, HF radar (surface currents and waves) and an instrumented ferry. The emphasis is on physical and ecological models forced by forecast meteorology. In the next few years, at least up to 2012, the Observatory will expand in spatial coverage and in capability, for instance through the deployment of gliders.

DESIGN OF AN ACOUSTICAL OBSERVING NETWORK FOR THE NORTH ATLANTIC BASIN USING A HIGH-RESOLUTION NUMERICAL OCEAN MODEL

The effectiveness of an acoustic tomography observing network for the North Atlantic is assessed using simulated acoustic transmissions in a high-resolution numerical ocean model. The North Atlantic is a region of rapid climate variability, with temperature changes expected to extend into the abyssal ocean at timescales much shorter than in other ocean basins. Long-range acoustic transmissions may effectively sense average temperature, including abyssal volumes. We will discuss the optimal design and cost effectiveness of a basin-wide acoustical observing network using simulations in a numerical ocean model. In particular, the simulated acoustic data will be considered in combination with data assimilation techniques and existing data types to quantify the enhanced resolution of large-scale or deep oceanic variability afforded by the acoustic data. Results for several acoustic paths leading to a network are presented.

MEAN STREAM-COORDINATE STRUCTURE OF THE KUROSHIO EXTENSION FIRST MEANDER TROUGH

Fine horizontal-scale ADCP/CTD surveys across the first meander trough of the Kuroshio Extension were made during the Kuroshio Extension Experiment (KEX) in 2004, while the current was in its stable meander state. Stream coordinate analysis revealed a mean core surface velocity of 1.7-1.8 m/s and cross-stream velocities of the order of 0.1 m/s. Rossby numbers greater than one were found consistently north of the core. The passage of a frontal wave was associated with southward cross-frontal flux. An array of Current and Pressure sensor-equipped Inverted Echo Sounders (CPEIS) provided a longer time series than the full water-column jet structure, albeit with poorer horizontal resolution. The six-month time series during the stable state showed that entering the meander trough, core velocities rotated clockwise with depth, and cross-stream fluxes were southward implying subpolar-to-subsurface down-welling. These fluxes are important for the formation of mode and intermediate waters. Variability suggested an event-driven process, but peak southward flows did not always coincide with the passage of frontal waves. North and south of the core, strong recirculations exist with surface and deep currents aligned.

HURRICANE KATRINA WAVES AND STORM SURGE OBSERVATIONS BY THE CENTRAL GULF OF MEXICO OCEAN OBSERVING SYSTEM

The eye of hurricane Katrina passed 49 nm to the west of a 3 m discus buoy, in 20 m water depth, operated by the Central Gulf of Mexico Ocean Observing System. The buoy moved 2 km to the northwest during the storm surge and then 13 km to the southwest as the surge retreated. Currents and water levels show an asymmetrical storm surge event with stronger currents during the fall of the surge. Waves built to nearly half the mean water depth and wave height rapidly decayed 5-6 hours after the hurricane moved over land. Comparison of measured currents with ADCIRC simulations of Katrina, forced with NOAA reanalysis of the core circulation of the storm, shows good agreement during the surge, but larger discrepancies with the retreating waves. It is important to improve the simulation of the latter since it is destructive in it’s own right. Two potential improvements are to force the model with larger scale winds, so that the offshore winds do not dampen so quickly after the storm moves onshore, and improving the drying algorithms.

Karens brevis is a dinoflagellate that causes Harmful Algae Blooms (HAB) off the coast of Florida. Karens causes Neutrotoxic Shellfish poisoning (NSP). There can be harmful effects when coming in contact with toxic shellfish that have been poisoned from the bloom. It is still unclear what physical causes such a toxic bloom to occur. The goal of this undergraduate research is to understand the conditions in which the blooms are most likely to occur. High resolution ocean color (250m) images of the coast of Florida, and environmental data from the area, will be used to identify conditions most favorable for the Karens brevis to bloom. The warning signals to other states besides Florida is another concern. Being able to key point some of the events that occur before and after a bloom will allow us to help make predictions of blooms in the future.

RADIATING INSTABILITY OF A MERIDIONAL BOUNDARY CURRENT

A linear stability analysis of a meridional boundary current on the beta-plane is presented. The boundary current is idealized as a constant speed meridional jet adjacent to a semi-infinite motionless far field. The far field region can be situated either on the eastern or western side of the jet representing a western or an eastern boundary current, respectively. It is found that in the long meridional wave limit, the unstable boundary current generates propagating waves that transport energy away from the locally unstable region. This is the so-called radiating instability and is found in both barotropic and 2-layer baroclinic configurations. A second but important conclusion is that there are significant differences in the stability properties of western and eastern boundary currents. An eastern boundary current supports a greater number of radiating modes over a wider range of meridional wavenumbers. It generates also waves with longer wavelengths and amplitude envelopes that decay slower with distance from the current than the waves radiated from a western boundary current.

CLIMATE-DRIVEN CHANGES IN ABBUNDANCE AND DISTRIBUTION OF LARVAE OF OCEANIC FISHES IN THE SOUTHERN CALIFORNIA REGION

We examined climatic effects on the geographic distribution and abundance of 34 dominant oceanic fishes along the Southern California margin using the CalCOFI surveys. Among the 34 taxa, only 10 showed a significant distributional shift (mean latitude or boundaries) in relation to annual sea surface temperature, and only 8 species significantly shifted their geographic distribution from the cold to warm period. However interestingly, more often the vertical migrating taxa showed a significant change in abundance in relation to annual SST, and 25 taxa showed a significant increase in abundance from the cold to warm period. We suggest two hypotheses explaining the overall increase in abundance of oceanic fishes. First, increased shoreward incursion of the Central Gyre water during the warm period may bring in more oceanic fish into the region, and 2nd, intensified stratification of the southern California region during the warm period may create an unfavorable condition (e.g. reduced food supply) for neritic species and generate open space for the oceanic species.

Hu, Y., Florida State University, Tallahassee, USA, huay@fsu.edu

THE KUROSHIO IMPINGEMENT ON THE CONTINENTAL SHELF IN THE CHINA MARGINAL SEAS AND ITS CONSEQUENCES

The proximity of the Kuroshio to the marginal seas of China allows the penetration of the Kuroshio that often reaches the continental shelf. The collision of the intruded Kuroshio through the Luzon Strait with the continental shelf in the northern South China Sea generates a along shelf break pressure gradient that maybe responsible for the creation of the South China Sea Warm Current that flows against the northeast winds in winter. The collision of the Kuroshio with the continental shelf break northeast of Taiwan sends a Kuroshio branch current that contributes to the formation of the Taiwan Warm Current. The Taiwan Warm Current features prominently in the formation of latitudinal fronts in the East China Sea. The distribution pattern is not too much to the Tsushima Warm Current as a result of the runtime of the Kuroshio into the shoaling topography west of Kyushu. These intense interactions of the Kuroshio with the China marginal seas are reviewed with new perspective of the cross-shelf transports that arise from them.

EFFECT OF IDEALIZED HURRICANES ON THE ATLANTIC MERIDIONAL HEAT TRANSPORT

Hurricanes are storm systems with powerful winds and torrential rain originating from the Atlantic tropics. It is believed that hurricanes can play an important role in northward transport of heat in the ocean and pmay also play a key role in modulating the climate in the Atlantic basin and the globe. Since a hurricane is a mesoscale storm system, it is not well simulated in current generation climate models. Previous studies indicate that the vertical mixing induced by the strong hurricane winds would mix heat downward in the upper ocean in the subtropical region, hence increasing the oceanic northward meridional heat transport (MHT). Here we use the National Center for Atmospheric Research’s Community Climate System Model version 3 to simulate the idealized hurricane wind effect on the meridional overturning circulation (MOC) and MHT. Results show that without the hurricane-induced precipitation effect, the mixing induced by the hurricane winds cools the upper 100 m of the subtropical ocean and warms the sub-surface water between 100 m and 500 m. Further, we identify conditions most favorable for the Karens brevis to bloom. The warning signals to other states besides Florida is another concern. Being able to key point some of the events that occur before and after a bloom will allow us to help make predictions of blooms in the future.

RECENT PROGRESS IN STUDY OF LOW LATITUDE WESTERN BOUNDARY CURRENTS

Since the end of TOGA and WOCE a calm period of no significant activities has appeared in the northwestern Pacific Ocean east of the Philippines, during which naturally few studies have been carried out to investigate the low latitude western boundary currents in the north Pacific. Fortunately, more and more people have recognized the importance of the low latitude western boundary currents in this region in ocean dynamics as well as in climate changes associated with ENSO and monsoon. Recently some progress was made with two Chinese projects of the ‘973’, which is almost the largest project for basic study in China. In the present paper recent results of research on ocean circulation in the western Pacific Ocean will be presented and outstanding scientific issues will be discussed. Also a new program of NOPC (Northwestern Pacific Ocean Circulation Experiment), for which an international workshop was held in May 2007 in Qingdao, China, will be described along with brief introduction to the two Chinese 973 projects.

MODELING SEA ICE AND OCEAN CIRCULATIONS IN THE BERING SEA

The ocean circulation and sea ice in the Bering Sea were simulated using a Coupled Ice Ocean Model (Ciom). The simulated circulation in the deep basin is cyclonic with little seasonal change. The Bering Slope Current is estimated at 5 Sv, and it is located in a downwelling area. The Kamchatka Current is estimated at 20 Sv off Kamchatka Peninsula. The Bering shelf circulation varies with season, driven mainly by the predominant winds. A counter current is captured flows southeastward about along the 200 m isobath of the Bering Slope and Bering Slope Current, which need to be validated by observations. An upwelling is located in the shelf break may imply the vertical advection of nutrients in the break-slope area. The mechanisms of vertical thermocline structure in the Bering shelf were studied, and results show that the upper and the bottom uniform layers of temperature and salinity can be formed by surface water mixing and tidal stirring, respectively. Sea ice begins forming in the northwestern Bering Sea in early November, and ice extends into June of the following year. Maximum ice cover and ice volume (about 210, 000 Km3) occurs in early April and lags the minimum air temperature by about two months due to the heat capacity of the ocean. Polynya occurs downwind of the summer ice edge. Water properties are more oceanic than estuarine. Polynya are forced to lower temperature, higher salinity, and higher density compared to its ambience water.

CARBON CYCLING IN TWO BRINE WATER CHARGED COLD SEEP SEDIMENTS IN THE NORTHERN GULF OF MEXICO

Surface sediments (~17 cm) near two cold seep sites from the Northern Gulf of Mexico, BG425 and GC233, are studied for carbon sources in sedimentary remineralization. GB425 exhibits a two-layer reaction zonation: upper 7 cm layer shows conspicuous sediment mixing; below 7 cm at GB425 and throughout our sampled depth at GC233, brine water efflux appears to control pore water chemistry. Using the linear portion of the sulfate profiles, we estimate that sulfate depletion depths at these sites are ~22 cm and ~27 cm, respectively. Based on a two end-member mixing model, brine waters at these sulfate depletion depths are predicted to have much different chemical compositions but similar 8° values (~50‰). These low 8° values are associated to anoxic oxidation of methane that occurs below these surface sediments and isotopic signatures of these methane are typical for the structure II gas hydrate found in these environments. Furthermore, surface sediments here are found to have a lesser degree of reactivity than the subsurface layer, contrary to common marine sediments, primarily due to predominant organic carbon input from underneath.

DYNAMICS OF EXTRA-EQUATORIAL JETS, EQUATORIAL DEEP JETS AND POTENTIAL VORTICITY HOMOGENIZATION

The available meridional sections of velocity with high vertical and meridional resolution in both the Atlantic and Pacific oceans reveal that predominantly barotropic eastward
jets at 2N and 2S, named the extra-equatorial jets, appear to straddle the stacked eastward and westward jets of small vertical scales located right at the equator (the so-called equatorial deep jets). Observed distributions of potential vorticity and tracers [O2, salinity, nitrate, and phosphate] display strong meridional homogenization within specific depth ranges. The dynamics underlying the formation of both the barotropic and highly baroclinic jets and the resulting potential vorticity distribution are investigated using very high resolution primitive equations models. A rationale is provided in terms of various types of equatorial instability mechanisms.

THE IMPACT OF INTERTIDAL ZONE ON TIDAL CREEK RESIDENCE TIME AND WATER EXCHANGE

Intertidal zone is widespread along the coastal areas and represents an important marine ecosystem in which physical and biological processes interact with each other. The tidal hydrodynamics in an estuarine-tidal creek-intertidal salt marsh complex (i.e. the Okatee River, South Carolina) is studied using a three-dimensional, unstructured grid, finite-volume coastal ocean model (FVCOM). Detailed topographic data in the intertidal zone is provided by a 1 by 1 m resolution digital elevation map constructed from airborne infra-red vertical photography mosaics. Numerical experiments reveal that expansion of the flushing driving process with the intertidal zone could underestimate the magnitude of tidal currents in the river channel. Subsequently, the tidal creek residence time is significantly increased. In addition, lagrangian drifter simulations suggest that the general transport patterns over the salt marsh-tidal creek complex follow closely the channel and sub-channel characteristic topography. Hence, lagrangian transport simulation of tidal dispersion and nutrient and plankton transport flux depends critically on detailed bottom topographic information of the study area, especially, the existence of the intertidal zone.

HORIZONTAL TEMPERATURE GRADIENT, VORTICITY, AND STRAIN IN THE SUBMESOSCALE OCEAN VARIABILITY FROM NUMERICAL SIMULATIONS

The dynamical structures and the statistical distributions of the horizontal temperature gradient, vorticity, and strain fields from a submesoscale—resolving ocean model simulations (300 meter resolution) are analyzed and compared with two sets of eddy—resolving and eddy—permitting simulations with 3 km and 18 km resolution, respectively. It is found that the magnitude of the simulated horizontal temperature gradient increases only mildly when the model resolution is changed from 18 to 3 km, while it increases dramatically when the resolution is further refined from 3 km to 300 m. In the 300 m simulations, the relative vorticity field exhibits a strong cyclone—anticyclone asymmetry with the strongest vortices overwhelmingly cyclonic. This evidence suggests that the ocean model successfully simulates the real physical fronts and the weak anticyclone—strong—cyclog—front triaminate only when they properly resolve the submesoscale. An additional analysis of an independent set of simulations with 1 and 10 km resolution is underway to test the robustness of this conclusion.

SEASONAL VARIATIONS IN THE SOURCE OF CHROMOPHORYIC DISSOLVED ORGANIC MATTER (CDOM) IN THE NEPONSET RIVER WATERSHED

Riverine chromophoric dissolved organic matter (CDOM) is often the major source of estuarine CDOM. Riverine CDOM has been thought to be constant, however, the concentration and characteristics of riverine CDOM are highly related with the land cover types in a watershed. In the Neponset Watershed, a typical urban watershed, 5 major land cover types were identified with a geographical information system (GIS). Water samples of each of these endmembers were collected monthly over the course of an entire year and incubated (filtered sample in dark bottle and unfiltered sample in clear bottle under sunlight for 5 days) right after collection. CDOM fluorescence, absorbance, excitation/emission matrix (EEM) spectroscopy, and dissolved organic carbon (DOC) were measured for all these endmembers, seasonal resolution of the 5 endmembers and their changing characteristics were determined, which help to estimate the characteristics of riverine CDOM and to further study the behavior of riverine CDOM in estuarine and coastal areas.

PSEUDO-NITZSCHIA COMMUNITY STRUCTURE IN THE ESTUARY, PUGET SOUND, WA

The Washington estuary Puget Sound consists of four hydrographically distinct but interconnected basins. Diatoms in the genus Pseudo-nitzschia are commonly detected in Puget Sound waters, but little is known about the distribution of species and strains among these different basins. A Pseudo-nitzschia specific automated Ribosomal Internal Spacer Analysis (ARISA) was used to determine Pseudo-nitzschia species composition at 21 stations in Puget Sound over a 3—day period in June 2006. Species composition varied significantly according to basin. Interestingly, the station with the most Pseudo-nitzschia species detected was “Triple Junction,” where waters from three basins mix together. One species, P. pungens, was detected at every station surveyed and in samples from ~80 m. Most species exhibited more restricted distributions, and some were detected at less than half the stations surveyed. We are currently generating Pseudo-nitzschia environmental clone libraries to determine if intraspecific populations similarly group according to basin. A prototype model-data visualizer, written in Java using the Processing.org toolkit, was developed to highlight correlations between community structure, water properties, and transient circulation features, and to give non-modelers access to model hindcasts.

ENVIRONMENTAL CHARACTERIZATION OF CRABEATER SEAL FORAGING ZONES ALONG THE WESTERN ANTARCTIC PENINSULA

We examined the relationships between physical features of the environment and the foraging behavior of Crabeater Seals along the Western Antarctic Peninsula in 2001, 2002 and 2007. We obtained data from 43 seals which were followed using Satellite Relay Data Loggers (SRDL) that provided information on location and diving behavior (all years), as well as temperature and salinity profiles (2002 and 2007 only). Satellite data on sea surface temperature, sea surface height, sea surface height anomaly, bathymetry, ice coverage, chlorophyll-a concentration and primary productivity were obtained for each location along the tracks. SRDLs transmitted data for between 25—150 days for 2001, 5—123 for 2002 and 2007 (two animals still transmitting as of October 1st, 2007). We identified areas where animals displayed potential foraging behavior, or Area—Restricted Search (ARS) zones, using the fractal landscape method. This approach, based on the estimation of fractal dimension, is an effective method to recognize locations that are within ARS zones, allowing us to characterize the foraging areas observed along the tracks versus segments where the animals were transiting.

THE WATERSHED WATCHERS PROGRAM: A COLLABORATIVE EFFORT TO INTEGRATE OCEAN OBSERVING DATA INTO A K—5 MARINE SCIENCE CURRICULUM

Effectively tapping into the vast resources of ocean observing data for educational purposes, both formal and informal, requires the development of data display and visualization tools tailored to meet the needs of these diverse audiences. The “Watershed Watchers” program is a collaborative effort between Campbell Park Elementary School Marine Science Center, The Pier Aquarium, and the University of South Florida (USF) College of Marine Science, is a prototype effort to incorporate real—time meteorological and water quality data into a cross—cutting K—5th grade marine science curriculum. Our experiences with classroom teachers, informal science institutions, scientists and school administrators highlight the necessity of maintaining an open and mediated dialogue among participants and can provide insight into the steps necessary to ensure that development of ocean observing data resources is consistent with the demands and requirements of the larger educational community. Short—term “Watershed Watchers” program goals include the development of innovative approaches to teaching complex ocean science and ocean literacy topics to younger students using ocean observing data, including the creation and design of web based and printed educational resources aligned with state science testing standards and academic achievement benchmarks.

THE HOME STRETCH: 3-D SWIMMING TRAJECTORIES OF SETTLEMENT-STAGE CORTAL RICH FISH LARVAE IN THE FLORIDA KEYS

Larval dispersal and connectivity result from biophysical interactions between larvae and their environment. While transport can be driven primarily by oceanographic processes, larval behavior can also be important. Settlement stage coral reef fish larvae often have considerable swimming abilities and use acoustic and olfactory cues for settlement habitat selection. In the Florida Keys, an extensive barrier reef system is in close proximity to a major western boundary current. In this environment, habitat selection behavior could greatly affect larval dispersal, depending on the distance larvae can effectively orient, navigate, and swim. To investigate the spatial scale of orientation and navigation, in situ observations of bicolor damselfish (Stegastes partitus) larvae were conducted 1 km offshore of Molasses Reef, Key Largo, Florida. Settlement larvae from light-trap samples were released by scuba divers and observed for 10 min. Swimming trajectories were reconstructed in 3-D from speed, direction, depth, and current measurements. Individual directionality and group choice of swimming direction were analyzed using circular statistics. Directionality and swimming speeds were used to estimate the spatial scale of effective navigation.

COMPARISON OF METABOLIC ACTIVITIES IN PERMEABLE NEARSHORE SEDIMENTS

In this presentation we contrast benthic metabolism in three permeable sandy sediments and their overlying water, located in tropical, sub tropical and a temperate climate, respectively. All sites were affected by advective pore water exchange and the sub-tropical and temperate sites also by seasonal changes in nutrient regime. Production and decomposition of organic matter activities were measured with benthic advection chambers and laboratory column reactors permitting defined pore water percolation rates through retrieved sediment cores. The results show high productivity and decomposition rates at all study locations and the link between the metabolic process in the sediment and overlying water column. The comparison reveals surprisingly similar rates and responses to flow in the sub tropical and temperate study sites but a stronger response to flow in the tropical environment.

EFFECTS OF MOC VARIABILITY ON THE UPPER LAYER TROPICAL ATLANTIC

The upper layer circulation in the tropical Atlantic can be understood as combination of a shallow wind-driven overturning cell between the sub tropics and tropics (STC) and the deep, interhemispheric meridional overturning circulation (MOC). The interaction of these two circulation cells leads to a predominantly hemispheric origin of the tropical Atlantic water masses. Earlier studies using idealized ocean models without a shallow wind-driven overturning cell but a stronger response to flow in the subtropical and temperate study sites but a stronger response to flow in the tropical environment. While the immediate response to bleaching may be species dependent, the reliance on heterotrophic feeding during recovery was universal at 4 and 16 weeks.

REGIONAL COMPARISON OF SURFACE TURBULENT FLUX PRODUCTS

This study compares the surface turbulent fluxes with the forcing variables from nine products and investigates the differences on both basin wide and regional scales over the Atlantic, Pacific, and Indian Oceans. The products based on weather models include the 2nd NCEP reanalysis, ECMWF 40-yr reanalysis (ERA-40), and Japanese 25-yr reanalysis (JRA-25). Data sets based on in situ observations include NOC (formerly SOC) and FSU. Purely satellite derived products include those from Goddard (GTSSTI), ISREMER, and the 2nd version of HOAPS. A hybrid NWP model and satellite product from WHOI is also included in this comparison. Zonal averages of the stress and heat fluxes reveal very large differences among the various products. For the Atlantic Ocean, the largest differences in the zonally averaged stress and sensible heat fluxes exceed 60 W/m2 and 15 W/m2 respectively. Comparables differences are also found over the Pacific and Indian Oceans. Regional analysis of the distribution of the fluxes shows large variations between products at all latitudes. In some regions, median latent heat flux values differ by 40 W/m2 between products.

COMPETITION AND FACILITATION BETWEEN UNICELLULAR N2-FIXING CYANOBACTERIA AND NON-N2-FIXING PHOTOPHYSIS SPECIES

Recent discoveries show that unicellular nitrogen-fixing cyanobacteria are more widespread than previously thought. We combined theory and experiments to investigate competition between these small unicellular diazotrophs and other phototrophic species. We...
developed a competition model that incorporates several physiological processes, including the light dependence of nitrogen fixation, the switch between nitrate assimilation and nitrogen fixation, and the release of fixed nitrogen. Model predictions were tested in competition experiments using the unicellular nitrogen-fixing cyanobacterium Cyanothece, the picocyanobacterium Synechococcus, and a small green alga (Chlorella sp.). In experiments with high nitrate input concentrations, the species with lowest critical light intensity (Synechococcus) competitively excluded the other species. At low nitrate input concentration, however, nitrogen release by Cyanothece enabled stable coexistence of Cyanothece and Synechococcus. In fact, release of fixed nitrogen by Cyanothece enabled Synechococcus to become more abundant in the species mixture than it would have been in monoculture. This interplay between competition and facilitation is likely to be a major determinant of the relative abundances of unicellular nitrogen-fixing cyanobacteria and non-nitrogen-fixing phytoplankton species in the oligotrophic ocean.

MUTANTS IN RECOVERIES FROM MASS EXTINCTIONS: A PHENOTYPIC REFLECTION OF ENVIRONMENTAL STRESS OR UNUSUAL GENOTYPES?

As the world ocean continues to be affected by anthropogenic change, our understanding of the recovery of oceanic ecosystems from past global perturbations becomes increasingly important. The recovery of pelagic ecosystems from the most recent mass extinction, the Cretaceous/Paleocene (K/P) boundary, offers insights into the pattern, timing, and mechanisms of evolutionary recovery. We conducted a high-resolution study of the relative species abundance of pelagic foraminifera in the western tropical Pacific following the extinction. This study revealed resurgence of several genera of microfossils in foraminifera during the initial, approximately 1 million-year long, “boom-bust” recovery period. While aberrant Parvularugoglobigerina euubien has been described previously, mutants in multiple genera have not. Aberrant test morphology may reflect either chamber malformation or increased environmental stress (not heritability) or presence of unusual genotypes. We describe the timing, abundance, and morphological regularity of mutant foraminifera throughout the K/P recovery relative to environmental proxies and the abundance and speciation/extinction rates of pelagic foraminifera. We examine these trends to determine the extent to which mutant foraminifera in evolutionary recoveries reflect environmentally induced chamber malformation or selection for unusual genotypes.

WAVE INSTABILITY CRITERIA FOR INTERFACIAL WAVES BREAKING OVER A RIDGE

Internal wave breaking at submerged bathymeric features such as ridges and seamounts is thought to be responsible for a substantial amount of the ocean’s vertical mixing. Laboratory experiments are used to investigate under what conditions periodic, interfacial wave trains become unstable when propagating over a submerged feature. Particle image velocimetry (PIV) and Planar laser-induced fluorescence (PLIF) are used to obtain highly spatially resolved measurements of density and velocity simultaneously during wave breaking. From such measurements, the local gradient Richardson number (Ri_g) can be calculated. Strong counter-rotating velocities due to nonlinear wave steepening at the ridge act to increase the critical value of Ri_g for instability above the canonical value of Ri_g = 0.25 for potential shear instability in parallel, steady shear flow.

A SPATIAL AND TEMPORAL ANALYSIS OF BENTHIC COMMUNITY STRUCTURE IN THE NORTHERN BERING SEA

The northern Bering Sea is a productive shelf ecosystem, in part because sea ice dynamics and primary production in the spring are intimately tied to export of labile organic carbon to the benthos. The rich benthic community supports large benthic predators (e.g., epibenthic crabs and snails, diving seaducks and marine mammals). Near-annual sampling over the past twenty years indicates a transition in the dominant bivalve from the large, thin-shelled Macoma calcarea to the comparatively smaller, thicker-shell Nuculidae radiata in addition to declining trends in overall benthic infaunal biomass. Changes in benthic community structure are being analyzed through similarity cluster analysis (Bray-Curtis index) to group stations from 16 oceanographic cruises over the past twenty years. Ordination through non-metric multi-dimensional scaling is used to analyze infaunal abundance in these benthic populations over time. In addition, station group separation is being evaluated with ecological parameters, such as sea ice cover/duration, hydrographic parameters, sediment variables, and spatial trends using the Geostatistical Analyst function of ArcGIS software. Results will be presented that evaluate potential forcing factors for the benthic changes being observed in this system.

STABLE ISOTOPE PROBING OF MICROCIBILITY COMMUNITY DYNAMICS ASSOCIATED WITH PHYTODETritUS DEGRADATION IN MARINE PERMEABLE SEDIMENTS

Stable isotope probing (SIP) in sediment core profiles was used to directly link denitrification and phytophoretic degradation to identification of active microbial populations in permeable sediments of the shallow Gulf of Mexico. Post-bloom conditions were simulated by the addition of isotopically-labeled, heat-killed Spirulina cells to whole-core sediment chambers. Relative to non-amended cores, the addition of phytoplankton resulted in sharply increased N fixation and dissolved inorganic nitrogen efflux as well as elevated oxygen consumption rates. Fingerprinting of the SSU RNA genes showed an enrichment of the Gammaproteobacteria in phytophoretic amended sediments, and SIP confirmed that the microbial groups that actively assimilated phytophoretic were predominated by the Gammaproteobacteria. Fingerprinting of denitrification genes (nosZ) paired with SIP revealed the dominant phytophoretic likely to catalyze nitrogen removal. Amino acid alignment showed a strong relatedness of 14C-derived clones to NosZ whereas 12C clones are less related. Thus, our preliminary results suggest that phytophoretic amendment influenced the enrichment of structural different NosZ proteins. Higher resolution sequence data is required to better elucidate the structure-function relationships of denitrifying prokaryotes in amended treatments.

PHYTOPLANKTON TRENDS IN MASSACHUSETTS BAY - 1992-2007

The Massachusetts Water Resources Authority (MWRA) has monitored the effluent and the quality of the ambient receiving waters of Massachusetts Bay and Boston Harbor since 1992. Our monitoring program was designed to assess the environmental effects of releasing an effluent discharge from Boston Harbor to Massachusetts Bay. Over eight years of baseline data and over six years of post-diversion data are available through September 2007. The MWRA has documented improvements to Boston Harbor following the transfer of the effluent offshore, addressed concerns about the effects of the offshore outfall, and documented the importance of regional factors on local variability and trends. These factors include annual variation in meteorologically-driven regional Alexandrium blooms and climate (temperature)-linked annual variation in Phaeocystis bloom duration. Although the accumulated information suggests that the outfall is generally benign, ongoing outfall monitoring provides surveillance for unusual events and contributes to understanding of regional factors affecting plankton blooms. Late summer ctenophore blooms may affect zooplankton and in turn planktonplankton (recent phenomena), and variable fall diatom bloom dynamics across the data set. This paper will explore the interplay between the regional/hemispheric factors and phytoplankton chlorophyll biomass of 15 plus years of measurements.

TEMPORAL TRENDS IN SEABIRDS NEAR THE PribILOF ISLANDS

We examined trends in the abundance of 12 species of marine birds around the Pribilof Islands in southeastern Bering Sea during the 1970s-2004. These species, which include Pacific loons, short-tailed shearwaters, forster's terns, red phalaropes) were scarce in the 1970s, were abundant in the 1980s, and declined in abundance in the 1990s and in 1999-2004. Planktivorous alcids that breed at the Pribilof Islands showed a remarkable 4x increase from the 1970s to the 1980s, and a rapid decline after the 1980s. In contrast, the abundance of piscivores (kittiwakes and murres) was high in the 1970s and declined thereafter. In 1999 and 2004, the total number of all seabirds at sea around the Pribilof Islands was well below the numbers seen in any other survey period. We hypothesize that these changes in the abundances and types of seabirds present through time reflect changes in the structure of the marine ecosystem of the eastern Bering Sea shelf. We suggest that changes in pathways of energy flow may be responsible for these shifts, although a decline in primary production cannot be ruled out.

SUB-TIDAL VARIABILITY IN THE HUDSON RIVER PLUME AS A RESULT OF HIGH-FREQUENCY FORCING

During the course of Lagrangian Transport and Transformation Experiment (LaTTE) in 2004 and 2005, the structure of the Hudson River plume was highly variable. Although forcing due to variations in discharge, low-frequency winds, and ambient shelf circulation are important, high-frequency forcing and sub-tidal response of the plume is apparent in the observations. Tidal mixing in the estuary manifests as fortnightly variability in plume stratification in the 2005 and 2006 mooring records. Diurnal wind variability related to the sea-land breeze system (SLBS), while episodic, accounts for up to 50% of the energy in surface currents in the New York Bight Apex at times. Regional Ocean Modeling
The applicability of a two-layer theory for abyssal current steering of upper ocean current pathways is investigated using HYCOM simulations with high vertical resolution (15-32 layers). This theory has the advantage that it is relatively easy to apply in simulations by comparing model results with oceanographic data from stratified basins. However, it is not as easy to apply to observations in the real ocean. This is because the two-layer theory is based on the assumption that the ocean is stratified, which is not always the case. Additionally, the two-layer theory does not take into account the effects of wind stress and tides, which are important factors in the ocean circulation. To address these limitations, we have developed a new model that incorporates a more realistic representation of the ocean circulation.

We demonstrate how our model can be used to predict the effects of wind stress and tides on the ocean circulation. Our results show that these factors can have a significant impact on the ocean circulation, and that our model is able to accurately predict these effects. This is important because it allows us to better understand the ocean circulation and its role in the Earth's climate system.

Vertical migrations are recognized as a critical component to the development of realistic models of larval dispersion. Unfortunately, our understanding of these behaviors lags well behind our ability to construct 3-dimensional flow-field models. We demonstrate how laboratory experiments can be used to resolve this problem. We examined the effect of ontogeny and temperature on vertical responses of larval Pacific cod to changes in light levels, but larvae at 4°C were more surface oriented than larvae at 8°C. The behavior of smaller larvae (<10 mm SL) showed no response to varying light levels, but larvae at 4°C were more surface oriented than larvae at 8°C. The behavior of larger larvae was consistent with a diel vertical migration and independent of temperature.

We also apply eight years of discreet-depth sampling in the Gulf of Alaska to validate and scale laboratory observations to the field. Field data for small larvae (c.1 mm) failed to show indications of vertical migration, a finding that was consistent with the laboratory results. However, field data were insufficient to determine patterns of vertical migration in larger larvae. These comparisons demonstrate the utility of independent laboratory observations in developing dispersal projections.

**ABYSSAL CURRENT STEERING OF UPPER OCEAN CURRENT PATHWAYS IN AN OCEAN MODEL WITH HIGH VERTICAL RESOLUTION**

The applicability of a two-layer theory for abyssal current steering of upper ocean current pathways is investigated using HYCOM simulations with high vertical resolution (15-32 layers). This theory has the advantage that it is relatively easy to apply in simulations by comparing model results with oceanographic data from stratified basins. However, it is not as easy to apply to observations in the real ocean. This is because the two-layer theory is based on the assumption that the ocean is stratified, which is not always the case. Additionally, the two-layer theory does not take into account the effects of wind stress and tides, which are important factors in the ocean circulation. To address these limitations, we have developed a new model that incorporates a more realistic representation of the ocean circulation.

We demonstrate how our model can be used to predict the effects of wind stress and tides on the ocean circulation. Our results show that these factors can have a significant impact on the ocean circulation, and that our model is able to accurately predict these effects. This is important because it allows us to better understand the ocean circulation and its role in the Earth's climate system.

Vertical migrations are recognized as a critical component to the development of realistic models of larval dispersion. Unfortunately, our understanding of these behaviors lags well behind our ability to construct 3-dimensional flow-field models. We demonstrate how laboratory experiments can be used to resolve this problem. We examined the effect of ontogeny and temperature on vertical responses of larval Pacific cod to changes in light levels, but larvae at 4°C were more surface oriented than larvae at 8°C. The behavior of smaller larvae (<10 mm SL) showed no response to varying light levels, but larvae at 4°C were more surface oriented than larvae at 8°C. The behavior of larger larvae was consistent with a diel vertical migration and independent of temperature.

We also apply eight years of discreet-depth sampling in the Gulf of Alaska to validate and scale laboratory observations to the field. Field data for small larvae (c.1 mm) failed to show indications of vertical migration, a finding that was consistent with the laboratory results. However, field data were insufficient to determine patterns of vertical migration in larger larvae. These comparisons demonstrate the utility of independent laboratory observations in developing dispersal projections.

**APPROPRIATELY DETAILED SURVEYS FOR EFFECTIVE SEAFLOOR SENSOR INSTALLATIONS**

Appropriate surveys of the seafloor where ocean observatories will be installed are critical to the success of these projects. The sensors must be located in an environment matched to their scientific objectives, and then installed and potentially serviced in a way that will not disrupt the provide energy for the upward transport of organic carbon. This is required for the deployment, there should be no interaction. The systems are generally designed to work in this pristine environment for on the order of 25 years. Initial design of any observatory requires swath bathymetry surveys and full seafloor characterization of a regional basin. In deep water, regional surveys from surface vessels might be followed by high-resolution deep-towed surveys. In most cases ultra-precise mapping using an AUV will then be needed for the waters near the sensors. The greatly increased cost of acquiring high-resolution data mandates that survey programs be designed well in advance of final observatory design and installation. This paper illustrates the resolution, and costs, of various survey techniques that need to be applied to the various stages of observatory implementation.

**VARIABILITY IN THE LIPID CLASS AND ISOTOPIC COMPOSITIONS OF THE HAWAIIAN CORAL, PORITES COMPRESSA, AND ITS SYMBIOTIC ZOOXANTHELLAE**

Lipid class and stable carbon and nitrogen isotopic variations of coral host tissue and zooxanthellae were examined at a range of spatial scales and two depths in order to understand the basic biogeochemistry of the Hawaiian coral Porites compressa in Kaneohe Bay, HI. Host and zooxanthellae tissues have significantly different lipid class compositions, which wax esters dominate host tissues and triglycerides dominate zooxanthellae tissues. Polar lipids, fatty acids, alcohols, and sterols are less abundant in both tissues. Host lipid concentrations were relatively homogeneous over all spatial scales (cm to km) where as zooxanthellae lipids exhibit heterogeneity. Host and symbiont 13C signatures correlate at reef crest suggesting zooxanthellae and host carbon cycles are tightly coupled. At 4m, however, depleted 13C values in host tissues suggest corals must supplement their carbon supply via heterotrophy. At the largest spatial scales (between reefs) significant variation in 13SN indicates regional variations in nitrogen input. Thus, both the variability within a system as well as the dynamics of the coral-zooxanthellae relationship must be considered when defining biogeochemical and trophic dynamics within the coral ecosystem.

**COMBINING LABORATORY AND FIELD OBSERVATIONS TO MODEL VERTICAL MOVEMENTS OF LARVAL PACIFIC COD: EFFECTS OF ONGENETY, TEMPERATURE, AND LIGHT**

Vertical migrations are recognized as a critical component to the development of realistic models of larval dispersion. Unfortunately, our understanding of these behaviors lags well behind our ability to construct 3-dimensional flow-field models. We demonstrate how laboratory experiments can be used to resolve this problem. We examined the effect of ontogeny and temperature on vertical responses of larval Pacific cod to changes in light conditions in vertical columns. Smaller larvae (<10 mm SL) showed no response to varying light levels, but larvae at 4°C were more surface oriented than larvae at 8°C. The behavior of larger larvae was consistent with a diel vertical migration and independent of temperature.

We also apply eight years of discreet-depth sampling in the Gulf of Alaska to validate and scale laboratory observations to the field. Field data for small larvae (c.1 mm) failed to show indications of vertical migration, a finding that was consistent with the laboratory results. However, field data were insufficient to determine patterns of vertical migration in larger larvae. These comparisons demonstrate the utility of independent laboratory observations in developing dispersal projections.

**RADICarbon Evidence for lateral supply of organic CARRON to the DEEP CANADA Basin**

Understanding the processes driving the carbon cycle in the Arctic Ocean is of fundamental importance for assessing the impacts of the predicted rapid and amplified anthropogenically-driven climate change in this critical region. However, our knowledge of these processes, especially in the permanently or seasonally ice-covered deep Arctic basins, is severely hampered by the paucity of information on fluxes and fate of biogenic materials exported from surface waters to the interior basins. We analyzed sinking particle samples intercepted by a time-series sediment trap deployed in the abyssal Canada Basin (3067m) in order to examine carbon export to the deep Arctic Ocean. Old radiocarbon ages (mean ~ 1900 14C years) of organic carbon, abundant lithogenic material (~80%), and mass flux variations temporally decoupled from the cycle of primary productivity in surface waters suggest that, unlike other ocean basins; the majority of the organic carbon on export in the deep Canada Basin is laterally advected from the surrounding margins. Whether this carbon derives from the continents or reflects marine productivity over the shelves and marginal seas remains unclear. Nevertheless, predicted changes in physical forcing on the Arctic Ocean suggest that this situation may change dramatically in the near future with uncertain biogeochemical and ecological consequences.
VORTEX-VORTEX MERGER AND INTERACTIONS BETWEEN THE LOOP CURRENT EDDIES

We describe vortex-vortex merger and interactions observed between the Loop Current Eddies (LCE) in the Gulf of Mexico (GoM) using satellite altimetry and HYCOM. GoM altimetry exhibits that two LCEs located in the western and central GoM ('west' and 'east' vortices) frequently collide and merge into a giant LCE, however, occasionally they remain/move apart without merger. Isolated vortex-vortex interaction models (two LCE-types, not embedded at different initial positions) reveal that vortex-vortex merger occurs when (1) the east vortex is bigger/stronger than the west vortex, (2) the west vortex strongly reflects offshore due to vortex-topography collapse and 3) the west vortex is strongly distorted and core-strained out by vortex-topography interactions. Vortex distortion/erosion due to vortex-topography collapse play a significant role in the merger. During the merger, the east vortex generally attracts and absorbs the west vortex, inducing vigorous momentum and mass transports. On the other hand, two approaching vortices occasionally remain apart or 'repose' to the opposite direction when the west vortex has strong swirl currents without distortion, which repels the east vortex south or north. During the vortex-vortex interaction, filaments detached from the west vortex often attach to the east vortex, producing a northward drift of the east vortex. We present examples of vortex-vortex merger and 'repose' from a realistic GoM model.

GEOCHEMICAL DATA AND SOURCE OF ORGANIC MATTER FROM THE SURFACE SEDIMENT OF THE TWO BAYS OF KOREA

Surface sediments of the two bays (Gwangyang and Masan) of Korea were conducted to estimate the sedimentary environments and to determine the source of organic matter (OM), the portion of terrestrial OM. Total 75 surface sediments from Gwangyang and Masan bay were analyzed and compared with C/N ratio of OM and other inorganic geochemical data. Analytical values of the carbon isotope of OM in Gwangyang bay ranges from -25.83% to -20.26%, and in Masan bay sediment it ranges from -20.76 to 19.92%. The terrigenous portion of OM was calculated by using 13C content as -28% in 13C CN. The terrigenous OM content is -27% in 13C CN. It ranges from 20.01 to 19.7% in Gwangyang bay (ave: 21.75%), and from 54.69 to 13.17 in Masan bay (ave: 25.18). Therefore, relatively large portion of terrigenous OM was supplied into the bay sediments. Especially, terrigenous OM mainly contributes to total organic carbon content near the river mouth area. The ratio of the OM also exceeds 10 in several samples indicating clear contribution of terrigenous organic matter input. However, both C/N ratio and carbon isotope of organic matter do not matched well in terms of terrigenous signals. This may be due to the sedimentary environments. In both bays, anoxic environment has been prevailed due to the sluggish ventilation and shallow water depth. The concentration redox-sensitive elements and other geochemical data support severe anoxic sedimentary environment.

COMPARING KELP COMMUNITIES ON THE INNER AND OUTER COASTS OF SOUTHEAST ALASKA

Variation in physical and biological processes in coastal ecosystems determines kelp productivity and influences community structure. Identifying regional patterns of community structure is necessary to interpret coastal ecosystem response to climate change. We compared kelp communities on the inside coast of southeast Alaska near Juneau, and the outer coast near Skitka. Greater seawater exchange and reduced freshwater runoff at the outer coast may result in greater kelp biomass, density, and diversity; however kelp communities have not been comparatively studied between subregions of southeast Alaska. Kelp communities were surveyed at nine sites in each location using SCUBA transects at 6 m and 12 m depths to characterize physical habitats, and quantity kelps. Water quality parameters were measured using a CTD. Kelp abundance was greater at 6 m in both locations, but there was no significant difference in kelp abundance or density between locations. Species richness and diversity were greater on the outer coast, although community evenness was similar between locations. Patterns of kelp community structure are evident within and between these coastal subregions of southeast Alaska.

NITROGEN FIXATION IN THE MEDITERRANEAN SEA

The Mediterranean Sea is an oligotrophic basin characterized by low nutrient levels and unusually high NO3/PO4 molar ratios in the deeper layers, that reach the maximum (N/P ≈ 28) in the Eastern Mediterranean. An external nitrogen source needs to be claimed in order to explain the nitrogen excess. Pantoja et al. (2002) found that the 15N/14N natural abundance in particulate and dissolved inorganic nitrogen display low values, suggesting an external source of “light” nitrogen source. Two hypotheses can be formulated to explain the west vortices: (i) nitrogen fixation from atmospheric deposition and/or (ii) atmospheric molecular nitrogen throughout nitrogen fixation. During TRANSMED oceanographic cruise carried out in

Coral reefs are an essential element of the economies, cultures and ecology of the Pacific Islands of Micronesia. While traditional stewardship practices have served to protect coral reefs and their related resources for generations, recent development activities and outside influences have threatened the sustainability of reef fisheries and have led to the regional decline of coral reef health and resilience. Poor land use practices within inland watersheds have led to the degradation of coastal reefs, with an accompanying cost to present populations of islanders and are threatening the legacy to be left to future generations. There is a need for modern science to help guide the management of human activities responsible for coral reef decline, and scientific data need to be presented to stakeholders and leaders in a form and format that can be used to develop and implement sound conservation policies. The integration of modern scientific techniques with traditional management activities has proven to be effective in several villages in Micronesia, and this experience serves a model for broader conservation efforts regionally and internationally.

**MODELING THE DYNAMICS AND TRANSPORT OF SOUTHERN CALIFORNIA STORMWATER PLUMES**

In the highly urbanized region of Southern California stormwater plumes carry considerable amounts of known and unknown pollutants, and have significant effects on coastal water quality. Understanding the dynamics and transport of these stormwater plumes is essential to proper management of coastal resources. The Regional Ocean Modeling System (ROMS) is used to investigate statistically the temporal and spatial variability of typical coastal plumes in response to the ever-changing ocean environment. Plume persistence and characteristic directions of transport are identified. Plume dispersion and dilution rates are used to compute the cumulative impact of stormwater pollutants, such as nutrients. The results of this investigation are compared with field measurements and satellite imagery of stormwater plumes.

**COCCOLITHOPHORE CALCIFICATION UNDER HIGH CO2**

From the mid-Mesozoic, marine calcifying phytoplankton, the coccolithophores, have been major calcium carbonate producers in the world's oceans. It has been suggested that the increasing anthropogenic CO2 absorbed by the oceans will cause ‘ocean acidification’ and that this will decrease calcification in coccolithophores. Recent results show that, in a scenario where the CO2 partial pressure in the world's oceans is twice that of pre-industrial concentrations compared to current levels, calcifying phytoplankton will double the rate at which they calcify and photosynthesize. Consequently, calcium carbonate to particulate organic carbon ratios are comparable across CO2 partial pressures ranging from pre-industrial to end of the century projections. These trends are consistent with those seen in the geological record of the calcified phytoplankton community in past periods of CO2 increase.

Our findings have significant implications for biogeochemical modeling of future oceans, and highlight acclimation and evolutionary versatility of a major calcareous group to past and future ocean acidification.

**PERFORMANCE OF THE 2ND ORDER TURBULENCE CLOSURES IN THE RED SEA OVERFLOW**

Mixing between overflows and ambient water masses is a critical problem of deep-water formation in the downwelling branch of the meridional overturning circulation of the ocean. Modeling approaches that have been tested so far rely either on algebraic parameterizations in hydrostatic ocean circulation models, or on large eddy simulations that resolve most of the mixing using nonhydrostatic models. In this study, performance of different closure models (k-ε, k-ω, KPP; and Mellor-Yamada) are evaluated by conducting numerical simulations of the Red Sea overflow and comparing the results to those observed in the Red Sea Outflow Experiment. We also use a new k-ε turbulence model without any closure assumptions to model the Red Sea Outflow. The results of this investigation are compared with field measurements of velocity and temperature at the outflow. It is found that most of the two-equation turbulence models capture the basic structure of the overflow, consisting of a well-mixed bottom layer (BL) and entraining intermediate layer (IL). KPP model leads to less mixing and thin IL; however Mellor-Yamada leads to high mixing and BL signal becomes weak. The other models including the new k-ε give reasonable result in error analysis with respect to the observations.

**A TOOL FOR EARLY DETECTION OF GLOBAL-SCALE CHANGES IN MARINE CALCIFICATION**

Ocean acidification is likely to impact calcification rates in many pelagic organisms, which may cause significant changes in marine ecosystem structure. We examine changes in marine CaCO3 production using the global biogeochemical ocean model HAMOCC in combination with observational data. Calcification in different organisms shows a wide range of sensitivities to saturation state. Therefore, we test different future calcification scenarios running the model until the year 2300 forced with anthropogenic CO2 emissions. Two assimilation systems based on a suboptimal extended Kalman filter have been developed to simultaneously assimilate physical and biochemical data into a complex ecosystem model of the Eastern Mediterranean. The three-dimensionnal ecosystem model is composed of two on-line coupled sub-models: the Princeton Ocean Model (POM) and the European Regional Seas Ecosystem Model (ERSEM). The filter is a variant of the extended Kalman filter which operates with low-rank error covariance matrices to reduce computational burden. Two different approaches have been considered: the “joint approach” for the “dueling filter”. In the first approach, one filter is used in which the state vector of the filter is composed of all prognostic variables of POM and ERSEM models. Basically, the numerical models are integrated forward in time to produce the (physical and biochemical) forecasts. The observations are then assimilated jointly to correct all forecast variables using the cross-correlations between all physical and biochemical forecast errors, which simultaneously provides the analyses for the physics and for the ecology. The dual approach consists of two filters, operating separately on the physics and on the ecology. We describe the two assimilation systems and discuss results of assimilation experiments with a coupled POM/ERFM model of the Mediterranean Sea ecosystem.

**LAGRANGIAN DATA ASSIMILATION: METHOD, APPLICATION AND STRATEGY**

The Lagrangian data assimilation (LaDA) is a method for the assimilation of Lagrangian observations directly into the model. By augmenting the model state vector with the coordinates of the Lagrangian instruments and computing their trajectories based on the model velocity, the LaDA removes the need for any commonly used approximations to transform the Lagrangian observations into the Eulerian velocity observations. We demonstrate the LaDAs efficacy using the ocean applications. By considering a volume of influence, we examine how and to what extent the LaDA propagates the information horizontally and vertically. When the drifter deployment locations are judiciously chosen, the LaDA is strikingly effective in both estimating the large-scale ocean circulation and tracking the ocean eddies. Using Lagrangian analysis based on dynamical systems theory, we present a strategy for observing system design that maximizes the impact of Lagrangian observations.

LAYERED ISOPYCNAL INTRUSIONS FROM A SLOPING BOUNDARY
Motivated to understand better the fate of baroclinic waves impinging on sloping boundary areas, fluorescent dye was released at a point ~15m above the critical sloping boundary of a Scottish fjord (maximum depth=150m) and tracked for four days with CTD/fluorometer casts at an average speed of 5m/s across the basin. Shear micro-stratification measurements were made, and a thermometer mooring deployed. The dye spread symmetrically in the vertical (Kz=1.5–10-4 m/s2) until the lower edge of the patch became influenced by the bottom boundary layer (BBL). The shallower portion of the BBL-influenced dye spread rapidly upslope (~1 km/day) in a 3 metre thick layer influenced by non-isopycnal distortions. The deeper portion of the BBL-influenced dye detached from the boundary and intrusted into the interior at a slower rate (~0.5 km/day) in three distinct layers along isopycnal surfaces. At the depth of the intrusions (50 to 70m) the baroclinic wave field was characterised by a clear M2 signal. It is argued that the layered intrusions result from the gravitational collapse of mixing patches created by the trapping of baroclinic energy on the critically sloping boundary.

ACCURATE TIDE MODELING AND SEMIDIURNAL SEICHS IN SOUTHEASTERN ALASKA
Oceanic tides in the foidic system of Southeastern Alaska are realistically simulated by a barotropic model. The simulated tides strongly depend on the seafloor bathymetric data sets. In the case of the GINA bathymetric data (Lindquist et al., 2004), the major M2 component tides are simulated with errors less than ten percents of the observational tides. Sea level in the vicinity of the Chatham Strait resonates with semidiurnal tides. The simulation with the ETOP02 bathymetric data (Smith and Sandwell, 1997) gives unrealistically amplified sea level response to the semidiurnal tides in the strait, since depths based on ETOP02 are shallower than those based on the GINA data sets by several tens meters in large areas of the Inner Passage. Especially in the head of the Chatham Strait, the M2 tide is amplified by several tens centimeters (i.e. a few tens percents of the observational M2 amplitude).

Ingardona, J. P. NOAA Northwest Fisheries Science Center, Seattle, USA, john.ingardona@noaa.gov

FISH EMBRYOS AS SENTINELS FOR UNEXPECTED HUMAN HEALTH THREATS
Developmental biology and genetics have revealed the high degree of evolutionary conservation among vertebrates. Thus the embryos of a fish (Danio rerio, zebrafish) have become a powerful tool for studying the molecular basis of human disease. As humans are difficult to study in lab, so are many native fish species. Zebrafish thus provide a powerful tool for the study of fish health as it relates to conservation biology and coastal resource management. Polycyclic aromatic hydrocarbons (PAHs) derived from fossil fuels are among the most abundant pollutants on the planet. To gain insight into how PAHs affect fish health, as demonstrated by the impacts of the Exxon Valdez oil spill on species such as pink salmon (Oncorhynchus gorbuscha), we are analyzing the effects of PAHs on zebrafish embryos. These studies identified the heart as a major target for tricyclic PAHs such as phenanthrene, which are very abundant in both water and air. Because the candidate molecular targets are conserved between fish and human hearts, tricyclic PAHs are a likely contributor to diseases, which are very abundant in both water and air. Air and concentration of DOM was applied to seawater samples from Effingham Inlet, British Columbia. To trace chemical transformations within the water column, DOM samples were characterized with total carbon and phosphorus magnetic resonance (NMR). The molar ratio of carbon to phosphorus in the one DOM sample analyzed to date is 235:1. This ratio is essentially identical to the average carbon to phosphorus ratio of 211:1 seen in open ocean DOM. Although DOM elemental ratios are similar in estuarine and open ocean samples, NMR analyses reveal large differences in the relative abundance of compound classes. Effingham Inlet samples contained phosphate esters (85-86%), phosphonates (3-5%) and, notably, polyphosphates, which accounted for 10-11% of the total dissolved phosphorus pool. In comparison, open ocean DOM samples are comprised of approximately 75% phosphate esters, 25% phosphonates, and have little or no polyphosphates present. Carbon, NMR spectra of Effingham Inlet samples indicate enrichment in alkyglycerol carbon and depletion in carboxydrate carbon relative to open ocean DOM samples.

INCREASING IMPACT AND REDUCING CHALLENGES OF AQUATIC SCIENCE EDUCATION AT THE UNDERGRADUATE LEVEL
A multiple-year assessment on a local constructed wetland has provided the framework to advance three important goals in aquatic sciences education at the undergraduate level: 1) expand interdisciplinary thinking in students and faculty, 2) promote females in science, and 3) foster ownership of learning by taking the research to the classroom, and the classroom to research. A three-way collaboration between chemistry, civil engineering, and applied biology faculty has led to students being trained more deeply in their own areas of expertise and broadly among the three disciplines. Framing the project in terms of human and environmental benefit has attracted many female students, far overrepresenting females relative to the student body. Techniques, tools, and skills resulting from the procedures developed by the undergraduate research collaborators have been incorporated into general classroom use, and classroom projects have been designed to model research. Although several challenges have been encountered, students have proven to be remarkably resilient, with most participants maintaining a long term commitment to the project and intending to pursue careers in the environmental sciences.

ON THE EFFECT OF A SILL ON DENSE WATER FORMATION IN A MARGINAL SEA
Dense and intermediate water formation in the North Atlantic, in the Nordic and Labrador Seas, respectively, contribute to the global ocean’s overturning circulation and poleward heat transport. One major difference between these two basins is the due to the Greenland-Scotland Ridge which isolates the deep waters of the Nordic Seas from those of the North Atlantic. In this study, we investigate the role of the sill in setting the properties of the water mass transformed by comparing convection in an idealized, semi-enclosed basin, subject to surface cooling, with and without a sill that separates it from the open-ocean. This study utilizes both numerical and theoretical tools to extend previous studies that addressed this problem in a sill-less basin. We find that denser (colder) waters are formed in and exported from a marginal sea with a sill compared to an identical basin with no sill. Dynamically, the sill impacts the convective process within the marginal sea both locally, by limiting the advection of heat into the basin (from the open-ocean), and non-locally by affecting the width and depth of the boundary current, which alters the stability of the boundary current as it flows around the marginal sea. While idealized, we believe these experiments capture the basic features of convection in the Nordic Seas and, furthermore, support the distinction between the dense waters formed in the interior of the basin and those exported by the outflows.

CONSEQUENCES OF INCREASED MOBILITY AND QUICKER DEVELOPMENT IN POND PLANTS, S. C. L., Georgia Institute of Technology, Atlanta, USA, ingel@seas.gatech.edu; Jackson, C. L., Georgia Institute of Technology, Atlanta, USA, dstl@seas.gatech.edu

COMPOSITION AND TRANSFORMATION OF ESTUARINE DISSOLVED ORGANIC MATTER FROM SAMPLES RECOVERED USING COMBINED ELECTROLYDIALYSIS AND REVERSE OSMOSIS
A new high yield technique combining electrolydialysis and reverse osmosis for the recovery and concentration of DOM was applied to seawater samples from Effingham Inlet, British Columbia. To trace chemical transformations within the water column, DOM samples were characterized with total carbon and phosphorus magnetic resonance (NMR). The molar ratio of carbon to phosphorus in the one DOM sample analyzed to date is 235:1. This ratio is essentially identical to the average carbon to phosphorus ratio of 211:1 seen in open ocean DOM. Although DOM elemental ratios are similar in estuarine and open ocean samples, NMR analyses reveal large differences in the relative abundance of compound classes. Effingham Inlet samples contained phosphate esters (85-86%), phosphonates (3-5%) and, notably, polyphosphates, which accounted for 10-11% of the total dissolved phosphorus pool. In comparison, open ocean DOM samples are comprised of approximately 75% phosphate esters, 25% phosphonates, and have little or no polyphosphates present. Carbon, NMR spectra of Effingham Inlet samples indicate enrichment in alkyglycerol carbon and depletion in carboxydrate carbon relative to open ocean DOM samples.
such as reduced water viscosity), these changes will enhance the mobility of fish larvae. A model of the pelagic phase of fish, which represents larval behavior explicitly, is used to simulate individual trajectories in a typical coastal environment. Rather than implementing the very few things we know about larval behavior, an optimization method allows to compute the best behavioral rules given a goal (i.e. recruitment) and realistic constraints (e.g. swimming speeds, larval duration, etc.). This model is used to examine the influence of enhanced swimming abilities and shorter larval durations on the ability of larvae to self-recruit. The optimization method as well as the consequences on population connectivity of predicted changes in recruitment dynamics are discussed.

VARIATIONS IN THE RESERVOIR AGE OF THE NE PACIFIC OVER 6000 YEARS

SUGGESTS CHANGES IN OCEAN CIRCULATION – LINKED TO CLIMATE?

Variations observed in the reservoir age of the ocean from a single site over time may indicate differences in ocean circulation, possibly reflecting changes in climate. Long-term data from single or closely associated sites in the NE Pacific are rare. We add to that meager body through data obtained from Mink Island, an archeological site in Katmai National Park & Preserve, located in the Shelikof Strait in the northern Gulf of Alaska. We compare 13C dates of paired marine and terrestrial material selected from different climate periods over the last 60,000 years. The dated terrestrial material is chosen from human occupation surfaces, while the marine dates are from midden shells of the bivalve, Saxidomus giganteus, surveyed to be at the same excavation level. A rigorous examination of the archeological context is being used to validate the pairings. The differences between the marine and terrestrial changes over time indicate that there is not a constant reservoir age for this NE Pacific location. These differences suggest that ocean circulation has changed over the last 60,000 years, possibly in response to climate.

SATELLITE DETECTION OF SEASONAL AND SECULAR CHANGE OF GLOBAL OCEAN BIOME DISTRIBUTIONS

Historically, the ecological concept of biome has been applied to static global ocean climatologies with the purpose of describing the basic biogeography of marine systems. However, because these biogeographical maps are not time-resolved, the seasonal and secular changes in ocean biome distribution have been missed. In this work, we use a biome classification scheme that is based on time-resolved satellite imagery. This method allows us to see seasonal and secular changes in global ocean biome distributions. This technique has been independently validated with in situ data. We find strong seasonal signals in biome distributions in all areas of the global ocean and find secular trends in the area of certain ocean biomes. For example, our analysis suggests that the most oligotrophic biomes in the global ocean may be increasing in size. Understanding the long-term secular trends in ocean biomes has implications for the future of global ocean primary production. In addition, we analyze the tempo-spatial variability of biomes to identify the most variable regions of the global ocean.

DIFFERENT DISCHARGE MECHANISMS OF WARM WATER BETWEEN NORTHERN AND SOUTHERN PACIFIC OCEANS DURING EL NINO

The discharge of warm water volume (WWV) in the tropical Pacific related with El Niño/Southern Oscillation (ENSO) is a key to understand the termination of ENSO. We have investigated interannual variation of the WWV transport above the 20°C isotherm by diagnosing the observed data and results from a numerical experiment. The results indicate that WWV transports in the western region play different roles in the northern and southern hemispheres. The transport across 8°S in the western region counterbalances the interior transport, and both are approximately explained in terms of the Sverdrup theory. In contrast, the boundary transport across 20°F does not balance because of remote effect by Rossby waves. Negative wind stress curl anomaly generated in the northern off-equatorial region after the mature state of ENSO deepens the 20°C isotherm depth that generates anomalous northward transport. Hence imbalance of the WWV transport between the western boundary and interior in the northern hemisphere has more impact on the variability of WWV in the tropical Pacific.

RECENT TRENDS OF THE VERTICAL DISTRIBUTION AND THE SIZE COMPOSITION OF CHLOROPHYLL- A IN THE WESTERN NORTH PACIFIC REGION

From the last several decadal data of the vertical distribution and the size composition of chlorophyll-a (Chl-a) in the western North Pacific, significant trends of three relating indices with Chl-a at summer season were found. (1) the proportion of Chl-a in the surface layer to that of the whole water column was linearly decreased by 0.4 % in the subtropical area along 137°E (STA137) and by 2.3 % year^-1 in the Kuroshio Extension area along 175°E (KEA175), respectively, (2) the depth of subsurface Chl-a maximum increased by 0.4 m year^-1 in STA137 and 2.6 m year^-1 in KEA175, and (3) larger-sized Chl-a (larger than 3 µm) decreased at the ratio of 2.5 % year^-1 in KEA175. We also found that the ratio of bio-genic opal/ biogenic CaCO3 in the sinking flux decreased -0.015 year^-1 in the subtropical region from 1997 to 2005. These trends indicate the possibility that larger phytoplankton, such as diatoms, has been decreasing during the past decade in the western North Pacific at least in the summer.

TREND OF DIC INCREASE IN THE WESTERN NORTH PACIFIC ALONG P9 AND P13

Trend of DIC increase in the WP core cruises along the same lines conducted by JMA and that of the WEST-COSMOS project, we have analyzed the decadal trend of total dissolved inorganic carbon (DIC) on various isopycnic surfaces in the northern limb of the subtropical gyre. The preformed NDIC (=DIC - 117 –170AOU/45) at layers ≤ 26.7 at 165˚S and 0 ≤ 26.1 at 137˚E are increasing at a rate of +0.7 to +1.2 µmol kg^-1 year^-1 that are in near equilibrium with the atmospheric CO2 increase. The rate of increase of preformed NTICO reduced moderately to +0.4 to +0.6 µmol kg^-1 year^-1 at 26.2 ≤ 26.5 at 137˚E, and it abruptly decreased in deeper layers and no significant increase was detected below 27.0 in both sections.

THE COLD-WATER BELT OFF THE SOYA WARM CURRENT IN THE NORTHEAST COAST OF HOARKAIDO

The cold-water belt (CWB) is frequently appeared off the Soya Warm Current in summer. The formation mechanism of the CWB has two formation mechanism (Ishizu et al., 2017). One is the upwelling of the so called “Sakhalin current” by topographic effect, the other is the upwelling in the northeast coast of Hokkaido, which is formed by the convergence due to the bottom Ekman transport of strong wind/wave forcing during storms. Net horizontal transport during supercell events is approximately downwind and associated cross-shelf transport is dependent on the angle between storm wind direction and shelf orientation. Net cross-shelf transport will be mediated by seasonal variability of storm frequency and directionality. With spring storm winds typically from the NE off much of the US east coast, supercell events often directed onshore transport across the inner shelf, acting as vectors for springtime movement of bioactive material towards the coast. Year-class success of fish stocks that spawn near the shelf break but rear in coastal

IMPACT OF INDIAN OCEAN DIPOLE ON INTRASEASONAL ZONAL CURRENT IN THE EASTERN EQUATORIAL INDIAN OCEAN

Impact of the Indian Ocean Dipole (IOD) on intraseasonal zonal currents in the eastern equatorial Indian Ocean is evaluated in an eddy-resolving OGCM. A neural network pattern recognition approach, so called self-organizing map (SOM), is applied to fourteen-year output fields from 1990 through 2003, which capture weak positive IOD event in 1991, strong positive IOD event in 1994, strong positive IOD event co-occurred with El Niño in 1997/98, and two negative IOD in 1996 and 1998-1999. The analysis identified change in dominant mode of variability associated with the IOD events. During positive IOD events, the intraseasonal zonal currents are mostly dominated by higher modes, while the first two modes become more dominant during negative IOD events. One potential contribution factor to these interannual variations is an apparent shoaling of psy-
OCEAN CARBON PUMPS AND AIR-INSECT DISSOLVING OF CO2. Dissolved Inorganic Carbon in surface waters can be significantly out of equilibrium due to the finite timescale of air-sea CO2 exchange. Surface dissolubility is carried into the thermocline and deep ocean through water mass formation and ventilation processes. This “dissolution carbon pump” can significantly impact the global ocean carbon storage. We formulate a highly idealized model to illustrate how it modulates solubility and biological carbon pumps and impacts on atmospheric CO2. The magnitudes of surface dissolution are controlled by the balance between entrainment, surface residence time, air-sea heat and gas exchange, and export production. The theory predicts that the dissolution pump amplifies the effect of soft-tissue carbon pump by up to a factor of 2. For example, if the sea ice cover can reduce the effect of soft tissue pump by increase air-sea dissolution. The theoretical predictions are supported by a suite of sensitivity experiments using a global ocean circulation and biogeochemistry model. These results highlight the importance of air-sea CO2 equilibration in the regions of water mass formation and its impacts on the oceanic carbon inventory.

SUBMEOSESCALE/MESOSCALE SYNTHESIS BASED ON DATA-DATA AND DATA-MODEL FUSION INVOLVING NON-PROBABILISTIC A PRIORI INFORMATION Novel approach for synthesis of a coastal ocean state through data-data and data-model fusion is presented. The fusion process is formulated as a global optimization problem for which direct search for the optimal solution (corresponding to enhanced estimate of environment) is performed under control of non-probabilistic a priori information coming from the historical data, different sensors, model simulations and expert opinions. Methods, based on control analysis, apply to sensor fusion, aggregation of expert opinions as well as merging databases. The approach represents the non-probabilistic a priori information and uncertainty associated with it through the so-called fuzzy sets. That results in convenient and fast numerical algorithms for searching the global extremum of the objective functions through high-performance parallel computing, allows using non-traditional information, such as synthetic aperture radar images and expert opinions, and combining pieces of information, which contradict one to another. The approach is targeted to synthesis of submesoscale/mesoscale fronts, jets, eddies and islands waters through fusing high-resolution satellite data and lower resolution in-situ data, as well as satellite data and numerical simulation results for Central and Southern California.

PROPAGATION OF SEASONAL SIGNAL IN THE ATLANTIC WATER LAYER IN THE ARCTIC OCEAN Warm and salty water of Atlantic origin (AW) enters the Arctic Ocean through the Fram Strait. In Fram Strait and north of Svalbard AW experiences strong seasonal variations due to the large volume of meltwater entering the Arctic Ocean in the North Atlantic Deep Water formation and the cold Arctic water from the Norwegian Sea. The seasonal cycle of AW is determined by the Svalbard Current, which flows southward on the eastern side of the Svalbard Archipelago. The Svalbard Current interacts with the Arctic Current, which transports cold and fresh water from the North Atlantic to the Arctic Ocean. This interaction results in a strong seasonal cycle of AW in the Arctic Ocean, with warm and salty water entering the Arctic Ocean in the summer and cold and fresh water entering in the winter. The seasonal cycle of AW is influenced by the Arctic Oscillation, which is a major mode of variability in the Arctic climate system. The Arctic Oscillation is characterized by a positive anomaly of atmospheric pressure in the Arctic, which results in increased inflow of Atlantic water to the Arctic Ocean and a negative anomaly of atmospheric pressure in the North Pacific, which results in decreased inflow of Atlantic water to the North Pacific. The Arctic Oscillation is a major driver of climate variability in the Arctic, and its variability is linked to global climate patterns such as the North Atlantic Oscillation and the El Niño-Southern Oscillation.

KUROSHIO-INDUCED COLD EDDY STREETS IN THE LEES OF ISOLATED ISLANDS A time series of SAR images acquired during summer of 2006 revealed island wakes in the lees of oceanic islands in the north of Japan. The wakes were formed not only of vortices, but also of eddy streets with diameters in the order of the islands. The Kuroshio flowed in the vicinity of these islands in summer of 2006, which indicates that the island wakes were induced by a Kuroshio-island interaction. Satellite sea surface temperature (SST) and Chlorophyll-a (Chl-a) images observed in summer of 2006 showed low SST and high Chl-a wakes, some of which included low SST eddy streets. A numerical simulation was performed to investigate their formation mechanism. The simulation qualitatively reproduced the cold eddy pattern, with eddy-driven mixing developing a mixed layer down to 100m, causing the low-SST island wakes. The shedding frequency and distance of the model-produced eddies were close to those of the Karman vortex theory, suggesting that Karman-type cold eddy streets are commonly formed behind the islands when the Kuroshio passed.

PROPOSITION OF SEASONAL SIGNAL IN THE ATLANTIC WATER LAYER IN THE ARCTIC OCEAN The accurate representation of the formation of North Atlantic Deep Water (NADW) is challenging for the current generation of climate models. Their resolution is insufficient to depict the entire range of scales associated with the important water mass formation processes. Some of the widely argued reasons for these model deficiencies are the poor representation of overflows, freshwater fluxes, and overestimated ice extent. In the current work we analyze the biases and their origins in NADW formation in terms of location, pathways, and formation rates, in a suite of IPCC model simulations. The fidelity of the models will be assessed with diagnostic metrics such as mixed layer depth, volumetric latitude, and volume fluxes through crucial inter-basin sections. The results will be compared to similar quantities from observational data sets and a finer resolution, coupled ocean-ice simulation, forced with realistic NCEP/NCAR atmospheric fluxes. Special focus will be given to the estimation of the water mass transport over the Nordic Seas, and its sensitivity to changes in the surface heat and freshwater fluxes. Finally, to further understand the inter-annual variability of NADW water mass formation related to the North Atlantic Oscillation we will examine the different ocean states during its opposite phases. Their connection to changes in the atmospheric and sea ice conditions will be investigated.

NUMERICAL STUDY OF THE BOTTOM-CONFINED INTENSE MIXING USING AN EIKONAL APPROACH Diapycnal mixing is thought to play an important role in global overturning circulation. Previous observations showed that background diapycnal diffusivity was O(10^5 m^2 s^(-1)), an order of magnitude less than required to maintain global overturning circulation (e.g. Gregg, 1987). Recently, enhanced mixing above rough bathymetry is thought to be a strong candidate for the missing mixing that might make up for the lack of diapycnal diffusivity in the thermocline. In such areas, diapycnal diffusivity rapidly increases exceeding 10^4 m^2 s^(-1) as the rough ocean bottom is approached (Polzin et al., 1997). In this study, as a first step to clarify the physical mechanism of bottom enhanced mixing, we carry out a series of numerical experiments using an “Eikonal Approach” (Hessey et al., 1986). It is clearly shown that vertical scales of bottom-confined mixing hotspots are strongly dependent on horizontal wavenumbers of internal tides emanating from the ocean bottom, local density stratification, and latitudes.

VARIABILITY OF THE CARBON BUDGET AND CONSEQUENTIAL FLUXES AT THE BATS SITE For decades, scientists have been trying to understand the carbon cycle of the ocean by exploring the various processes that regulate carbon within the upper ocean. Typically, the net exchange of CO2 between the atmosphere and upper-ocean is dominated by surface fluxes. Measurements made over the last eleven years from the BATS project have shown some interesting results. Within the DIC pool, long-term changes are evident and represent a significant component of the total carbon pool of the water column. On the other hand, monthly variations in the total carbon budget (0-300m) are large (~1.5 to 3.5 moles C m(-2)) as compared to the assumed total mixed waters (summarized sediment trap fluxes, gas flux and active transport by zooplankton typically < 0.2 to 0.5 moles C m(-2) year(-1)). It appears much of this residual imbalance in carbon change is associated with the physical processes such as mesoscale eddies or horizontal advection rather than biological (i.e. Redfield). We investigate the extent of these physical processes and devise a simple box model approach to investigate the flux variability of the total and individual pools of carbon.

THE PACIFIC OCEAN SHELF TRACKING PROJECT, PROVIDING A WINDOW ON THE MOVEMENT OF SALMON AND OTHER SPECIES

The Pacific Ocean Shelf Tracking (POST) array is an expanding telemetry array for tracking fish in coastal and freshwater regions of the Pacific Northwest. The array is one of two Census of Marine Life projects focusing on movement of marine organisms using electronic tagging technology. POST’s marine array currently spans over 2,200 km from Willapa Bay, WA, in the north to San Diego, CA, and almost 900 km up the Colombia-Snake River. The acoustic technology used allows the seamless tracking of fish in both freshwater and marine environments. POST has successfully measured the migration paths, swimming speed and estimated survival of migrating salmon smolts from numerous species and stocks in the Pacific Northwest. Adult salmon have been tagged at sea and tracked back to their natal rivers and young salmon have been tagged with ‘sleeping tags’ that turned back on prior to their return spawning migration. The array has revealed remarkable long distance migration of other species such as green sturgeon. POST can help answer questions critical to conservation, fisheries management and the role of fitness in salmon smolt survival.

REAL-TIME TURBULENT ODD PLUME QUANTIFICATION: II. CORRELATION TO SPECIALIZED BEHAVIORS IN BLUE CRABS

Previous behavioral studies suggest that blue crabs (Callinectes sapidus) utilize chemical signals arriving at their antennules in combination with perception of flow direction (odor-gated rheotaxis) to move towards sources of attractive odors. Experimental evidence also suggests that bilateral comparison of spatially-separated chemosensory must occur simultane-ously with odor-gated rheotaxis for C. sapidus to successfully navigate chemical plumes and locate attractive sources, such as food and mates. To further test these hypotheses, we use three-dimensional laser-induced fluorescence (3DLIF) data to evaluate correlations linking chemical signal properties at the antennules to simultaneous upstream motion and correlations connecting the signal contrast across transversely-separated leg chemosensors to simultaneous side-to-side position adjustments. Preliminary data indicate that the intensity of concentration maxima at the antennules significantly correlates with the duration of upstream motion surges in tracking C. sapidus. Further, the intensity of concentration maxima at the antennules directly correlates with the magnitude of the resulting change in upstream crab walking speed. Additional data evaluating relationships between behavior and signals arriving at the antennules or the leg chemosensors will also be presented.

SEDIMENTARY SIGNATURES OF PALEOTUSSUNI DEPOSITS IN SRI LANKA

The subsurface of Sri Lankan coastal lagoon sediments include at least two deposits analogous to the 2004 tsunami deposit. Sediment cores collected during two field campaigns to Karagan Lagoon, southeastern Sri Lanka, were sampled along transects parallel and perpendicular to the coastline. The 2004 tsunami layer is characterized by inversely graded coarse quartz sand intermixed with some silt and shell fragments. Based on similar trends in sorting, grain size, and their deposits are 10 cm thick and are composed of inversely graded coarse quartz sand intermixed with some silt and shell fragments.  Based on similar trends in sorting, grain size, and their ages (3690 to 4570 radiocarbon years), these deposits are interpreted to represent paleotsuna layers. These deeper deposits are taken as evidence for tsunamis that occurred during periods of increased sea level. The 2004 tsunami deposit in Karagan Lagoon thus provides a modern analog by which we can interpret the deeper sand layers. Our study provides evidence that there were at least two paleotsunamis that affected Karagan Lagoon during the Holocene.

TIDAL EFFECTS ON THE MEDITERRANEAN OVERFLOW

We investigate the influence of a barotropic tide on the mixing through the Strait of Gibraltar, and hence on the Mediterranean overflow. A barotropic tide could have several effects on the water flowing through the strait: firstly it could enable dense water to move over the strait, leading to a denser overflow; secondly, the greater kinetic energy could generate more mixing through turbulent bottom stresses, leading to a less dense overflow; and thirdly, the barotropic tide could generate more shear through interactions with topography leading to greater mixing and a less dense overflow. Our initial results suggest that the properties of the outflow are relatively insensitive to the amount and source of mixing in the strait, since there are negative feedbacks in the steep slope region downstream of the strait.

A TRACER RELEASE EXPERIMENT ON THE EAST PACIFIC RISE (9°N TO 10°N): IMPLICATIONS FOR LARVAL DISPERSION

Tracer release experiments can provide estimates of dispersion of passive particles including some larvae. To investigate dispersion of hydrothermal vent larvae, sulfur hexafluoride was released in a 1.2 km long streak in the axial summit trough (AST) of the East Pacific Rise at 9°N. A survey approximately 40 days after the injection revealed complex horizontal and vertical distributions of the tracer. Only a small percentage of the tracer (about 3%) remained on the ridge crest and this patch was spread along an 80 km section of the ridge with the main concentration near 9°59°N, an Integrated Study Site of the Ridge 2000 program. These observations provide direct evidence of connectivity between vent communities on the ridge. The tracer distribution was heavily influenced by the topography and hydrothermal vent plumes in the area. Analysis of the vertical distribution of the tracer suggests as much as 16% of the tracer was exported in hydrothermal plumes. Comparison of the tracer distribution with a three-dimensional hydrodynamic model prediction is encouraging and gives further insight into the evolution of the tracer patch.

SEAFLOOR SALINITY AND TRANSPORT: VARIABILITY TO SURFACE FORCING CHANGES

In nature and coupled models, ocean-atmosphere feedbacks of freshwater are mutually compensated by evaporation and precipitation. However, in stand-alone ocean circulation model (OGCM) studies, precipitation is prescribed from forcing datasets and evaporation is computed using a variety surface boundary conditions. In this paper, the sea surface temperature, salinity variability and the associated transports are investigated for many existing forcing datasets and varying boundary conditions using a global primitive equation model. Results show a significant variability in the surface transport with a very different ocean state for the forcing datasets. While a systematic surface salinity and temperature increase is found, the near-dynamic equilibrium solution converges to a fresher state compared to climatology. An additional source of variability in the numerical simulations is the parameterization of ocean mixing. In general, differences due to mixing are large in the near-equatorial band between 30°S and 30°N latitudes. The overall goal of this work is to understand and quantify the role of fluxes in the surface salinity distribution in the ocean in relevance to the upcoming Aquarius SSS mission to be launched in 2009.

OPERATIONAL OCEAN ENVIRONMENT PREDICTION BASED ON SATELLITE OBSERVATIONS

Satellite observations are a critically necessary piece of information required to forecast the ocean environment for operational uses. Broadly, the ocean processes can be categorized into 1) predictable processes such as tides for which forcing is accurately known and predictions made, 2) deterministic processes such as inundation that given accurate forcing predictions may be constructed, and 3) nondeterministic processes such as mesoscale instabilities for which continual observations are required as small errors grow in time. Within each of these categories, satellites provide necessary data that makes operational prediction possible. For all these, satellite observations are very limited to the ocean surface and are often sparsely distributed through space and time. A coordinated effort must be made to join satellite observations with additional knowledge of the ocean in order to extend the observation influence. This additional knowledge takes the form of understanding the dynamics and representation in numerical model systems, information based on historical data that shows relations between surface and subsurface ocean state and in situ sensors that provide direct surface to subsurface observations. All these components must come together on a daily basis to provide predictions that are used by many government agencies and people for applications from recreation to fishing to search and rescue.

COMPARISON OF DIFFERENT SUBMESOSCALE LATERAL MIXING SCENARIOS: A NUMERICAL STUDY

Our understanding of lateral dispersion at the submesoscales is largely limited by our incomplete knowledge of the dynamical mechanisms that act at these scales. We compare the characteristics of the lateral mixing produced by a variety of numerically simulated submesoscale flows, including fields of vortices created by the adjustment of mixed-fluid patches, rotating-stratified turbulence and near-inertial waves.
We present here an inversion for surface fluxes of carbon dioxide using the global carbon cycle inversion framework. The inversion is conducted on a semi-enclosed bay in northern Norway. The bay is characterized by a high biological productivity and a complex circulation regime. The inversion is based on a 6-year, high-resolution record of above-water, near-surface radiation (PAR) fluxes and above-water meteorological parameters. The inversion is performed using a flexible partitioning of carbon between anthropogenic and natural DIC pools. The inversion is conducted independently on these two components, a technique that does not allow for the exchange of carbon between the two pools. Instead, the two pools are treated as independent and the observed fluxes are partitioned between them. The inversion is repeated using a 1-D model and a 2-D model, and the results are compared.

VIDEO PLANKTON RECORDER REVEALS A THIN LAYER OF HYDROMEDUSAES IN A SEMI-ENCLOSED NORTH NORWEGIAN BAY.

High resolution images of zooplankton organisms were recorded in situ by a digital autonomic Video Plankton Recorder (VPR) in a semi-enclosed bay in northern Norway. The bay is characterized by a high biological productivity and a complex circulation regime. The VPR is a flexible platform that can be used for the recording of high-resolution images of zooplankton organisms. The VPR is a valuable tool for the study of zooplankton biodiversity and ecology.

In the past, the study of zooplankton biodiversity and ecology has been limited by the availability of high-resolution images of zooplankton organisms. The VPR provides a valuable tool for the study of zooplankton biodiversity and ecology. The VPR is a valuable tool for the study of zooplankton biodiversity and ecology.
seasonal patterns are not predicted by near-surface measurements, above-water measurements or estimates of dissolution, demonstrating that accurate assessment of the ecological and geochemical role of benthic production requires high-resolution in situ measurement.

DEVELOPING A CONSISTENT FRAMEWORK FOR QUANTIFYING CARBON EXCHANGES AT CONTINENTAL MARGINS

Continental shelf and slope (margin) systems are increasingly recognized as disproportionately important in global biogeochemical cycles and yet their inclusion in global flux models has been very limited. In part this is because a single definition of the margin is not universally employed, resulting in confusion from a range of carbon exchange flux estimates. In particular, the boundary between open-ocean and margin ecosystems is often placed at specific isobaths, e.g., 200m or 2000m, or at political boundaries such as the EEZ which do not correspond to regions of differing controlling processes. Here it is argued that the ocean - margin boundary should reflect the location where the processes controlling ecosystem characteristics and fluxes transition between domination by margin processes such as coastal upwelling, lateral exchange, fresh water input and bottom friction, and domination by open ocean processes such as eddy pumping, vertical diffusive exchange and vertical particle sinking. A relatively simple framework is presented here that considers both margin morphology and overall oceanographic setting and permits a more realistic integration and comparison of margin carbon fluxes.

MODULATION OF HURRICANE-INDUCED MIXED LAYER COOLING IN GULF OF MEXICO’S MESOSCALE OCEANIC EDDIES

Mesoscale oceanic eddies have been previously shown to impact the efficiency of hurricanes to cool the ocean mixed layer (OML), affecting the hurricane energy source and inducing storm intensity fluctuations. Understanding the degree of hurricane-induced OML cooling in ocean eddies has important implications for oceanic feedback to hurricane intensity. To illustrate this point, observations in the Gulf of Mexico during hurricanes Katrina and Rita (2005) and idealized numerical experiments of hurricane-induced OML entrainment in ocean eddies underscore the importance of the OML topography on hurricane intensity changes. Both storms deepened to category 5 status during interaction with warm oceanic features, then weakened after encountering a cold eddy prior to making landfall. Profiler measurements indicated that during both storms, increased cooling (4-5°C) was associated with shallower OML in cold eddies, while reduced cooling (<2°C) was observed in warm-eddies. The early storm season and oceanic eddy characteristics are not captured by satellite-derived sea surface temperature distributions that prevail in the GOM during the hurricane season, must be accounted for in coupled models to improve hurricane-induced OML cooling and intensity forecasting.

ENERGY FLUX AND THE DISSIPATION DEFICIT IN THE MARINE SURFACE LAYER

The evaluation of turbulent kinetic energy (TKE) budget equations over oceans is central to many studies on air-sea interaction. Although a number of studies to carefully evaluate the various terms of TKE budget, the problem is far from being closed. For example, measurements from recent field programs suggest that the waves substantially modify the shear and pressure transport terms of the TKE budget in the wave dominated boundary layer where the wave induced stress is a considerable fraction of the total stress. To illustrate this, we present results from the Marine Boundary Layers (MBL) and Coupled Boundary Layers and Air-Sea Transfer (CBLAST) field campaign where vertical profiles of heat and momentum fluxes, wind mixing, and downwelling in the winter 2006-07 contributed to the cool winter mixing and decreased coastal freshwater discharge. While anomalies in winter heat fluxes, wind mixing, and downwelling in the winter 2006-07 contributed to the cooling, it also appears that the winter runoff reduced shelf stratification and enhanced deep mixing. Our results underscore the sensitive dependence of temperature distributions on salinity for this shelf. Anomalously cold waters persisted through fall 2007. This observation, in conjunction with the evolving La Nina and a positive Arctic Oscillation Index suggest that the anomalous cooling may continue in the coming winter.

SILL PROCESSES IN THE SAGUENAY FJORD

Laterally-averaged nonhydrostrophic numerical simulations are used to investigate internal wave generation and turbulence production near a sill in the Saguenay Fjord, Quebec. The results suggest that the conditions in this environment (current, stratification, topography) are favorable for the development of large-amplitude, tidally-driven, internal solitary waves (ISWs) and provide insights into where and when turbulent kinetic energy is produced. Guided by the results of the numerical simulations a field experiment was undertaken to observe ISWs remotely, with shore-based cameras, and directly, with current and turbulence profilers. More than 20 internal wave events were encountered with many of them appearing to propagate cross-channel since a two-dimensional model cannot resolve cross-channel motion the fate of such internal waves is of particular interest.

ON THE NATURE OF THE 2006-07 WINTER COOLING ON THE NORTHERN GULF OF ALASKA SHELF

The 37-year temperature and salinity time series from the coastal hydrographic station GAK 1 on the northern Gulf of Alaska (GOA) shelf and NCEP meteorological data are used to describe the anomalous cooling of the winter 2006-07. That cooling interrupted a <1°C/30 yr increase in deep (>150 m) temperatures on the shelf and resulted in spring 2007 temperatures being <1°C lower than normal throughout the water column. The deep temperature has not recovered since 1973. Spring salinities were also anomalous being fresher at depth and saltier at the surface, and consistent with abnormally strong winter mixing and decreased coastal freshwater discharge. While anomalies in winter heat fluxes, wind mixing, and downwelling in the winter 2006-07 contributed to the cooling, it also appears that the winter runoff reduced shelf stratification and enhanced deep mixing. Our results underscore the sensitive dependence of temperature distributions on salinity for this shelf. Anomalously cold waters persisted through fall 2007. This observation, in conjunction with the evolving La Nina and a positive Arctic Oscillation Index suggest that the anomalous cooling may continue in the coming winter.

HEAVY METAL UPTAKE BY PERMEABLE SEDIMENTS

The sink-source characteristics of permeable river beds, following the release of heavy metals to surface waters, were investigated with stirred, cylindrical chambers. The effect of advective pore water transport on heavy metal fluxes was studied by comparing two stirring speeds, inducing (1) very low and (2) moderate rates of advection, and two sediments with different grain size and permeability, (1) coarse sand (0.5-1 mm, K=3.4 x10⁻¹¹ m²/s) and (2) medium sand (<0.5 mm, K=3.6x10⁻¹⁰ m²/s). The overlying water was spiked with Cadmium, Copper, Lead, and Nickel (250mmol L⁻¹) and sampled over a period of 3d. Heavy metals were generally scavenged at rates that followed the sequence Ga > Ni > Cd > Pb. In both sediments, advection strongly enhanced uptake rates. The largest effect was found in the coarse sand, where moderate advective transport increased heavy metal uptake up to 4.5-fold, and where heavy metal concentrations dropped by up to 30% in the first hour. This implies, that in the case of heavy metal discharge to rivers, permeable beds are efficient filters, thereby passing on contamination from the pelagic to the benthic zone.

EXTREME WAVES ON THE CONTINENTAL SHELF

Early scientific observers of monstrous waves on the oceans were often openly ridiculed. However, since the successful application of random process theory in the description of ocean waves, the existence of extremely large waves is no longer disputed. In fact, such giants should occur, just with low probability. But how rare are they really? Accumulated empirical evidence suggests that extreme waves are not as rare as the linear theory predicts. Nonlinear corrections have been shown to drive enhanced likelihood of extreme events in idealized wave fields, but the implications of non-Gaussian statistics for realistic sea states over variable depth are generally not well understood. In this study we present
of organic carbon additions. The addition of organic carbon substrate had a rapid and positive effect on denitrification rates as a whole, although the extent of this effect appears to be dependent on the amount of carbon amended to the sediment. Incubation cores receiving the greatest amounts of organic carbon yielded N2 fluxes three to four times greater than control incubations. Microbial denitrification in these cores was greatest within 68 hours of carbon deposition. This shift in denitrification can be attributed to both autotrophic andallochthonous nitrate pathways, as 60-70% of denitrification resulted from coupled nitritification processes. This rapid benthic response suggests that denitrification is significantly enhanced during the initial stages of a phytoplankton bloom, and is an important pathway for the removal of estuarine nitrate.

MESOZOOPLANKTON DISTRIBUTION ACROSS THE SOUTHERN INDIAN OCEAN WITH EMPHASIS ON APPENDICULARIANS

Mesozooplankton distribution across the Southern Indian Ocean and, in particular, appendicularia abundances and trophic interactions in the oligotrophic ocean area, is poorly described. We investigated the distribution of the two major mesozooplankton groups, appendicularians and copepods, across the Southern Indian Ocean. Copepod nauplii, copepods (including adults) and appendicularians dominated the mesozooplankton community - 20 µm (max. 26.432, 15.946 and 1.611 individuals m⁻², respectively). Copepods were most abundant off Southwest Africa facing Agulhas current and Southern Ocean waters while decreasing toward subtropical and tropical areas. Appendicularians showed the inverse pattern. The overall size distributions were very small, especially P. hirta with 90% < 320 µm in trunk length but showing increasing average sizes towards warmer waters. We conclude that the < 200 µm mesozooplankton fraction is of significant importance and should therefore been taken into account in future investigations concerning specific local areas. We present a statistical model to evaluate mesozooplankton abundances and biomasses in relation to food regimes (microbial loop components, fractionated chlorophyll), physical and biological settings to conclude about the role of appendicularians in the food web.

PRELIMINARY OCEANOGRAPHIC STUDIES AROUND TRINIDAD AND TOBAGO

In 13 stations sampled [CORE Project 1990], diatoms were predominant species. Faunal diversity varied from 14-25 in the vertical and 8-22 in horizontal samples. High silicates concentrations [1.0µ mol dm⁻³] in the surface waters were associated with low salinities presumably due to Orinoco river. The concentration of Chl a on the surface varied from 0.003 to 2.57 µg m⁻³. Two water masses - high salinity subtropical water and low salinity Antarctic intermediate water were observed. The rising isotherms near north coast at 50 m indicated upwelling. Bathymetric profiles showed sea bed devoid of sediments, piercement structures rising from beneath 50 m sediments and indication of turbidity currents. The data collected off companies, on the west and east coast of Trinidad have been used to reconstruct the structural and sedimentary history of the basin. However, there is need to study the area for oceanographic parameters in view of the active mixing processes in the region, the fluxes of nutrients and trace metals and influence of the Orinoco and Amazon rivers discharge.

EFFECTS OF CLAY MINERALOGY ON RETENTION AND MOBILITY OF ANTHROPOGENIC RADIONUCLIDES IN PUERTO RICO

Radionuclides, such as 137Cs, can be traced by observing sediment mineralogy. Sediments from Vieques and Rincon, Puerto Rico were tested to examine the retention capability of radionuclides. Beginning in 1944 and continuing until 2003, Vieques was used as an ammunition facility and bombing range. If 137Cs is retained here, there are sediments present that may also retain depleted Uranium. The BONUS Facility, a nuclear power plant located in Rincon, operated in the 1960s and was decommissioned and shut down completely by 1970, partly due to its 106 unintentional reactor shutdown. Sediment mineralogy was studied here to determine if the power plant was properly cleaned after its decommissioning. Gamma spectroscopy results indicated activity of 137Cs in the sediments of Vieques and Rincon. X-ray diffraction analysis indicated that both sites contain the clay smectite, which will facilitate radionuclide retention. Since Vieques sediments contain 137Cs and smectite, they also have the capability to retain other common radionuclides. Retention of 137Cs at Rincon can be from two sources: global fallout or the radioactive material that was not removed.

Observations from the Kuroshio Extension System Study (KESS) demonstrate the existence of recirculation gyres flanking the Kuroshio Extension. The KESS program had its observational stage over a 2-year period from June 2004 - June 2006 during which an array spanning the jet axis consisting of current meter moorings and inverted echo sounders equipped with near-bottom pressure and current sensors was deployed, additionally profiling CTD data were collected. Results from the KESS observations have found evidence for barotropic recirculation gyres both to the south and for the first time north of the jet. Direct evidence comes from the moored current meters, which show an eastward flow under the surface jet flanked by a barotropic western flow in the abyssal ocean to the north and south of the jet. The existence of a pair of recirculation gyres is also suggested by maps of the echo sounder and float data. Additional evidence for the recirculation gyres comes from the analysis of an eddy-resolving model simulation of the region. Estimates of the gyre transports are computed and the dynamics of the recirculation gyres are explored.

THE EFFECTS OF UV AND TEMPERATURE ON MICROBIAL COMMUNITY STRUCTURE IN A TEMPERATE LAKE

UV effects are temperature independent while their enzymatic repair may be temperature dependent. This may be particularly important in temperate lakes when spring water temperatures are still cold while UV is relatively high. We manipulated temperatures and UV treatments from the surface to the bottom, using microstructure profiles from the NOAA R/V Pisces IV. Net daily calculations of CO2 flux, using a physically based transfer velocity (k), are compared to wind speeds. Phase-dependent wind speed and cloud fraction with respect to solar insolation was reduced as the effects on solubility and k act in opposite directions. Additional evidence comes from the analysis of an eddy-resolving model simulation of the region. Estimates of the gyre transports are computed and the dynamics of the recirculation gyres are explored.

GLOBAL ESTIMATES OF NET COMMUNITY PRODUCTION (NCP) ESTIMATED FROM SEASONAL CLIMATOLOGICAL MAPS OF INORGANIC CARBON DATA

The global seasonal variability of upper ocean inorganic carbon parameters was used to estimate global rates of net community production (NCP). Multiple linear regression (MLR) methods were used to interpolate and extrapolate the temporally and geographically limited dissolved inorganic carbon (DIC) and total alkalinity (TA) data (collected as part of the 1996 TCOC cruises in the Atlantic) to the global ocean using other climatological and hydrographic data. The resultant climatological model has a temporal resolution of monthly, spatial resolution of 1° and vertical resolution throughout the water-column. Model uncertainty is evaluated by comparing our data to ocean carbon data collected at time-series such as HOT and BATs, and crust data from the Arabian Sea, Indonesia and Southern Ocean, for example. Estimates of air-sea CO2 gas exchange, vertical diffusion, entrainment and detrainment, and horizontal advection were used to compute global rates of NCP through mass balance approaches. Our estimates of global NCP were 11.8 ± 5.5 Pg year-1, which we compare to estimates from other approaches, including Jin et al., 2007 and Najjar et al., 2007.

ELUCIDATING CONTROLS ON ESTUARINE SEDIMENT NITROGEN CYCLING PROCESSES USING GENE ACTIVITY AND FLUX MEASUREMENTS

Denitrifiers in coastal and estuarine sediments remove anthropogenic inputs of nitrogen (N). N-fixers are not thought to be active in nitrogen-loaded ecosystems, however, the sediments in Narragansett Bay recently switched from being N sink to a N source from January to September. This switch in sediment microbial activity may be coupled to decreased benthic organic deposition. To better understand controls on benthic N cycling processes, we are following functional gene activity for nitrogen fixation and denitrification in combination with N-flux measurements from Bay sediments and in cores maintained in mesocosm experiments with manipulations of temperature and organic matter loading. Expression of nitrogeanase sequences (nifH) is evidence of active N-fixation and correlates with decreased organic matter deposition. These sequences are related to nifH genes from cultivated sulfate reducers. In samples with low nifH expression, denitrification genes ( nirS and nirK) are expressed. We are using quantitative PCR methods to compare gene
activity levels across nutrient loading gradients. These experiments should help elucidate how biogeochemical cycles of N, C, and sulfur are linked and how changing environmental conditions impact microbial N cycling.

THE HELIUM-3 FLUX GAUGE IN THE SUBTROPICAL NORTH ATLANTIC: WHAT DOES IT TELL US ABOUT NUTRIENT FLUXES AND NEW PRODUCTION IN AN OLGOTROPHIC GYRE?

The apparent correlation between tritogenic helium-3 and nutrients within the North Atlantic subtropical main thermocline can be used in combination with surface mixed layer measurements to estimate the flux of tritogenic helium into the subtropical gyn euphotic zone. We report observations extending over a period almost 3 decades. The flux thus estimated is approximately 0.9 moles of nitrogen per square meter per year, and appears to be significantly larger than tracer-based estimates of net community or export production near Bermuda. We discuss the reasons for this apparent difference and suggest that the dilemma can be resolved by consideration of the characteristic time-scales and timing of the underlying processes. We present the observational evidence for these conclusions, and frame them within a quasi-Lagrangian one-dimensional upper ocean model that emulates these processes.

MOMENTUM TRANSFER BETWEEN SEMIDIURNAL INTERNAL WAVES AND SUBINERTIAL FLOW AT A DISSPATISSING SURFACE REFLECTION

Full-depth profile data depicts semidiurnal internal waves radiating from Mendocino Escarpment. Previous analysis shows an energy-flux convergence at the station closest to the first surface reflection (Althaus et al., 2003). A plausible interpretation is that this energy is dissipated by superposition of the incident and reflected waves. Momentum flux is also diminished after the reflection. Because there is no profile data in the superposition region, a theoretical approach is used to overcome the data gaps. Assuming no zonal dependence, constant stratification and linear decay over the dissipation region, this forcing is calculated with parameters specific to Mendocino Escarpment data. Both superposition and dissipation can cause momentum flux divergence forcing. Comparisons with remaining forces at Mendocino Escarpment enable a more thorough understanding of momentum transfer. When zonal dependence is included, the zonal velocity is no longer out of phase with the meridional and vertical velocities. As a result, all the momentum flux divergences in the u-momentum equation remain, and the complexity of the scaling arguments increases. Reference: Althaus, A., E. Kunze, and T. Sanford, 2003: Internal tide radiation from Mendocino Escarpment. Journal of Physical Oceanography, 33, 1510-1527.

PHYLOGENETICS AND GLOBAL GENETIC DIVERSITY OF PTEROPODS (PELAGIC MARINE SNAILS)

Pteropods, or pelagic snails, comprise about 110 species of shelled (thecosome) and shell-less (pealeosome) gastropod mollusks that are entirely planktonic. The group’s taxonomy has a long history of revision and reinforcement by morphologists and molecular biologists, alternately arguing for cohesion of Tereosomatida and Gymnosomata (i.e. a monophyletic Pteropoda) versus multiple radiations of gastropods into the pelagic realm. While many species have been reported to occur in every major ocean basin, it is unclear whether such cosmopolitan species can be used to construct and constrain predictive models for river and estuarine flows. Here we present an overview of the project, which is a unique combination of closely coupled field and numerical model experiments to predict, interpret, characterize, and understand coherent structures. The project includes two major field experiments with both in situ and remote sensing measurements on the Shooshomich River near Everett, WA. We introduce the results from the first experiment in 2006 and outlines plans for the second experiment scheduled for the summer of 2008.

RETROSPECTIVE ANALYSES OF NORTON SOUND, ALASKA BENTHIC FAUNA

This study retrospectively examined evidence of changes in distribution and abundance of benthic epifauna and demersal fishes of Norton Sound Alaska, northeast Bering Sea from 1976 to 2006, based on triennial bottom-trawl surveys. Throughout the period, average bottom temperature did not increase, rather it decreased by 2°C, and overall abundance index increased exponentially by 370% with annual rate of 3% per year. Out of 40 selected species/taxa, 35 showed positive increase. Of those, 16 showed r > 0.5. However, those taxa had no significant correlations with any global ocean climate indices, such as AO, PDO, SOI, NP, PNA, or 19 physical or oceanographic variables specific to Norton Sound. There were also dramatic changes in species or taxa composition. About 70% of fauna was dominated by sea stars, of which Asterias amurensis was the most dominant. The data suggest that Norton Sound benthic fauna has not been significantly affected by climate changes.

INFLUENCE OF SCOTTISH SHELF WATER INFLOW ON PHYTOPLANKTON DYNAMICS IN THE GULF OF MAINE: DATA ANALYSIS AND MODELING

Continental shelf waters from the Labrador Sea to the Mid-Atlantic Bight experienced significant freshening in the late 1990s, likely caused by increasing glacial melting and enhanced precipitation and river runoff at higher latitudes (as a result of climate change). The freshening of the ocean can alter circulation and stratification of shelf waters and may influence the phytoplankton dynamics and ecosystem productivity. We used a 3-D coupled biological-physical model to examine the influence of freshening on the timing and magnitude of the plankton blooms and primary productivity in the Gulf of Maine/Scottish Shelf region. The model captured the general pattern of westward propagation of spring phytoplankton blooms from the Scottish Shelf to the western Gulf of Maine, con-
sistent with the observed increasing sea surface salinity and associated decreasing stability of the water column. The model showed that increased freshwater can further enhance the spatial gradients in timing by stimulating earlier blooms upstream (the Scotian Shelf), but has less impact downstream (the western Gulf of Maine). The model results suggest that surface water freshening may impede winter convection and decrease nutrient supply from deep water to the surface, thus influencing the overall seasonal primary productivity.

DO SOUTHERLY WINDS CONTROL THE LATITUDINAL ASYMMETRY IN THE SEASONAL CYCLE OF THE SST IN THE EASTERN PACIFIC? It has been hypothesized that during the fall southerly winds initiate the latitudinal asymmetry in the sea surface temperature anomaly about the equator in the eastern Pacific with southerly winds forcing northward currents that act to create the asymmetry. However, observations along 95°W in the Pacific ocean during EPIC (Eastern Pacific Investigation of Climate processes) show that from March 2000 to March 2003, when the winds were southerly between June and December, meridional currents were southward north of the equator. A three-dimensional ocean model forced by QuikSCAT winds, ISCCP shortwave, and NCEP other atmospheric variables was consistent with the observational analysis. The momentum budget was analyzed in the model to investigate the dynamics that result in the currents being in the opposite direction to the southerly winds. Preliminary results suggest that in the meridional momentum budget, the southerly wind stress is balanced by a meridional pressure gradient and that advection of southward momentum into the mixed layer from below is important in maintaining the near surface currents against the southerly winds.

Jiang, H., Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA, hjiang@whoi.edu; Paffenhofer, G. A., Skidaway Institute of Oceanography, Savannah, GA, 31411, USA, Gustav.Paffenhofer@skio.usg.edu

COMPUTATIONAL FLUID DYNAMICS SIMULATIONS OF PROTIST SINKING, SWIMMING, JUMPING, OR INTERACTING WITH EACH OTHER The original motivation of this work was to quantify the spatio-temporal hydrodynamic signals created by a ciliate swimming near an ambush-feeding Oithona plumefera female and to understand the role of hydrodynamic signal detection in mediating the copepod’s capture behavior. As a result, a suite of hydrodynamic numerical models were developed to simulate the total flow created by several groups of protists at their body scales. The model constructions were based on published information on body forms, propulsion machineries and global motility patterns of considered microorganisms. Flows of different complexities were simulated ranging from flow surrounding a phytoplankton settling from rest, flow created by a model flagellate, dinoflagellate or ciliate in steady swimming, flow behind a model ciliate jumping from a stationary position, to hydrodynamic interactions between two self-propelled protists in close proximity. Results of flow patterns (with comparison to the stresslet model), mechanical energy consumption, mass transfer, and hydrodynamic signal generation will be reported. It would be interesting to apply these models to investigate small-scale biological-physical-chemical interactions associated with these microorganisms, many of which are important players in the microbial loop.

AN UPWELLING COMPARATIVE STUDY BETWEEN US WEST AND EAST COAST WITH A DEVELOPMENT OF AN IMPROVED UPWELLING INDEX AND NUMERICAL MODELS Coastal upwellings off idealized US west and east coasts with different shelf widths are compared using a 3-D numerical model, with both hydrostatic and non-hydrostatic versions studied and compared. The results show that the distance of the upwelling front is proportional to both the strength and the duration of the wind forcing. 2D shelves do not prevent upward motion, but it reduces the sea surface temperature drop mainly due to lack of cold water supply at depth. To further compare the two different upwelling areas, an improved upwelling index, Upwelling Velocity Index (UVI), based on Ekman theory is derived from the divergence of the Ekman transport. It successfully estimates the vertical velocities on a shallow east coast shelf. The results are in good agreement with vertical velocities produced by a numerical model, with a correlation of 0.8. Being applicable to both US, east and west coasts, the UVI shows the coastal upwelling velocity along the east coast will typically be an order of magnitude smaller than upwelling along west coast due to the different shelf slopes.

CARBON DIOXIDE DEGASSING IN RIVER- AND MARINE-DOMINATED ESTUARIES: IMPORTANCE OF FRESHWATER RUNOFF The partial pressure of carbon dioxide (pCO2) and other inorganic carbon parameters were measured during both high tide and low tide in the surface water of three salt marsh estuaries off Georgia, USA from September 2002 to May 2004. Of the three estuaries, Sapelo and Doboy Sounds are marine-dominated estuaries that receive little freshwater besides precipitation, while Altamaha Sound is a typical river-dominated estuary that is dominated by freshwater runoff. During all of the sampling months, the three estuaries were super-saturated in CO2 with respect to the atmosphere (39.5-342.5 Pa, or 390 - 3380 μatm) due to inputs from intertidal marshes and freshwater runoff. Overall, the pCO2 in the river-dominated estuary is much higher than that in the marine-dominated estuaries. The calculated annual air-water CO2 flux in Altamaha Sound (88.8 mmol m-2 d-1) is 2-3 times of those of Sapelo and Doboy Sounds (36.9-38.0 mmol m-2 d-1). The higher CO2 degassing in the river-dominated estuary is fueled by the extra CO2 loading from freshwater runoff. Due to the large differences of the air-water CO2 fluxes in river- and marine-dominated estuaries, the current estimates of the air-water CO2 fluxes of global estuaries, which were exclusively based on river-dominated estuaries, could have been overestimated.

MODELING COASTAL PROCESSES IN MASSACHUSETTS BAY AND BUZZARDS BAY The western Maine Coastal Current (WMCC) bifurcates near Cape Ann, Massachusetts and a portion of which intrudes into Massachusetts Bay. The intruding flow is important to phytoplankton bloom, and transport of zooplankton and fish larvae in Massachusetts Bay. The specific nature of the bifurcation and the underlying mechanism, however, remain to be understood. We examine the roles of surface winds, freshwater input from Merrimack River, and upstream flow conditions in this process, using a numerical model and field observations that indicate the intruding flow either go around the Cape Ann or separate from the coast, depending on the strength of the WMCC near Cape Ann and surface winds. A strong intruding flow may become unstable under favorable conditions. Consequently, a cyclonic eddy may form near Cape Ann, propagate downstream, and further interact with nutrient-rich inflow from Georges Bank and in western Massachusetts Bay. We will also introduce our modeling work in Buzzards Bay. Preliminary results suggest a pronounced thermal front exists throughout the year separating Buzzards Bay from offshore, consistent with satellite images.

GEOCHEMICAL BEHAVIOR OF URANIUM IN THE YELLOW RIVER PLUME (YELLOW RIVER ESTUARY) The Yellow River (Huanghe) is the second largest river in China and is known for its high turbidity. It also has remarkably high level of dissolved uranium (DU) concentrations. To examine the mixing behavior of DU between river water and seawater, surface water samples were collected along a salinity gradient from the Yellow River plume during September 2004 and measured for DU concentration. DU activity ratio, PO4/P, and suspended particulate matter. In addition, laboratory experiments were conducted to simulate the mixing process in the Yellow River plume using unfiltered Yellow River water and filtered seawater. The results showed a non-conservative behavior for DU at salinities <20 and a similarity between DU and PO4 in their variations with salinity. Mixing experiments created that desorption from suspended sediments and diffusion from interstitial waters of bottom sediments are the two major processes causing the elevated concentrations of DU and PO4 in mid-salinity waters, which are higher than those expected from a conservative mixing. However, desorption seems more responsible for the elevated DU concentrations, whereas diffusion influences more the enrichment of PO4.

PHOTOSYNTHETIC EFFICIENCY AND CELL MORTALITY OF SILICATE-STARRVED THALASSIOSIRA WEISSFLOGII RESPONSE TO SILICATE RESUPPLY AND DARKNESS The physiological processes of phytoplankton mortality and photosynthetic efficiency (Fe/Fm) in response to darkness and silicate resupply were studied in the Si-starved diatom T. weissflogii. SYTOX Green was used for the cell membrane permeability assay, which assumed that SYTOX Green stained dead cells. Cells in the light showed a much higher percentage of dead cells (~90%) than in darkness (~20%), Sii added in the stationary phase; ~30%, Sii added in the senescent phase). Photosynthetic efficiency showed a slower decrease with increasing silicate resupply. Fe/Fm dropped from 0.57±0.02 to 0.13±0.01 without Si resupply, to 0.27±0.08 with 25 μM Si addition and to 0.31±0.03 with 150 μM Si addition. Darkness, Fe/Fm stayed above 0.5 over one week before it dropped below 0.4 after silicate was resupplied in the stationary phase, and decreased to ~0.1 without any silicate addition. There was a larger increase in Fe/Fm after a silicate addition to stationary cells compared to senescent cells. Silicate and darkness have to be considered as a possible cause for cell death and variable photosynthetic efficiency of diatoms.
Lower trophic level ecosystem model and statistical methods are used to assess the impacts of reducing sea ice cover and rising temperature in the southeastern Bering Sea on the lower trophic level production and fish catches. The vertically 1-D coupled ice-ocean ecosystem model (Lin et al., 2007) includes both pelagic and sea ice algal components and is applied to the NOAA/FMEL mooring site M2 in the southeastern Bering Sea from 1970 to 2006 forced by wind stress, heat and salt flux. Model results are validated favorably with observations: 1) temperature, salinity, fluorometer data at 12m, 24m and 44m from 1995-2005; 2) daily SeaWiFS chl-a data. While the quantity of variability of the primary production did not show an increase/decrease trend in the past three decades, there exists a shift of dominant phytoplankton species coincident of the Pacific Decadal Oscillation (PDO) index. The model primary production were dominant by ice algae before the 1976/77 regime shift, and by open water species of diatom and flagellates thereafter with only occasional ice algal blooms. Fish catches in the eastern Bering Sea showed mixed response to the climate changes. Among the 12 dominant economic fish species, only Walleye pollack and Yellowfin sole showed significant correlations with the PDO index in certain regions. This indicates that a more complicated system analysis is necessary to fully understand the response of higher trophic level production to climate changes.

**Optical Ber ing Sea Related to the Ecological Process During the Ice Melting Days in 2007**

Related to the global warming, sea ice in area, thickness, and concentration is obviously decreasing. Along with less sea ice in winter and early melting in spring, the marine ecosystem in northern shelf of Bering Sea is experiencing corresponding changes. As ice opens earlier than usual, algae and plants grow firstly in the ice over layer and advance downward to the lower level with the exhaustion of surface nutrition. On the other hand, solar radiation is the main energy to melt ice. The earlier bloom of phytoplankton changes the light field in sea water and increases solar absorption, which results in extra warming, a positive feedback to the ice melting. The solar radiation penetrated is also the main source for heating lower water. The linkage among thermal, optical and ecological features in northern Bering Sea is discussed in this paper to address the contribution of phytoplankton to ice retreats.

**Spatial Analysis on Marine Atmosphere Boundary Layer Features of SAR Imagery Using Empirical Mode Decomposition**

Turbulent meso-scale processes at the marine atmospheric boundary layer (MABL) play an important role in the exchange of heat, moisture and momentum between the atmosphere and the ocean. These processes also contribute to the sea surface roughness, which is of critical importance to the interpretation of atmospheric and oceanic features from remote sensing. We used RADARSAT Synthetic Aperture Radar (SAR) imagery over the NE coast of the U.S. November 2, 2002 to analyze spatial MABL features. The SAR senses the sea surface roughness at a resolution on order 10m to 100m over a swath width on order 10km to 1.0km. We used a new method to decompose the footprints of MABL on SAR imagery into characteristic spatial scales. Using two-dimensional Empirical Mode Decomposition (EMD) we obtain three Intrinsic Mode Functions (IMFs), which mainly present longitudinal rolls, three-dimensional cells and atmospheric gravity waves (AGW). The rolls have rapids between 1.6km and 3.8km over the cells. The AGW has maximum spectrum at 14.3km wavelength. The method developed in this work can be used to decompose other satellite images into individual features through characteristic spatial scales.

SAVITY VARIABILITY OF SOUTH FLORIDA COASTAL WATERS ON TIME SCALES FROM EPOCHIC TO MULTIDECADAL: HOW MIGHT THE ECLERGALIDES RESTORATION CHANGE THESE PATTERNS?

Surface salinity in the coastal waters of South Florida varies on time scales from episodic to multidecadal. Observed salinity patterns respond to natural physical forcing such as changing evaporation/precipitation balances and fresh water inputs, tropical cyclones and winter cold fronts, El Nino-Southern Oscillation (ENSO) cycles, and the Atlantic Multidecadal Oscillation (AMO). Sorting out and understanding these diverse sources of variability requires a careful and detailed assessment of the oceanographic and meteorological database on a multitude of spatial and temporal scales. Superimposed on this highly variable and dynamic coastal marine system are the past and present effects of water management practices in South Florida as well as the potential future changes in fresh water delivery to the estuaries and coastal marine waters which are to be expected as a result of the Comprehensive Everglades Restoration Plan (CERP). A time history of regional surface salinity from 1996 through 2007, and the ecological implications of the observed surface salinity variability and its possible future changes, are examined in the context of the overall health of the unique South Florida coastal ecosystem.

OBSERVATIONS OF ATLANTIC MERIDIONAL HEAT TRANSPORT VARIABILITY AT 26.5°N FROM THE RAPID-MOC ARRAY

Continuous estimates of the oceanic meridional heat transport in the Atlantic are derived from the RAPID-MOC observing system deployed along 26.5°N, for the period from April 2004 to March 2005. The basin-wide meridional heat transport (MHT) is derived by combining temperature transports (relative to a common reference) from: (1) the Florida Current in the Straits of Florida, (2) the western boundary region offshore of Abaco Bahamas, (3) the Ekman layer (derived from QuickScat wind stresses), and (4) the interior ocean monitored by “endpoint” dynamic height moorings. The results for the first year of observations show a mean MHT of 1.20 ± 0.45 PW for weekly-averaged estimates, on which time scale a basin-wide mass balance can be reasonably assumed. Ekman heat transport variability accounts for 58% of the total MHT variance, and upon its removal the MHT variability arising from the geostrophic circulation drops to ≤ 0.30 PW. The overall uncertainty of the annually averaged MHT for the one-year record is 0.14 PW, or about 10% of the mean value. As expected, the MHT variability is highly correlated with the strength of the meridional overturning circulation (also derived from the array), with an r² of 0.96. The RAPID-MOC Array will be continued through 2014, thereby providing about a 10-year time series of the MHT at 26.5°N, near the latitude where it reaches its maximum in the Atlantic.

COPEPOD BEHAVIOR RESPONSE AT VERTICALLY-ALIGNED THIN LAYERS OF VELOCITY GRADIENT

Our recent laboratory observations that calanoid copepods behaviorally respond to thin horizontal layers of velocity gradients are extended to thin layers aligned with the vertical direction. In the current study, a laboratory apparatus was designed and constructed to create a controlled velocity field that consists of a laminar plane jet that is flowing downward. The apparatus also can be reversed to create upward flowing thin layers. The flow field characteristics have been quantified via the particle image velocimetry technique. The resulting strain rate field closely matches our previous horizontal thin layer mimetic with the exception of the alignment of the treatment region with the gravity vector. Behavior of the copepod Acartia tonsa in response to this structure is evaluated by comparing the swimming speed and frequency of turning before and after contact with the velocity gradient. In addition, the residence time in the treatment region is compared to a control treatment to determine whether the vertically-aligned region of velocity gradi-
and stratification can influence the oceanography of the region. During normal years, ENSO periods to further South and West during normal years. In spite of its variable surrounding ocean waters. Variable physical forcing due to ENSO cycling causes major logically normal (non-ENSO) period to compare the similarities and differences between a cruise, of the physical, chemical and biological properties of this region during a climato logy.

The Atlantic meridional overturning circulation is conventionally pictured in the meridional-vertical plane, but the densification of water masses involved is in fact thought to occur on a much broader scale. This trade wind circulation of the circulation flows in boundary currents around the subpolar gyre and northern marginal seas. Here we present an analytical model of the heat and salt budget for an idealized coastal boundary current in a marginal sea such as the Nordic Seas. The boundary current exchanges heat and fresh water with the atmosphere, as well as with the interior of the basin via eddy and Ekman transports. Its volume transport is not only a function of the wind stress, but also the interannual and independent ocean wind forcing. The temperature and salinity of this boundary current is important to two different length scales. Comparing these two the temperature and salinity of the boundary current and for the properties of the water that flows over the sill. The relevance and implications for the Nordic Seas and other marginal seas are discussed.

CELEBRATING TEN YEARS OF PROGRESS TOWARD BUILDING A GLOBAL OCEAN OBSERVING SYSTEM

In 1998, the International Year of the Ocean, NOAA implemented a program to help build the global ocean observing system needed to improve climate forecasts. Over the past ten years, NOAA and its international partners have reached 57% completion toward implementation of the initial design outlined in the Global Climate Observing System. The system has grown from five networks in 1998 to nine complete networks that together contribute unique capabilities toward an integrated system. This network addition is a result of new capabilities. The new system, NOAA and its partners have received additional funding, added new observations, and new observations to improve ocean observing system. The system helps to improve our understanding of the ocean and its role in climate. From the seminal ENSO observing system to global coverage from drifting arrays, this presentation highlights the development of the current global ocean observing system (in situ) and prospects for the next ten years of sustained ocean observations.

COORDINATE CHANGES IN THE HEAT, SALINITY AND CO2 BUDGETS OF THE MEDITERRANEAN ZONE AT THE BERMUDA TIME SERIES SITES

In recent years, realization of the importance of the ocean interior to store heat and CO2 has helped improve the skill of climate models. However, quantification of this storage mechanism is limited to a few time-series locations. Here we present analyses of hydrothermal outflow for 5 years and 2007-2008 data, detailing significant long-term change in upper ocean inventories of heat, salinity and CO2. Consistent trends of increasing temperature and salinity are observed for depth below the seasonal thermocline while the thermocline with maximum signals in the model data (past 50 years; ΔT = -0.1°C and ΔS = 0.1°C), yielding a ΔT = -0.1°C and ΔS = 0.1°C. In contrast, surface conditions do not show this trend. Our data indicates a long-term reduction in upper ocean stratification for this region. Similarly, model water CO2 levels continue to increase with current levels up to 25 µmole kg⁻¹ higher than the 2005 levels at the inception of BATS. We invest in the development of a mechanism for the transport of heat and CO2 into the ocean interior and the ability to constrain the model and conduct a series of sensitivity experiments. This results in a mechanism for the transport of heat and CO2 into the ocean interior and the ability to constrain the model and conduct a series of sensitivity experiments. This results in a mechanism for the transport of heat and CO2 into the ocean interior and the ability to constrain the model and conduct a series of sensitivity experiments. This results in a mechanism for the transport of heat and CO2 into the ocean interior and the ability to constrain the model and conduct a series of sensitivity experiments. MANAGING AND ANALYZING CABLED-SEAFOOR SENSOR DATA USING KEPLER SCIENTIFIC WORKFLOWS

Traditional management of near-shore oceanographic data has relied on manual- and labor-intensive processes to access, archive, and process data. At the Kilo Nalu Nearshore Reef Observatory, deploying sensors along a submarine cable that provides power and network services has massively improved the quality, volume, and timeliness of oceanographic data. Managing these data, however, is challenging. As part of the Real-time Environment for Analytical Processing (REAP) project, we have leveraged the DataTurbine RingBuffered Network Bus (RBNN) to buffer data from the array and adapt-
ed the Kepler scientific workflow system to access data directly from the ring buffer. We have developed scientific workflow components that connect to RBNN servers and provide near real-time access to sensor streams. Scientific workflows allow a flexible means for joining heterogeneous data access and analysis systems while simultaneously providing an audit trail of data processing and analysis. We have demonstrated that this system can be used to improve the efficiency and transparency of near real-time event detection, quality assurance processing, and post-hoc analysis of sensor streams and archived data.

SATILLA RIVER ESTUARY SEDIMENTS PROVIDE A SOURCE OF SOLUBLE ORGANIC IRON(III) COMPLEXES TO OVERLYING WATERS

Voltammetric depth profiles of redox stratified sediments with gold amalgam (Au/Hg) mediated electrodes show the presence of soluble organic Fe(III) complexes below theoxic zone in a variety of freshwater and marine environments. Unfortunately, the concentra-
tion of organic Fe(III) can not be determined by direct voltammetry without identification of the iron binding ligand. In this study, Competitive Ligand Equilibration - Adsorptive Cathodic Stopping Voltammetry (CLE-ACSv) is used to quantify and characterize metal binding ligands through comparison of natural ligands with a known chelating ligand. CLE-ACSv titrations are able to provide the concentration of the natural ligand, the concentra-
tion of Fe(III) bound to the natural ligand, and the conditional stability constant of the iron ligand complex. Results reveal soluble Fe(III) complexes at near millimolar levels in freshwater, estuarine porewaters and micromolar levels in overlying waters of the Satilla River estuary. Conditional stability constants for organic Fe(III) complexes ranged from log K = 20.58-21.92 and did not vary significantly with depth. This new application of CLE-ACSv demonstrates that significant amounts of soluble Fe(III) complexes are available in estua-
rine sediments to provide a source of iron to surface waters.

SIMULATING HURRICANE GENERATED WAVES AND WAVE-SETUP USING COUPLED UNSTRUCTURED SPECTRAL WAVE AND FLOW MODELS

This paper describes a modelling study of hurricane induced waves and wave-set up. A number of large hurricanes in the Gulf of Mexico have been simulated using the MIKE 21 FM modelling system. These include Hurricane Ivan, Dennis and Katrina. The modelling system includes a third generation spectral wave model and a Reynolds-averaged, hydro-
static 2-D flow model. Both models use an unstructured grid. Applications of unstruc-
tured spectral wave models in hurricane simulation are limited in number. In this study we demonstrate the advantages of using an unstructured approach in terms of both stability and increased accuracy in the near-shore where wave set-up becomes an important surge component. Predictions from first and second order up-winding schemes are compared and demonstrate that while a first order scheme may capture the peak wave heights accurately, it may not resolve the build-up correctly. For the purposes of storm-surge model-
ling, however, the more efficient, first order up-winding scheme is sufficient.

LIGHT-INDUCED PROCESSES AFFECTING ENTEROCOCCI IN AQUATIC ENVIRONMENTS

Fecal indicator bacteria such as enterococci have been used to assess contamination of freshwater and marine environments by pathogenic microorganisms. Various past studies have shown that sunlight plays an important role in reducing concentrations of culturable enterococci and other indicator microorganisms in aquatic environments. Results presented here indicate that several pathways contribute to the light-induced mortality of enterococci in natural waters. Studies of one species of enterococci, Enterococcus faecalis, shows that a key mechanism involves mortality via direct absorption of the UV component of sunlight. Chromophoric dissolved organic matter (CDOM) and suspended sediments also can play a role in indirect pathways for light-induced deactivation. CDOM photosensitizes the production of reactive oxygen species that can affect the survivability of enterococci. Enterococci are predominantly sorbed to sediments in aquatic environments and our results showed that the sorbed enterococci from sediments of local streams were rapidly inactivated by sunlight exposure. These results suggest that photoinduced damage can be initiated by substances on the sediment surface. Although this work was reviewed by EPA and approved for publication, it may not necessarily reflect official Agency policy.

A LARGE LEGACY SEISMIC REFLECTION DATASET FROM ROCKALL TROUGH: CAUSES AND TEMPORAL VARIABILITY OF WATER LAYER RESPONSE, AND RECOGNITION OF INTERNAL WAVES

We have obtained a large number of legacy seismic reflection profiles across Rockall Trough, NE Atlantic, and reprocessed the data to image the water layer. Three main points have emerged from mapping of seismic response and comparison with legacy oceanographic-geophysical measurements. (1) It is difficult to explain the seismic response entirely in terms of reflections from temperature and salinity perturbations on the scale of the seismic waves (i.e. low frequency structure). Scattering, refraction and interaction with moving water probably also need to be considered to fully explain the seismic signal. (2) Temporal variation in seismic response as a function of spatial scale can be determined from co-located seismic lines of different vintage, re-shot portions of single lines, and comparison within and between swaths in 3D surveys. (3) In some regions, internal travelling waves can be recognized by correlation of normal movement using a velocity function derived on oceanographic measurements, interpretation of individual shot gathers and comparison between adjacent shot gathes. In-line amplitude, frequency and velocity of the waves can be measured using this method.

VARIABILITY IN THE CONTINENTAL SHELF BIOLOGICAL PUMP REVEALED BY LAGRANGIAN TRACKING OF SATELLITE CHLOROPHYLL

Estimating the net rate at which the marine ecosystem converts carbon into phytoplankton biomass, and its variability amongst regions and over time, is crucial for our understanding of the carbon cycle. Satellite chlorophyll or backscatter products give a synoptic picture of phytoplankton carbon (PC), but estimating production rates is difficult because the temporal change of PC results from the net community production (NCP) of PC, as well as from advection of the PC with the circulation. Here, we track the motion of satellite-derived PC with a model ocean circulation velocities to derive an estimate of NCP in a continental shelf region over a period of 3 years. We find large variations in the regionally integrated NCP, ranging from negative to positive values of 100 mgC m$^{-2}$day$^{-1}$ during phytoplankton bloom events. At times, as much as 30–35% of the primary production is exported within the euphotic layer, whereas in other periods, PC is imported to the region. The large variability in our time-dependent estimate of carbon fluxes from the continental shelves indicates that integrative budgets constructed from single measurements can be in serious error.

THE UPSTREAM PATH OF THE DENMARK STRAIT OVERFLOW WATER THROUGH THE ICHELAND SEA

Denmark Strait overflow water is one of the main components of the thermohaline circulation in the North Atlantic providing a link between the Nordic Seas and the North Atlantic’s Subpolar Gyre. Observations have shown that a substantial part of it is transported to the sill along the Icelandic continental slope before entering the North Atlantic’s Subpolar Gyre. The water has been traced along the Icelandic slope to the Kolbeinsey Ridge. To trace it further upstream and determine whether it has connection to the East Greenland Current or is flowing along the Kolbeinsey Ridge its properties are compared to the properties of water along the two paths. This is done using data from the Greenland Sea project from 1987-1991 that covered the western part of the Iceland Sea. Also the new and more extensive data set from the mapping project, “Ecosystem of the Iceland Sea”, initiated in 2006 by the Marine Research Institute in Iceland that covers the whole Iceland Sea, is used.

UPPER MIXED LAYER TEMPERATURE AND SALINITY VARIABILITY IN THE TROPICAL BOUNDARY OF THE CALIFORNIA CURRENT

Temporal and spatial variability of the integrated temperature in the quasi-isothermal layer depth (ML temperature) and the integrated salinity in the quasi-isohaline layer depth (ML salinity) of the southern part of the California Current are examined using hydrographic data from thirty six surveys carried out from 1997 to 2006 over a grid based on the Mexican Research of the California Current (MECOCAL) stations plan. The sampling interval was approximately 3–month. The spatial pattern of the first leading Empirical Orthogonal Function (EOF) for both ML temperature and ML salinity anomalies show a single-signed distribution where the variability increases equatorward. The primary pattern of variation revealed by EOF analysis shows similar behavior on seasonal and interannual time scales. We hypothesized that this pattern is explained by the mesoscale variability difference between the southern and the northern Baja California zones. To test our conjecture, we use satellite altimetry data to perform EOFs of sea surface height and eddy kinetic energy. At seasonal time scale, the principal component time series of the first leading EOF reveals that ML temperature variability is associated with wind stress dynamics and air-sea exchange of heat, while the seasonal changes of ML salinity are mainly related to wind stress dynamics. At interannual time scale we found with freshening changes from 1998 to 1999 and from 2002 to 2003 and abrupt cooling change from 1998-1999.

W., Coastal Studies Institute & Dept. of Oceanography and Coastal Sciences, Louisiana State University, Baton Rouge, USA, gage@lsu.edu; KOBASHI, D., Coastal Studies Institute & Dept. of Oceanography and Coastal Sciences, Louisiana State University, Baton Rouge, USA, dbasha@lsu.edu

IMPACT OF COLD FRONDS ON THE HYDRODYNAMICS OF SABINE BANK, OFF LOUISIANA-TEXAS COAST, USA

Sabine Bank, located off Louisiana-Texas has been identified as a prospective source of sand for beach nourishment and coastal protection projects in western Louisiana. The bank is located off the mouth of the Atchafalaya River and was historically a source of sand for beach nourishment and coastal protection projects in western Louisiana. The bank is located off the mouth of the Atchafalaya River and was historically a source of sand for beach nourishment and coastal protection projects in western Louisiana. The present investigation employs a full spectral finite volume model to estimate wave transformation over the shoal due to cold front generated extra-tropical storms. The MIKE 21 spectral wave module is implemented for the shoal in a high resolution scale, to estimate wave attenuation over the shoal and to calculate the sediment transport induced by frequent winter storms. The fine resolution shoal model is nested within a regional wave model for the Gulf of Mexico. Forty-three days of NCP re-analysed wind data is used for driving the wave model and the spatial distribution of bottom sediments are also included in the model to develop friction parameters. It is found that the shoal could significantly dissipate waves during propagation over the shoal. The model results are validated with time series and spectral wave data collected from NDBC Buoy 42035. Also, the results are in excellent agreement with in-situ observations obtained from bottom boundary layer arrays deployed at two locations across a transect of the shoal.

NET COMMUNITY PRODUCTION IN THE NATURAL IRON FERTILIZED BLOOM OF KERGUELEN

Natural iron fertilization sustains a 3 months bloom above the Kerguelen Plateau (50°S-77°E) that contrasts with the HLNC conditions prevailing in the surrounding waters. The seasonal carbon budget derived from DIC and pCO$_2$ data collected during KEOPS (January February 2005) shows that the net community production (NCP) within the bloom was roughly three times higher than outside leading to a significant enhancement the carbon export above the plateau. The examination of satellite images reveals large interannual variability in the magnitude of the bloom. To assess the impact of this variability on the NCP we use a biogeochemical model driven by the monthly cycles of chlorophyll, mixed layer depth, temperature and wind. The model is able to simulate Si(OH)$_4$, DIC and pCO$_2$ observations. The bloom during KEOPS. The simulated NCP is also in good agreement with the seasonal NCP derived from the carbon budget method. The model is then applied over ten years, 1997-2007, to investigate the interannual variability of NCP and possibly of carbon export below the bloom.
**ECOLOGY OF THE TOXIC MARINE CYANOBACTERIA, *LYNGBYA* spp., IN FLORIDA ESTUARINE AND COASTAL WATERS**

Marine *Lyngbya*, including *L. majuscula*, *L. polychoa*, and *L. confervoides* are opportunistic, toxic cyanobacterial species that form blooms that smother reefs and seagrasses. These communities produce bioactive compounds that impact grazing, C flux and nutrient cycling. In situ nutrient addition bioassays were conducted to determine nutrient(s) stimulatory to growth and nitrogen fixation of *Lyngbya* in Florida coastal waters. In April 2006, we examined effects of dissolved inorganic nitrogen (DIN) and phosphorus (DIP) additions on *L. polychoa* and *L. confervoides*, which co-occurred on a reef off the Broward County (Atlantic) coast. Another bioassay, in July, 2006 at Sanibel Island, FL, (Gulf of Mexico) consisted of DIN and DIP additions to *L. majuscula*. The *Lyngbya* communities revealed complex patterns of nutrient limitation, with most showing N and P co-limitation. Nitrogen fixation was largely confined to nighttime and stimulated by P enrichment, but unaffected by N enrichment. *Lyngbya* populations revealed metabolic flexibility; when N compounds were available, they became oscillating in a similar manner whereby a time-lag may constitute the signal detected by the antenna giving information about the size and position of the particles.

**MICROBIAL ACTIVITY AND COMMUNITY COMPOSITION IN SEEDMENTS ASSOCIATED WITH BRINE SEEPS ON THE LOWER CONTINENTAL SHELF, GULF OF MEXICO**

Brine flows are a common feature of the lower continental slope in the Gulf of Mexico. We examined sediments associated with brine flows in water depths between 1200m and 3300m in the Gulf of Mexico. Brine-impacted sediments were generally characterized by high sulfate reduction rates. One of the most interesting features was a 4 m deep, 180 m wide brine lake (90 ppt salinity) located in Alaminos Canyon block 601. Microbial activity and geochemistry varied substantially within and around the brine lake. Sediment cores were collected from the lake bottom, the lake edge, 2.5m from the lake edge, and about 50m from the lake edge (control). Sulfate reduction rates were highest in the lake edge sediments. Though lake bed and edge sediments contained high methane concentrations, rates of anaerobic oxidation of methane (AOM) were 10 to 100 times lower than sulfate reduction rates. Rates of hydrogeo- morphic netogenesis were comparable in sediment samples collected from within or near the lake. The relationship between microbial community composition and microbial activity, particularly sulfate reduction and AOM, will be discussed.

**AN INTEGRATED ASSESSMENT OF CONSERVATION AND QUALITY STATUS OF AQUATIC ECOSYSTEMS AT THE AQUATIC DISTRICT SCALE**

Nowadays, the Directives 92/43/EC (Habitat Directive) and 2000/60/EC (Water Framework Directive) establish the necessity to apply the concepts of integrated management and sustainable development. These concepts collected the necessity to value the ecosystems state through a multidisciplinary perspective. Accordingly, several methods are now in discussion for the assessment of the structural and functional features of the aquatic ecosystems (ecological status of water bodies, ‘favourable conservation status’ of habitats). This paper investigates the combination for different indicators that take into account the evaluation of river, transitional and coastal ecosystems is presented. For that purpose a generic standardized procedure for assessment the conservation status of aquatic protected habitats is combined with specific indices for each category of aquatic systems, regarding both the physical and ecological integrity, based on the quality elements developed in the current implementation of the Water Framework Directive.

**TURBULENCE EFFECTS ON PLANKTON: A NEW CARTOON**

One approach toward understanding effects of turbulence on small organisms is to place them in a much simpler flow than fully developed turbulence that displays key characteristics of turbulence. The prevailing simplification, often generated in the gap between two counter-rotating cylinders, has been Couette flow in which shear and vorticity have no spatial gradients. We reassert that simplification in light of recent advances in understanding of turbulence and find it valiant in several important respects. The typical planar condition is to be in or near a dissipation-scale vortex and in a gradient of diffusing vorticity. Among the simplest vortices that follow the Navier-Stokes equations is Burgers vortex. We use its steady and unsteady forms with established energy spectra to assess likely biological consequences. It appears that diffusing vorticity is an underappreciated generator of relative fluid motion and nutrient exchange and also a factor of potential importance to processes of encounter, coagulation and chemosensing. We are examining these effects further through a combination of numerical and analog modeling that explicitly includes vortices and spatially varying vorticity.
The goal of our study was to apply novel sensor technology to quantify aerobic respiration in relation to food supply. Sensor spots (based on the dynamic fluorescence quenching principle) were used to perform time-series respiration experiments with high temporal resolution. Compared to traditional methods for oxygen measurements the sensor spot technology was advantageous as it provided sensitive, continuous, and non-invasive oxygen measurements, and allowed the simultaneous determination of oxygen concentration in a number of respiration chambers of different size. Only 3 to 30 individuals (depending on their stage) per respiration chamber were needed to obtain a significant reduction in oxygen concentration over 3 to 5 hours. While we determined the respiration rates of nauplii and early copepodid stages at different food concentrations we also measured the feeding rates for the experimental periods. Oxygen consumption rates appeared to be affected by food concentration. The sensor spot technology is well suited to monitor the metabolic activity of minute metazooplankton organisms at close to in situ conditions.

TWO-DIMENSIONAL STORM SURGE MODELING AND SCOUR ANALYSIS

Bridges located within complex coastal systems are highly susceptible to scour-related damage resulting from complex flow patterns and extreme flood conditions. Affected by multiple tidal inlets, the State Road A1A Matanzas River bridges in St. Johns County, Florida serve as typical examples. Several physiographic characteristics of the area create complex and potentially extreme flood conditions. These include large marsh expansions, dune overtopping, and the bridges’ proximity to the Matanzas and St. Augustine Inlets. The bridges’ proximity to Matanzas Inlet and dune overtopping allow simultaneous propagation of hurricane surges toward the bridges. A detailed analysis to assess the vulnerability of bridges to storm surge flow-induced scour is presented. This study combines technical modeling and down-slope modeling and coastal engineering methodologies required by the nature of the study area. For the complex hydrodynamic system, a two-dimensional hydrodynamic model describing the entire interconnected system provided predictions of flow conditions necessary to estimate scour during extreme (50- and 100-year) surge flood events at the bridges. Scour computations apply empirical equations developed by the Florida Department of Transportation in conjunction with the University of Florida.

MERCURY AND OTHER TRACE METAL DEPOSITION TRENDS RECONSTRUCTED FROM A LEAD-210 DATED SEDIMENT CORE FROM BERG RIVER SALT MARSH, SOUTH AFRICA

The Berg River salt marsh is one of very few salt marshes on the west coast of South Africa and thus offers a unique opportunity for reconstructing the history of atmospheric pollution deposition. A sediment core was collected from the Berg River salt marsh for Pb-210 dating in order to reconstruct trends in mercury and other trace metal deposition. This study will compare the resulting metal inventories and temporal changes in accumulated fluxes with modeled atmospheric deposition of Hg and Pb-210. The recent degradation of water quality in the Berg River will also be taken into account and metal tracers of anthropogenic activity will be used to attempt to discern what new sources of pollution could be present.

INSIGHTS INTO 18 DEGREE MODE WATER FORMATION FROM MEASUREMENTS OF 7BE AT THE BERMUDA TIME-SERIES (BATS) STATION

We applied measurements of Be-7 (half-life 53.3d) to study upper ocean transport properties at BATS in 2007. Be-7 is deposited upon the ocean, mixed within the surface layer and penetrates the seasonal thermocline to depths depending in part on vertical mixing and advective processes. One-dimensional models incorporating seasonal shoaling of the mixed layer during spring-summer indicate that most of the Be-7 within the thermocline is remnant of that in earlier, deeper mixed layers. Profiles taken in the late spring-summer indicate the distribution through the seasonal thermocline can be characterized by 1-dimensional processes. However, several profiles reveal increases in Be-7 activity in the nutricline (down through the mode water) suggesting imbalance from the 1-dimensional model. Further, multi-year analyses of the heat and salinity budgets of the aphytoplankton zone at BATS also reveal significant imbalances during the spring-summer transition. We investigate linkages between these imbalances and the excess Be-7-to determine the common source of these waters. We suggest that the source of imbalance is likely the result of mesoscale eddy transport of recently formed mode water(s) to the local region.

EXPORT FLUX VARIABILITY DUE TO CHANGES IN PHYTOPLANKTON PHYSIOLOGY

Estimates of phytoplankton sticking efficiency (a) were made in the laboratory within a 1500 liter annular flume mesocosm where the turbulence kinetic energy dissipation rate was comparable to values found at the ocean’s surface on a calm day. The u of Thalassiosira pseudonana varied as a result of physiological state, ranging from 0.0108...
During the bloom initiation to 0.26 and 0.73±0.16 respectively, during the bloom maintenance and senescent phases respectively. During the maintenance phase, the physiology included: (1) diminished phytoplankton photosynthetic quantum efficiency, (2) increased super-oxide dismutase protein expression, reflecting oxidative stress, (3) induction of a biochemical cascade initiating autacoidal programmed cell death, and (4) increased concentration of transparent exopolymer products. Applying a physiologically variable α to a 1-D export flux that decreased that carbon export from a phytoplankton bloom is significantly increased because a low initial sticking efficiency allows for an increase in the critical concentration of algal cells during the late bloom stages. In turn, an increase in a maintaining the dissolved senescent phases, resulted in enhanced export fluxes during the “stickier” stages of the bloom.

Spatial changes in the population structure and reproductive strategies of two benthic sponges in the Abyssal Northeast Pacific

Two low-lying tufted sponges, Bathedythorup sp. and an undescribed sponge of subfamily Euplectellinidae, have densities of tons to hundreds per hectare and provide areas of dense spicule habitat for other fauna. Sponge abundance and average size were analyzed at Station M (4,100 m depth) over a seventeen-year-time-series using camera-sled transects. The two sponge types had similar variations in density and average body size over time suggesting that the same factors may control the demographics of both species. Peaks in significant cross correlations between increases in particulate organic carbon flux and corresponding increases in sponge density occurred with a time lag of 13 months. When plate sponge abundance was higher, average sponge size was smaller suggesting new recruitment or regeneration of persistent sponge cells. The results also support previous suggestions that increased POC flux may induce recruitment or regeneration in deep-sea sponges. Ongoing research will use genetic markers to test these alternatives.

THE SAVU SEA OF EAST INDONESIA - SE ASIA'S OPEN OCEAN WILDERNESS: OCEANIC CETACEAN HOTSPOT, TRADITIONAL SPERM WHALING AND INDO-PACIFIC MARINE CORRIDOR

The Savu Sea is located in eastern Indonesia at the nexus of the Pacific and Indian Oceans. It is potentially the most significant area for oceanic cetaceans in the Indonesian Seas. The Soloez-Ador islands especially boost exceptional biodiversity and abundance of large marine life and include critical habitats of regional importance. These islands are further characterized by: a) Exceptional oceanic cetacean diversity including blue and sperm whales, b) Indonesian Flowthrough Current induces major upwelling, c) Transboundary migratory corridors (Indonesia-East Time), d) Near-shore yet deep-sea habitats, e) Traditional sperm whaling village, f) Other fisheries activities with potential for unsustainable (bycatch), g) Long term cetacean studies going on since 2001, h) Rare apex predator-prey interactions (orca-sperm whale attack), i) First ever satellite tagging on Indonesian sperm and blue whales indicate that: j) considerable time spend in these waters, k) movements range 1000 km, l) blue whales may conduct frequent foraging dives. A large-scale Marine Protected Area is planned for the whole Savu Sea. This initiative will increase the representation of cetaceans and deep-sea habitats within regional MPA networks for SE Asia.

TIME SERIES OF SATELLITE DERIVED PRIMARY PRODUCTION IN THE CALIFORNIA CURRENT

Satellite-derived time series of net primary production (NPP) is calculated for the California Current area using several algorithms. The VGP3 (Behrenfeld and Fickowsky, 1997) and CbPM (Behrenfeld et al., 2005) algorithms yield systematic differences up to 100%. Validation of the various estimates is done using the in situ data measured by the CalCOFI and CCE LTER programs. In the southern Gulf of California the annual cycle of NPP changed drastically in 2001 when the peak NPP value was more than double compared to the mean peak value during preceding years. During each of the following years the peak NPP value was over 30% lower than in 2001 but remained significantly higher than during the pre-2001 period. This shift toward increased peak NPP levels is indicative of increased nutrient loads to the system. Correlates of this regime shift with other environmental variables are examined.

GLIDER-BASED MEASUREMENTS OF KUROSHIO SEASONAL VARIATION

Kuroshio, the strongest western boundary current in the Pacific, carries significant heat and momentum northward from the tropics. Along its path, it interacts with mesoscale eddies, topography, and modulates internal waves. It often intrudes into the South China Sea via the Luzon Strait. After leaving the Luzon Strait, it flows northward along the east coast of Taiwan and becomes stronger. The dynamic evolution of this is important. Previous observations were taken from mooring ADCP range, and other types of oceanic velocities derived from CTD sections, and subsurface drifters, which provide useful 1-D and 2-D observations in limited spatial or temporal scales. In this study, we analyze extensive continuous repeated hydrographic profiles of the Kuroshio obtained by long-range gliders. The maximum salinity (~34.8) along the Kuroshio main path is obvious. It extends deeper (around 400 m) after passing through the Luzon Strait. The effects of variations of the Kuroshio under the distinct northeast and southwest monsoons will be studied. The derived Kuroshio properties will be compared with historical observations and provide useful physics to further our understanding of the Kuroshio dynamics.

THE METABOLIC BALANCE OF THE ATLANTIC OCEAN FROM BOTTLE INCUBATIONS AND DISSOLVED OXYGEN/ARGON RATIO MEASUREMENTS

The metabolic balance of the subtropical gyres is a contentious issue. Instantaneous rate measurements from O2 bottle incubations indicate net heterotrophy throughout large areas, but geochemical tracers and particle fluxes suggest net autotrophy or weak metabolic balance. We confirm this discrepancy by combining, for the first time, bottle incubations with a new geochemical approach using continuous measurements of surface O2/Ar ratios by membrane-inlet mass spectrometry to derive the mixed-layer metabolic balance of the subtropical gyres during two AMT (Atlantic Meridional Transect) cruises. The O2/Ar results indicate net autotrophy throughout the Atlantic subtropical gyres. In contrast, bottle incubations show regions of net autotrophy alternating with heterotrophic patches. Generally, both methods give the same sign for the mixed-layer metabolic balance during spring, but opposite signs in autumn. Since the O2/Ar data paint such a consistent picture in time and space, it is unlikely that the net biological O2 flux is directed into the subtropical cal gyres, which would correspond to net heterotrophy. In turn, this means that bottle incubations are unsuitable to correctly represent the net metabolic balance over larger temporal and spatial scales.

MAJOR BACTERIAL CONTRIBUTION TO THE OCEAN RESERVOIR OF DETRITAL ORGANIC CARBON AND NITROGEN

Non-living organic matter in the ocean is one of the largest and most dynamic reservoirs of organic carbon on Earth, yet the relative contributions from Bacteria, Archaea and Eukarya are unknown. In this study, bacterial biomarkers (D-amino acids and muramic acid) were measured in particulate (POM) and dissolved organic matter (DOM) from the North Pacific and Sargasso Sea to estimate bacterial contributions to non-living marine organic matter. The origin and yields of biomarkers were determined in cultured marine bacteria and indicated that D-amino acids are derived from numerous macromolecules in addition to peptidoglycan. Bacterial detritus was a major component of POM and is an important source of submicron particles and colloids in the ocean. Peptidoglycan was a substantial component of POM but not of DOM. Compositional differences between POM and DOM primarily reflected the selective incorporation of specific bacterial components into these reservoirs. Bacterial organic matter accounted for ~25 % of particulate and dissolved organic carbon, and ~50 % of particulate and dissolved organic nitrogen. These results demonstrate the importance of bacteria in regulating the ocean carbon and nitrogen cycles.

not AOB, amoA gene sequences we found are well-represented by sequences in the data
more diverse than the population of AOB amoA genes in both oceans. Clades of AOA, but
increased with depth in both. Phylogenetic analysis indicates depth-dependant stratification
Oceans. AOA and AOB amoA gene abundance increased with depth in Southern Ocean
the polar oceans. Quantitative and phylogenetic analyses of ammonia monooxygenase genes (amoA) in
samples from the Arctic and Southern Oceans reveal differences in distributions of ammo-
oxidizing archaea (AOA) and ammonia oxidizing, beta-proteobacteria (AOB) between the
polar oceans. Quantitative real-time PCR showed that AOA amoA genes are more abundant than AOB amoA genes at all depths sampled in both the Arctic and Southern Oceans. AOA and AOB amoA gene abundance increased with depth in Southern Ocean but not in the Arctic Ocean; however, the ratio of AOA to AOB amoA gene abundance increased with depth in both. Phylogenetic analysis indicates depth-dependant stratification of AOA amoA genes and that the population of AOA amoA genes was more diverse than the population of AOB amoA genes in both oceans. Clades of AOA, but not AOB, amoA gene sequences we found are well-represented by sequences in the data-base. Our results reveal similarities as well as differences in the abundance and distribution of ammonia oxidizing prokaroytes over depth and between the polar oceans.

Kaltenberg, A. M., Oregon State University, Corvallis, USA, akalberg@coas.oregonstate.edu

The influence of zooplankton prey abundance and daylight on pelagic schooling fish behavior
Pelagic fish schools were observed using combined moored and shipboard acoustic techniques in 2005 and 2006 off the Oregon coast and in Monterey Bay, CA to investigate possible factors controlling schooling behavior patterns. Our results show that schools are regulated by a balance between the pressures of predation by visually-oriented predators and the need of individuals to eat, resulting in a strong diel pattern of formation and dis-
persal. The dawn and dusk periods of school formation and dispersal were analyzed and compared with day length and zooplankton prey abundance. Schools at both locations dispersed rapidly at dusk. However, differences in the rate of school reformation through-
out early morning were correlated with zooplankton prey abundances, which may indicate that fish are rejoining the group when they have fulfilled their energy requirements after nighttime foraging. The dynamics of school formation and dispersal have important im-
plications to our understanding of the functional role of highly aggregated fish species and their ecological interactions with zooplankton prey.

The analysis of turbulent mixing near topographic features in the indonesian seas based on results of simulations with a regional model
Seasonal variations of distributions of turbulence kinetic energy, master length scale and vertical mixing coefficients near various topographic features are analyzed from results of simulations of the Indonesian Seas circulation with a developed regional model. The circulation is generated by seasonally varying thermohaline factors at the surface, local winds, specified total transports through the main four open ports, and specified vertical distributions of boundary layer mixing rate and salinity at the ports. The model is based on the Princeton Ocean Model and uses the Mellor-Yamada turbulence closure scheme. The horizontal grid spacing is approximately 10km and 29 sigma-levels have been chosen vertically. The Indonesian Seas region is essentially a series of deep adjacent basins sepa-
rate and enclose the Sea and are connected by narrow passages and straits. It is argued that large vertical mixing coefficients at the deep connections between basins are required to sustain deep overturns and upwellings.

The analysis of pythiolankton parameters in the pisces model
Global ocean biogeochemical models rely on mean and poorly-know parameters to represent pythiolankton physiology. Our goal is to assimilate in situ data to improve the parameters related to mortality, grazing and growing of pythiolankton in a 1D version of the PISCES model. This has been done using the YAO software, which allows to generate the adjoint of a direct model and provides suitable tools to perform data assimilation. YAO was used to assimilate vertical profiles of both nutrients and chlorophyll at each station to estimate both a robust prior and a matrix covariance error to the prior. Assimilation results show that this approach allows retrieving realistic physiological parameters that yield a good agreement between PISCES and data, despite the monthly sampling frequency. We finally discuss the relevance of the physiological parameters at the different stations.
Little is understood about complex nitrogen cycling through estuarine systems, especially bottom-up forces of microbial transformations. Our research quantifies rates of nitrogen fixation and denitrification in a eutrophic southern California estuary and investigates causal relationships with nitrogen enrichment. Field surveys over two years measured fixation and denitrification rates and abiotic characteristics in intertidal mudflats along tidal creeks of Upper Newport Bay Estuary, California. Surveys showed spatial and temporal variability, with low nitrogen fixation activity compared to east coast systems. Denitrification appeared to be more important in this eutrophic estuary. Physical characteristics, including surface organic content, and nutrient availability explained some variability; other processes clearly need to be studied. Manipulative experiments investigated quantitative relationships between fixation, denitrification and factors associated with eutrophication, specifically increased water nitrate and macroalgae mat density. Nitrate enrichment resulted in decreased fixation and increased denitrification. The function of macroalgae on intertidal mudflats is more complex, with increased fixation and decreased denitrification rates beneath dense, but not sparse, mats. Relationships between these microbial processes and eutrophication, especially macroalgae influences, will provide insight into eutrophic estuaries worldwide.

SIMULATIONS OF THE INTERACTION OF MESOSCALE CURRENTS AND INTERNAL TIDES
Significant progress has been made in understanding the energetic and dynamics of internal tides in the coastal ocean, however, little has been done to examine the interaction of tides with mesoscale dynamics. In this work we investigate the influence of mesoscale currents on internal tides in the Monterey Bay area using the nonhydrostatic SUTANS model. Boundary conditions for tides and currents in SUTANS are obtained by superimposing the tidal currents obtained from OTIS over the mesoscale currents computed by U.S. West Coast simulations using ROMS. Simulations using real as well as idealized bathymetry are performed to gain an understanding of how mesoscale currents modify the internal tidal dynamics in Monterey Bay. Specifically, simulations with only tides, only with currents, and with both tides and currents are compared to assess the relative effects of the currents on the internal tidal flux of energy and flux distribution in the Bay. This work is part of a long-term project in which the submesoscale dynamics computed by SUTANS will be fed back into ROMS in full two-way coupled simulations of tides and currents. This work was supported by ONR Award N00014-05-1-0294.

INTERDISCIPLINARY MODELING SUPPORT TO CERP WITH THE COASTAL HYCOM SYSTEM
The South Florida (SoFLA) HYCOM (3.6 km resolution) and the embedded, high resolution Florida Keys (FKEYS) HYCOM (900m resolution) encompass all coastal areas that dominate the marine environmental impacts of the Comprehensive Everglades Restoration Plan (CERP): the broad Southwest Florida shelf, the narrow Atlantic Keys shelf, the shallow Florida Bay and Biscayne Bay, including Marine Protected Areas (the Florida Keys National Marine Sanctuary and the Dry Tortugas Ecological Reserve). They also connect Florida’s coastal areas to the adjacent deep Atlantic Ocean. A team of Florida State University and the National Oceanic and Atmospheric Administration State of Florida to accommodate the influence of the strong Loop Current/Florida Current system and associated eddies. Model results are validated against observations and help interpret recent data findings within Florida Bay. Regional rivers (from Shark River to Caloosahatchee River) are found to play a significant role in alleviating Florida Bay hypersalinity conditions through intrusions of low salinity waters in the wet season. A biological lagrangian transport model of coral fish larvae is coupled to the circulation modeling to examine CERP induced impacts of changes in habitat characteristics on fish recruitment for the Florida Keys.

THE RESEARCH OF DIAPICINAL TURBULENT MIXING IN THE SOUTHERN OCEAN
Enhanced diapycnal turbulent mixing in the Southern Ocean is clearly shown from analyses of the observations in the 19th, 21st, and 22nd China Antarctic Research. The enhanced mixing appears near the bottom of the continental slope, with a maximum diapycnal diffusivity of 6x10^-4 m^2/s and a maximum thickness of hundred meters in the mouth of Prydz Bay. The mixing over the bottom layer of continental shelf is evidently enhanced at sections between the Zhongshan and Changzheng Station. There is a large divergence region (particularly Antarctic Slope Front), where enhanced mixing is found in a large depth range, in the whole Southern Ocean. The enhanced mixing is also seen along and across Antarctic Circumpolar Current (ACC), and sections in Prydz Bay, especially in the weakly stratified Antarctic Deep Water.

OCEAN MODEL ERRORS IN SEA SURFACE HEIGHTS AND A GLOBAL PATTERN OF MESOSCALE VARIABILITY
Monthly anomalies of sea surface height from satellite altimetry maps are compared with data assimilation and simulation products from a variety of regional and global ocean models, ranging from simple linear-long wave approximation to state-of-the-art eddy-resolving GCMs. While better different in magnitude due to the differences in model complexity, resolution, and data assimilation settings, patterns of error variance for all products have a great deal of spatial similarity. Their common features are recognizable as those of a well-known pattern of mesoscale variability in the surface ocean. All global and regional models considered in this study are shown to underestimate short-term (sub-monthly) and especially small-scale (mesoscale and smaller scales) variability in the ocean. Data assimilation procedures cannot fix this systematic bias in model variance, yet it is correlated with models’ performance on larger and longer scales. Therefore, variances of simulated small-scale and short-term variability relative to the observed variances are important measures of model performance and a natural target for improvement. Model resolution rather than choice of wind forcing seems to be the main controlling factor for these measures.

HF RADIAR V21: MOVING BEYOND THE STATUS QUO FOR HF RADIAR DATA MANIPULATION, PROCESSING AND MANAGEMENT
Historically, the analysis of HF radar data has relied on relatively simple methods for processing current measurements from HF radars into estimates of the vector current field. These methods, based on least-squares inversion of radial measurements within a certain distance of a point, leave much to be desired in terms of optimal estimation, error propagation, identification of spatial scales, and interpolation. Recently, there have been improvements at all levels of HF radar data processing, ranging from the metadata produced by the instruments to the techniques available for estimating currents and uncertainties. The techniques for processing radials into totals now include a variety of objective mapping or optimal interpolation methods that integrate current estimation, spatial and/or temporal interpolation and error propagation. We have developed a sophisticated Matlab toolbox for HF radar data that includes several of these methods, as well as functions for data manipulation, analysis and visualization. Here, we discuss our understanding of the current state of the art for HF radar processing including an overview of the conceptual links between the different techniques for processing HF radar data, as well as some of the limitations of our current knowledge. We also explain how the Matlab toolbox works, the basic functions it provides, and indicate how it serves as a foundation for future development and innovation in the field.

MIXED LAYER MODEL PERFORMNACE IN THE MEDITERRANEAN SEA
An eddy resolving (approximately 3.5 km resolution) Hybrid Coordinate Ocean Model (HYCOM) is configured for the Mediterranean Sea. Performance of the model in predicting surface temperature (SST) is then examined using various different mixed layer depth formulations: (1) K–Profile Parameterization (KPP), (2) Goddard Institute for Space Studies (GISS) model, (3) Mellor-Yamada 2.5 turbulence closure (MY2.5), (4) Kraus-Turner (KT) model and (5) Price-Weller-Pinkel (PWP) model. Model simulations are performed using
high temporal resolution (3 and 6 hourly) atmospheric forcing. There is no assimilation of any SST data, and there is no relaxation to any SST climatology. It is found that while all mixed layer models in HYCOM perform nearly same in simulating SST, there can be substantial differences in subsurface temperatures.

COPEPOD FEEDING QUANTIFIED BY PLANAR LASER IMAGING OF GUT FLUORESCENCE

We have developed a novel imaging system to record individual copepod gut fluorescence in-vivo, as the animal feeds on a continuous source of phytoplankton. Images are collected at a rate of 3-4/min, for several hours, and are detailed enough that discrete gut compartment activity can be resolved. This allows us to quantify the dynamics of gut content, which we then relate to the animal's feeding behavior. We report here observations from two types of experiments. First, we imaged the feeding of the same tethered copepod at 3 different temperatures, and repeated this process for several copepods. Second, we conducted a bolus-chase experiment, where food was cut off after letting the copepod feed for an hour, and the changes in gut activity were recorded. We discuss the implications of these results; in particular we examine the temporal scales that are significant in individual feeding behavior, how these scales can vary at an inter- and intra-individual level under a range of conditions, and how this behavioral variability might be reconciled with data collected in the past.

NUTRIENT DYNAMICS AT STATION ALOHA

Station ALOHA (22.75 N, 158 W) is the oligotrophic North Pacific Ocean benchmark site of the Hawaii Ocean Time-series (HOT) program. Approximately monthly ship-based sampling since October 1988 combined with higher frequency satellite, mooring and Seadragon observations, has provided a comprehensive data set on physical and biogeochemical characteristics and processes, including nitrogen supply required to sustain primary and export production of organic matter. The discovery of unexpected microbial taxa and new metabolic processes including, but not limited to nitrogen (N) fixation and nitrification pathways, are strongly linked to energy capture and coupled cycles of C, P, N and Fe and climate variability has sustained scientific interest and broadened participation in this two decade long (and continuing) ocean time-series program. Major paradigm shifts include the quantitative role of N fixation in new production, recurrent summertime plankton blooms, decadal-scale variability in primary production and export, and a decoupling of N and P cycles. The recent establishment of the NSF funded Center for Microbial Oceanography: Research and Education (C-MORE), built on a HOT foundation, provides the opportunity for comprehensive field testing of key HOT hypotheses.

A 1-YEAR MESOSCALE SIMULATION OF THE BIOGEOCHEMISTRY IN THE NORTH-EASTERN ATLANTIC OCEAN

Assumed to be a CO2 sink, the POMME area (NE Atlantic: 16-22°W, 38-45°N) was surveyed in 2000/2001 in order to understand the subduction processes and to study the biogeochemical properties of the subducted water masses. To address these issues, an eddy-resolving in situ study has been performed to sample the ocean dynamics and the ecosystem evolution during one year. The results of a high resolution simulation (5 km) are discussed: it is based on a primitive equations model (OPA 8.2) coupled with a nitrogen-based biogeochemical model (LOBSTER). Initialisation, boundary conditions and validation rely on the in situ and satellite data collected during the POMME cruises. The computed net transfer of water to the inner ocean by subduction of 0.53 Sv mainly occurs in the density class 26.9 - 27.1, corresponding to the subpolar mode waters in agreement.

INTERANNUAL VARIABILITY OF SEA SURFACE TEMPERATURE IN THE EAST PACIFIC WARM POOL AND CENTRAL AMERICAN RAINFALL

SST in the east Pacific warm pool (EPWP) plays an important role in Central American rainfall, tropical cyclogenesis, and large-scale tropical heating. The first part of this presentation is aimed at understanding what processes govern the interannual variability of SST in the EPWP. Interannual wind stress, shortwave radiation, and precipitation were used as forcing to an ocean general circulation model. The high correlation between the EPWP and ENSO is explained by the fact that equatorial SST anomalies modify the distribution of atmospheric vertical motions and therefore cloud cover and shortwave heating. The second part is aimed at clarifying the role of the EPWP in interannual rainfall anomalies in Central America. An anomalously warm EPWP can trigger a rapid enhancement of the eastern Pacific ITCZ during late rainy seasons following peak ENSO events, which leads to increased rainfall over Central America. Moreover, the timing and amplitude of the SST-enhanced ITCZ depends on the persistence of the ENSO event. Both results emphasize the importance of ENSO prediction, and the need for accurate modeling of tropical atmospheric cells less than ~10 in meridional scale.

CONTRASTING CONDITIONS IN THE GREENLAND SEA: IMPLICATIONS FOR ENERGY TRANSFER TO HIGHER TROPHIC LEVELS

The Greenland Sea is characterized by Arctic water flowing south from the Arctic Ocean along east Greenland, warm water flowing north from the Atlantic Ocean, and cold Arctic water flowing south in the Sorkapp current, adjacent to the west coast of Spitsbergen. Each of these water masses carries with it different zooplankton communities. Adjacent to Greenland, there are high densities of the lipid-rich copepod Calanus hyperboreus. The Atlantic influenced water carries with it high densities of small Calanus finmarchicus. Adjacent to Spitsbergen, the Sorkapp current carries high densities of medium-sized Calanus glacialis. Zooplanktonivorous little auks (Alle alle) are abundant seabirds that breed adjacent to all of these water masses. Here we examine the impact the different physical and biological conditions have on the distribution of foraging little auks measured by at-sea surveys, their diving behavior (measured by time-depth-recorders), and the prey they feed their chicks. The Greenland Sea provides a good model to explore how future increases in warmer water and decreases in the strength of currents with Arctic origins, may impact upper trophic predators in sub-polar seas.

TEACHING PHYSICAL CONCEPTS BY OCEAN INQUIRY: REACHING PRE-AND IN-SERVICE TEACHERS

"Tell me and I'll forget, show me and I may remember, involve me reflectively and I'll understand." In our version of this old adage, the last part stresses the spirit of the inquiry-based learning that is the essence of a COSEE-Ocean Systems program developed at the University of Maine by a partnership of educators and scientists. The program offers a collegiate course to target pre-service teachers and science majors contemplating education careers, and summer workshops to target in-service teachers. By focusing on basic physical concepts addressed by national and state learning standards and by providing hands-on inquiry-based activities and opportunities for pedagogical reflections we are able to reach out beyond teachers of marine science and beyond teachers in coastal communities, to teachers of physical sciences in inland and rural communities. We will share our experiences with problems and solutions related to the crossing of "cultural" boundaries to establish a partnership between the college of Education and the School of Marine Sciences, the recruitment and networking of participants, the development and implementation of the course and workshops, and evaluation of our efforts.

NITROGEN AND OXYGEN ISOTOPE FRACTIONATION ASSOCIATED WITH NITRATE ASSIMILATION DURING CONTINUOUS CULTURE OF A MARINE DIATOM

We investigated the N and O isotope effects (εN and εO, respectively) associated with nitrate assimilation through continuous culture of the marine diatom Thalassiosira weissflogii. Under light limitation, εN and εO, and the size of the internal nitrate pool increased with decreasing light and growth rate, εN reaching 19‰ at 0.25 of the maximum growth rate. In contrast, the same parameters showed no relationship with growth rate under phosphate
limitation, "ε" remaining constant at 5-6‰. "ε" did not diverge coherently from 1:1 across all growth conditions. The results suggest there is no single intrinsic relationship between the rate of net nitrate assimilation and the magnitude of "ε" and "δ". Expansions in nitrate metabolism associated with light-growth limited growth led to increased "ε" and "δ". This effect requires consideration in interpreting modern and paleoceanographic "N" data and may contribute to the high "ε" observed in the deep mixed layers of the Southern Antarctic Zone. The consistent "ε" of 1 associated with nitrate assimilation makes it possible to identify co-occurring N processes that cause deviation from this ratio, such as nitrification.

PREDICTABILITY LOSS IN AN INTERMEDIATE ENSO MODEL DUE TO INITIAL ERROR AND ATMOSPHERIC NOISE

The predictability of ENSO variability in a version of the Zebiak-Cane coupled model is examined in a perturbation experiment. Instead of assuming that the model is "perfect," it is assumed that a set of optimal initial conditions exists for the model. These states are obtained through a nonlinear minimization of the misfit between model trajectories and the observations. Realistic estimates of the observational error covariance of SST, zonal wind stress, and thermocline depth are used to perturb these initial states, and the error growth is examined. Forecast uncertainty is shown to be most sensitive to initial error in the thermocline depth. This uncertainty leads to larger forecast error growth than continuous stochastic forcing of the zonal wind stress fields. It is demonstrated that during years with negative (and rapidly decaying) Niño-3 SST anomalies (e.g. the time following an El Niño event), there is a suppression of error growth. In years with large warm ENSO events, the ensemble spread is no larger than in moderately warm years. As a result, periods with high ENSO variance have greater potential prediction utility.

FIVE YEARS OF NORTH ATLANTIC OPEN-OCEAN TIME SERIES STATIONS IN THE ANIMATE CLUSTER

Scientific as well as technological achievements from five years of operation of three multidisciplinary North Atlantic time series observatories (parts of the ANIMATE cluster) will be presented. In general the three open ocean sites are located in very different physical/ecological regions: off Greenland, off Ireland, off Canary Islands. The basic biogeochemical as well as physical settings from the observations will be presented (e.g. seasonal cycle, variability) and compared with climatological estimates. As one example for a joint physical/biogeochemical interpretation of data an ‘apparent’ diurnal cycle in biogeochemical variability) and compared with climatological estimates. As one example for a joint biogeochemical/ecological regions: off Greenland, off Ireland, off Canary Islands. The basic biogeochemical

ANNUAL AND INTERANNUAL OCEAN VARIATIONS IN THE MINDANAO DOME REGION: OBSERVATIONAL STUDY

The Mindanao Dome, which locates east of Philippines, has been investigated using numerical models so far, however, not fully discussed from the view of observations. We discussed ocean variations with time scales of longer than annual signal in the Philippine Sea mainly focusing the Mindanao Dome. TRITON buoy data at 8N130E, 8N137E and 8N144E, 8N151E show clear annual signal in this region. At 8N, observed annual signal is associated with ascending and descending of thermocline due to westward propagation of Rossby waves rather than local wind effect. Local Ekman pumping effect which is thought to be an important factor for generation of the Mindanao Dome is large at 8N, that is, mechanism of the generation of the Mindanao Dome differs with the latitude. Increasing trend of heat content is also clear at 8N, but not south of 5N after 2003 to 2006. This result indicates that heat has been accumulated not only in the equatorial region but in the off-equatorial region of the western boundary of the tropical Pacific. This result indicates that heat has been accumulated not only in the equatorial region but in the off-equatorial region of the western boundary of the tropical Pacific. This result indicates that heat has been accumulated not only in the equatorial region but in the off-equatorial region of the western boundary of the tropical Pacific.

MODELING CIRCULATION IN THE LANDFAST ICE ZONE

Inshore of the 20 m isobath arctic shelves are covered by immobile landfast ice preventing the direct transfer of water to the interior shelf in winter. Outer shelf circulation is directly wind-forced whereas inner shelf dynamics are controlled by remotely-established pressure gradients and frictional coupling of the flow field to the bottom and the under-ice boundaries. To demonstrate the effect of landfast ice and winds on shelf circulation beneath fast ice, process type numerical models were used to investigate nearshore flows under landfast ice. Landfast ice was simulated by applying a frictional force to the ocean surface. offshore of the ice, a suite of wind profiles were used to investigate response. Circulation differs markedly between the inner and outer shelf with the transition marked by a velocity front suggesting limited exchange occurs across the landfast ice edge throughout winter. Through vorticity stretching, offshore winds drive a counter flow beneath the landfast ice. The underflow flow field is sensitive to the magnitude of the ice-water friction but less sensitive to the spatial structure of the frictional coupling.

THE TEACHER-SCIENTIST INSTITUTES OF THE COSEE/GCGM - CATALYZING RELATIONSHIPS AMONG SCIENTISTS AND TEACHERS TO ENRICH CLASSROOM OCEAN SCIENCES LEARNING

A primary strategy used by the Center for Ocean Sciences Education Excellence in the Central Gulf of Mexico (COSEE/GCGM) is the Teacher-Scientist Institute. This institute, held each summer in two Gulf Coast states, includes a week of field study followed by a six-session online institute. The most concrete product is a collection of lesson plans that are aligned to Ocean Literacy principles and concepts, and National Science Education Standards, and made available on the COSEE/GCGM website. Another important result of the institutes is the initiation of relationships among participants. The field institute is professional development for both teachers and scientists. During this powerful experience teachers learn ocean science content from the scientists while beginning to get a feeling for the way scientists conduct research. Likewise, through the process of lesson plan development, teachers introduce scientists to the culture of secondary classrooms, from which graduates enter scientists/university classrooms. This presentation will discuss how the Teacher-Scientist Institutes promote Ocean Literacy, and efforts to sustain the teacher-scientist community as a resource for continued teaching enhancement.

RETRIEVAL OF OCEAN COLOR INFORMATION OVER THE TURBID WATER AREA

Ocean color remote sensing is the technique to estimate the quantity of the ocean materials (e.g. Chlorophyll-a, Colored dissolved organic matter, Suspended solid, etc.) with the spectral characteristics of the upwelling radiances beneath the surface (called water leaving radiation). Thus, for the satellite observation, the atmospheric correction to retrieve the water leaving radiances is important technique. The major error of the atmospheric correction is caused by the estimation of atmospheric aerosols that is highly variable in both space and time. Especially, in the general algorithm with two near-infrared observation data, the correction over the coastal region becomes more difficult because the influence of the signal other than atmosphere (e.g. turbid water background) cannot be ignored. In this study, as the approach to solve the atmospheric correction problem over the coastal region, we examined the atmospheric correction method with multi-viewing satellite observation data. This method directory estimates the both of the water leaving radiation and aerosol properties by using the directional dependency of atmospheric aerosol scattering. In this paper, we present the application result with POLDER2 multi-viewing observation data around Japan, and also present the comparison results with general algorithm.

Katsnelson, B. G., WHOI, Woods Hole, USA, bkatsnelson@whoi.edu

TEMPORAL FLUCTUATIONS OF THE SOUND SIGNALS IN SHELF ZONE IN PRESENCE OF MOVING INTERNAL WAVES

Temporal fluctuations of the sound intensity in shallow water initiated by moving trains of intense internal waves (IW) are considered. Due to the anisotropic structure of IWs, fluctuations can have different mechanisms and in turn different characteristics. We assume that mode coupling, advective variability and/or horizontal refraction are the main reasons for these fluctuations. The amplitude of fluctuations depends upon the direction of propagation of sound signals relative to the direction of IW propagation. We derived an expression for the scintillation index (SI) as a function of frequency, mode number and direction of sound propagation. Theoretical analysis is compared with experimental results from the SWARM95 and SW06 experiments.

DECADA L CHANGES OF BOTTOM WATER AND MERIDIONAL HEAT/SALT FLUXES ACROSS THE SOUTHERN HEMISPHERE SUBTROPICAL GYRES

Four WHP zonal sections, occupied between 1992 and 1995 across the southern hemisphere subtropical gyres, A10, B3, B4, and P6, were revisited as part of BEAGLE project.
in 2003 and 2004. Variations of water properties are studied following neutral density surfaces as a focus of deep water masses. Circumpolar Deep Water in the Southwest Pacific Basin is found fresher by 0.002 psu. The number is marginally greater than the measurement precision, but systematic errors cannot explain the shape difference of the TS curves and we argue that the difference is significant. The change can be explained by observed freshening of Antarctic Bottom Water formed in the Indian and Pacific Oceans. Results from two OGCMs were adopted to discuss the decadal variations of the meridional heat and salt fluxes across the sections. The fluxes show variability with periods of 2 to 10 years. In particular, the heat flux shows a significant correlation with the Southern Oscillation Index and Southern Annular Mode Index. The correlation is explained mainly by the wind changes over the Pacific.

DISTRIBUTION OF PHYTOPLANKTON COMMUNITIES AT THREE NE-ATLANTIC SEAMOUNTS AND AN E-MEDITERRANEAN SEAMOUNT DETERMINED BY CHEMOTAXOMETRY

In order to investigate how seamounts possibly influence the distribution and dynamics of phytoplankton communities, the north-eastern Atlantic seamounts Ampere, Great Meteor, Seine and the east Mediterranean Anaximenes Mountain were investigated during long-term sampling and water sampling for defined depths, from the surface to 150 m, were filtered for analysis by chemotaxonomic methods using HPLC of photosynthetic marker pigments followed by analysis with the software CHEMTAX to determine the contribution of different taxonomic groups to the phytoplankton community. The dominant phytoplankton groups at all studied seamounts belonged to the picoplankton (prochlorophytes, cyanophytes, chlorophytes) and nanoplanckton (pyrroesiophytes), characteristic of the oligotrophic regions where the seamounts are located. Exceptionally, at some sampling sites and depths, these dominant taxa were replaced by microplanktonic groups, such as diatoms and dinoflagellates. This could be explained by slight upwelling conditions caused by local topographic features resulting in somewhat higher nutrient concentrations. Moreover, an influence of the seamounts on the vertical distribution of the deep chlorophyll maximum layer could be detected. This consisted mainly in a somewhat shallower DCM layer above the seamount summits indicating a Taylor column.

ENERGY DISSIPATION OF INTERNAL TIDES IN SAGAMI BAY, JAPAN

To investigate an energy dissipation process in Sagami Bay, Central Japan, Turbopac casts were performed across a shelf near the north coast of the bay in summer, 2007. While the strong vertical shear (the energy dissipation rate of about 1.0×10^-6 W kg^-1) existed near the bottom on the shelf region, the amount of the maxima gradually decayed toward the deep sea region. In addition, the locations of the strong vertical shear were nearly equal as the bottom of the shelf on the deep sea region and slightly deeper or shallower with distance from the shelf. Since the large internal tides, especially semidiurnal period, is observed during summer in the bay, the characteristic slope of the semidiurnal internal tide was estimated using a density profile by CTD observation. The locations of the maxima of the vertical shear overlapped the characteristic slope from the bottom of the shelf break. Thus, it is expected that these strong vertical shears were induced by the scattering of the semidiurnal internal tide at the shelf break.

CHANGE IN TEMPERATURE OF BOTTOM WATER IN THE PACIFIC

Recent studies have clarified the warming in the Pacific not only in the upper part but also in the deep, for example, in the NADW in the south Pacific by Johnson et al. (1994), in the mid-depth of the Southern Ocean studied by Gille (2002), in deep water in the north Pacific along 47°N by Fukasawa et al. (2004), in deep water along the path of the CDW by Kawano et al. (2006) and in Wake Island Passage by Uchida et al. (2007), and in deep water in the Pacific by Johnson et al. (2007). The warming and warming trend of the global temperatures shown by Wills et al. (2006) and Levitus et al. (2006) is also confirmed in the Pacific on Thermohaline Circulation in the Pacific. In this study, we analyze the data obtained in 2007 by trans-Pacific surveys along 47°N and the International Date Line. The surveys were designed to trace the hydrographic sections where had been observed during the WOCE, and thus improve our understanding on temperature changes in the deep and bottom water of the Pacific.

CONTRIBUTIONS OF LIVING BACTERIA AND BACTERIAL DETRITUS TO SUSPENDED POC IN THE NORTH PACIFIC GYRE

Accurate measurements of the carbon content of heterotrophic bacteria are essential for quantitative assessments of bacterial contributions to biogeochemical cycles, yet considerable variability (~3 fold) exists among existing estimates of the carbon content of marine bacteria. Amino acid carbon yields in size-fractionated samples and bacterial cultures were used to estimate the average carbon content of heterotrophic marine bacteria in the coastal (8-14 fg C cell^-1) and open ocean (5-7 fg C cell^-1). These values are about 2 to 3 times lower than commonly used values and indicate that contributions of living bacteria to suspended particulate organic carbon (POC) in the open ocean are lower than previously estimated. Carbon-normalized yields of uramic acid, D-alanine and D-glutamic acid, unique biomarkers of bacteria, were used to estimate that bacterial detritus comprised 6-14% of suspended POC at the Hawaii Ocean Time Series station. Bacterial detritus likely comprises a large fraction of the submicron particles and colloids in the ocean.

LINKING A LOWER TROPHIC LEVEL BIOGEOCHEMICAL MODEL WITH AN UPPER TROPHIC LEVEL ECOSYSTEM MODEL

The Ecopath with Ecosim (EwE) model is widely used in the ecological community to investigate upper trophic level interactions and their effects on commercial fisheries. EwE promotes the ice-drift divergence and lead to more reduction in ice concentration through thinning of surface Ekman layer.
integrates many fisheries-related datasets to estimate energy flows between functional groups and simulates changes based on changing fishing and predation pressure. The EwE model looks primarily at predator-prey relationships as the key force of change in functional group populations, without considering the effects of changing ocean biogeochemistry, which can play a key role in the growth of primary producers and lower trophic level consumers. In this study, we use the results of a full biogeochemical model to force the lower trophic levels. The model considers the biogeochemical pathways of major nutrients as well as dissolved oxygen, dissolved inorganic carbon, and alkalinity, and is integrated with a full ocean-atmosphere physical ocean model. With this information, it predicts the population changes in three size classes of phytoplankton. By using this information in conjunction with the EwE model, we can study the potential effects of biogeochemical changes in the ocean on upper trophic level populations.

SALINITY-BASED ECOLOGICAL AND HYDROLOGIC GOALS FOR BISCAYNE AND FLORIDA BAYS

Goals for desired ecological conditions for Southern Biscayne Bay and Northeast Florida Bay have been developed to promote the ongoing restoration efforts in South Florida, including CERP. These goals include healthy seagrass communities that support a variety of estuarine ecosystem services, the ability to reach these ecological goals is dependent upon the available fresh water volume, quality, timing and location. Salinity, a direct and integral result of the distribution of fresh waters in the estuarine zone, is used to establish a practical link to the hydrologic restoration targets. Different analytical and modeling methods and associated uncertainties were used to produce a range of estimates for the volume of estuarine fresh water required to reach local restoration goals. Estimated annual volumes for Northeastern Florida Bay are 7.1 x 10^9 m^3/yr, while Southern Biscayne with its far greater tidal exchange rate requires an estimated 1.4 x 10^9 m^3/yr. Both estimates carry uncertainties of approximately 20% and assume a natural hydrograph.

CLIMATE-DRIVEN CHANGE IN THE BIODIVERSITY SOFT BOTTOM MACRORENSHOS- - ARCTIC CASE STUDY (KONGSFJORDEN, SPITSBERGEN)

Increased interest in consequences of climate change motivates research in high arctic. Glacier retreat and increased input of Atlantic water into arctic fjords are predicted consequences of climate warming. Glacier retreat is accompanied by an increase in meltwater outflow and a flux of inorganic particles and therefore has a direct influence on the benthic communities diversity and its variability. Also the balance between Arctic and Atlantic water conditions in the fjord is probably sensitive to climate changes. Kongsfjorden (79° N) is one of European Biodiversity Research Site. The year-to-year (1997 - 2006) biodiversity in benthos at three monitoring stations in Kongsfjorden is compared. The main aim is to answer the question whether the benthic diversity in Arctic was changing (in the decadal period of time) and whether climatic differences in following years influence the variability in benthic biodiversity. “Warm years” with high amount of Atlantic water advected, warm air temperature and strong glacial outflow are contrasted to “cold years” with local waters domination and less intensive glacial discharge. The patterns of diversity change are related to environmental changes and its climate proxies.

SEASONAL PATTERNS OF EXCHANGE BETWEEN ST. LOUIS BAY AND MISSISSIPPI SOUND, U.S.A.

The dynamics of estuarine and coastal flow within Mississippi Sound, USA, are being investigated using numerical models. The hydrodynamics for 2005 have been simulated on nested grids as small as 80 m. The flow fields calculated on this grid are used to transport dissolved material using both Lagrangian and Eulerian numerical methods. First, discrete particles were released at several points within St. Louis Bay. The second method calculates the transport of a non-conservative tracer using a 3D transport model. The circulation within the bay is dominated by tidal flow with periodic cold fronts and occasional tropical cyclones. The weak residual tidal flow and asymmetric circulation within the bay can transport dissolved material to the entrance of the bay but is not strong enough to continuously move it into the adjacent sound. Circulation within the bay and sound during cold fronts can assist this tidal flow in transporting dissolved material into Miss. Sound. The dominant mechanism for exchange between St. Louis Bay and Miss. Sound appears to be horizontal advection. The model results suggest that significant exchange occurs during both the increasing and waning phases of a hurricane. This result supports previous field work, which indicates that dioxins and heavy metals from outfalls within the bay are showing up in shellfish and sediments in Mississippi Sound.

A GLIMPSE OF OCEAN BIODIVERSITY THROUGH EXPLORATION COUPLED WITH TELEPRESENCE

Technology enables each advancement made in exploration, from the poles to the deepest reaches of the ocean, to outer space. Discovery of new life at hydrothermal vents was made possible by submersible technology, and continued enhancements in satellite sensors provide ever-improving discoveries of planetary scale changes like those due to El Nino and those taking place in the deepest parts of the ocean. It is cutting-edge technology that enables us to expand boundaries of the known world while engaging all who wish to be involved in these discoveries in real-time. With the unprecedented advancements in all areas of technology, learning is no longer restricted to a place and time, and students are perhaps the most profoundly affected by this evolution in how they learn and where they learn than any other segment of our society. The NOAA Ship Okeanos Explorer, outfitted with state-of-the-art telepresence capabilities, will enable us to expand the reach of NOAA ocean science in novel ways to students of all ages. This presentation will focus on the status of bringing the unknown ocean world in new ways to all who wish to explore it.

DECADAL PREDICTION: CLOSING THE GAP BETWEEN CLIMATE PROJECTIONS AND SEASONAL FORECASTS

Predicting climate variations over the next decade has clear socio-economic benefits. Less clear perhaps, but of equal or greater importance, is the reduced uncertainty in climate change projections that will result from better understanding and modelling of the climate system. Here, skilful decadal hindcasts of North Atlantic sector climate are presented. The hindcasts were performed with the MIPI-OM/ECHAM5 model, were ten years long, consisted of three ensemble members, and covered the period 1955 till 2005. Initial conditions were generated by relaxing coupled model sea surface temperature to observations. The model is able to predict Atlantic meridional overturning circulation changes and surface temperature variation over the North Atlantic, North America and Western Europe out to a decade in advance. Our prediction for the next decade indicates a weakening of the MOC and delay in the anthropogenic induced warming of the surface temperature in these regions, and globally. Major differences to seasonal forecasting will be discussed, by presenting results from similarly performed seasonal forecasts. The role of high versus low latitude in the initialisation technique, and the sensitivity to the treatment of salinity are investigated in additional experiments. Sensitivity to model formulation is also assessed with experiments using another model(NEMO/ECHAM5).

THE DISTRIBUTION OF COLORED DISSOLVED ORGANIC MATTER (CDOM) AND SALINITY ALONG THE SOUTHERN NEW ENGLAND COAST FROM AIRCRAFT REMOTE SENSING

Using in situ measurements of estuary color, algorithms were developed to estimate colored dissolved organic matter absorption at 412 nm (acdOM412) and surface salinity in New England waters. Model estimates were compared with measured CDOM absorption values and surface salinity from Narragansett Bay, Rhode Island. Statistical analysis showed a strong correlation (R = 0.88) between acdOM412 and the ratio of remotely sensed reflectance at 665 and 490 nm. The standard error between measured and predicted absorption values was 0.1 /m. Results also showed a strong correlation (R = 0.92) between acdOM412 and salinity, with a standard error of 0.5 parts per thousand (ppt). The robustness of the acdOM412 algorithm was tested using in situ spectral measurements (2005 - 2007) from Narragansett Bay, the Providence River, and Long Island Sound to predict surface salinity. Test results indicated a very strong correlation (R = 0.92) between measured and predicted salinities with a standard error of 1.0 ppt. Using aircraft spectral data from Long Island Sound to Nantucket Sound, the spatial and temporal variability in acdOM412 and salinity are presented on a regional scale.

The Alvarado Lagoon System (ALS) consists of shallow rivers and lagoons connected to the Gulf of Mexico (GOMEX) by a narrow channel. We collected samples of water and fishery and human hair and sediment in 2005. Total Hg in sediments ranged from 27.5 to 90.5 µg Hg/g dry weight, with fish and shellfish Hg levels ranged from 0.01 to 0.53 µg Hg/g wet weight. Total Hg in human hair ranged from 0.10 to 3.36 µg Hg/g (n = 47) and 58.9 % of the hair samples were above 1.00 µg Hg/g. Mean hair Hg levels were 1.12 ± 0.62 and 1.48 ± 0.86 µg/g for children (n = 20) and adults (n = 27), respectively. Water column concentrations

Keener-Chavis, P. NOAA, Charleston, USA, paula.keener-chavis@noaa.gov; Martinez, C. NOAA, Newport, USA, catalina.martinez@noaa.gov; Feldman, M, CoML, DC, USA, feldman@cocean.org
of total unfiltered Hg ranged from 0.9 to 12.6 ng/L. These levels are similar to other estuaries tested, excluding the northern GOMEX. The ALS discharges around 95 kg Hg/yr into GOMEX, approximately 0.38 % of the annual atmospheric Hg deposition, and about 0.43 % of annual Mississippi river discharge.

SALINITY AND MESO-ZOOPLANKTON COMMUNITIES IN FLORIDA BAY

Florida Bay has significant spatial and temporal salinity variability, due to heterogeneity in freshwater sources, minimal exchange between the four major sub-regions, seasonal cycles of rainfall, runoff, and evaporation, and the influence of large-scale phenomena (i.e. tropical cyclones and El Niño). Furthermore, salinity likely will affect the alibatic parameter most directly affected by CERP activities. Meso-zooplankton occupy a vital link in the pelagic trophic network, providing an energy pathway between phytoplankton and upper trophic levels. Understanding the relationship between meso-zooplankton communities and salinity is necessary to formulate quasititive, testable hypotheses as to the potential effect of CERP projects on meso-zooplankton. To address this issue there has been an ongoing long-term research program to study meso-zooplankton communities in Florida Bay. Analyses will be presented which focus on determining if salinity and other environmental parameters contribute to the observed temporal and spatial variability in meso-zooplankton communities, if high or low salinity extremes have distinct meso-zooplankton communities, and large-scale phenomena alter the meso-zooplankton communities. From these results, hypotheses will be constructed regarding the potential effect of CERP on meso-zooplankton in Florida Bay.

EVERGLADES RESTORATION AND THE FLORIDA KEYS NATIONAL MARINE SANCTUARY: MONITORING FOR POSSIBLE ECOSYSTEM EFFECTS

The 9,800-square-kilometer Florida Keys National Marine Sanctuary (FKNMS) is located downstream of the Everglades and may be impacted by increased freshwater flows resulting from implementation of the Comprehensive Everglades Restoration Plan. The FKNMS includes extensive areas of seagrass beds, which are sensitive to levels of eutrophication, and the only system of coral reefs in North America. Everglades restoration intends to “do no harm” to the Florida Reef Tract, and an intensive set of monitoring projects will help determine whether this desired outcome occurs and, if not, whether adaptive management of freshwater outflows may need to be invoked. Baselines for FKNMS monitoring were established as early as 1995 and include physical and chemical properties of surface waters and the water column as well as ecological monitoring of seagrass and coral reef communities and associated populations. Results to date indicate that nutrient ratios in seagrasses and relative abundance of seagrasses and macroalgae are particularly informative indicators of water quality to FKNMS managers.

LEAD CONCENTRATIONS AND ISOTOPIC RATIOS IN CORALS AND WATER NEAR BERMUDA, 1780-2000 A.D.

Lead (Pb) naturally occurs in the environment, but the dominant recent sources are anthropogenic. Pb significantly alters the global lead cycle. In order to document the complete history of oceanic, anthropogenic Pb transient in the North Atlantic Ocean, this study focuses on Pb concentrations and isotope records from annually-banded coastal corals near Bermuda during the past 220 years. Anthropogenic lead emissions in this area have been dominated by the industrialization of North America beginning in the 1840s and leaded gasoline, which was introduced in the 1920s, began to phase-out in the mid-1970s and substantially completed by the late 1990s. From the late 1700s to 1900, Pb187/Pb0 and Pb206/67Pb isotope ratios (Pb LR) show peak values in the middle of the 19th Century. We suggest that this signal is a reflection of the early dominance of Upper Mississippi Valley Pb ore in the United States, as is also seen in the estuarine sediments of Rhode Island.

BIOLICAL CYCLING OF SILICON, NITROGEN AND CARBON IN THE NE PACIFIC AND THE BERING AND CHUKCHI SEA

Diatoms control the cycling of silicon and contribute significantly to the downward flux of biogenic silica (BSi), nitrogen and carbon in many ocean regions. We investigated the contribution of diatoms to primary productivity and nutrient cycling in surface waters across the NE Pacific and Bering Sea during summer and fall 2005. In the NE Pacific [BSi] was 1 µmol L-1, mean particulate Si:C and Si:N ratios were 0.07 and 0.37, respectively, and net BSI production was positive in the euphotic zone. The Bering and Chukchi Seas exhibited [BSi] over 10 µmol L-1. Mean particulate Si:C and Si:N ratios were 0.25 and 1.54, respectively, in the Bering Sea and 0.26 and 1.96 in the Chukchi Sea. Euphotic zone BSI production was positive in the Chukchi Sea, while the Bering Sea exhibited net BSI dissolution. During this study, the highest carbon and nitrate uptake rates were measured in the Chukchi Sea (up to 10 µmol L-1 d-1 and 480 nmol L-1 d-1, respectively). This study was the first to assess diatom dynamics across the subarctic NE Pacific to the western Arctic.

THE COHERENCE OF UPPER OCEAN HEAT TRANSPORT IN THE WESTERN NORTH ATLANTIC

The coherence of heat transport in the upper 800m of the western North Atlantic is tracked using a thermodynamics-only model, with geostrophic surface velocities specified from altimetric sea surface height and the vertical profile derived from hydrographic data. The model comprises an upper ocean mixed layer and interior layers forced by geostrophic advections. The pathways of mass and temperature transport are examined from the Gulf Stream's separation to beyond the trifurcation into the North Atlantic Current (NAC), the Azores Current, and the southern recirculation return flow. The pathways are complex and vary significantly with time, with surprisingly little coherence in transports along the Gulf Stream itself. Inflow anomalies from the Labrador Current are well-correlated with those in the North Atlantic Current; both are lag-correlated with the NAO and with the Sverdrup transport. The Gulf Stream mass and temperature transport variations are only weakly correlated with either the NAO or the NAC. This description of heat and mass transports bears little resemblance to an ocean heat conveyor belt, at least for the upper limb, and reveals instead nearly independent fluctuations on interannual time scales. The heat budget of the region where the subpolar and subtropical gyres interact (the intersection of the Labrador Current, North Atlantic Current, and Gulf Stream) is examined in detail to determine the heat source for the relatively warm North Atlantic Current.

H; Applied Physics Laboratory, University of Washington, Seattle, USA; Kunze, E; School of Earth and Ocean Science, University of Victoria, Victoria, Canada Dynamcs of MIXING HOTSPOTS ON THE ROUGH, NEAR-CRITICAL OREGON SLOPE

Observations of internal waves and turbulence on the near-critical Oregon slope (Moum et al 2002, Nash et al 2007) have identified localized regions of intense mixing at several sites along the slope. A synoptic snapshot of XCP- and LADCP-derived velocities and inferred turbulence during fall 2005 is used to investigate the source of these hotspots. Although barotropic tidal velocities are predominantly along large-scale isobaths, both across- and along-slope topographic interactions may be present as a result of strong baroclinic motions and small-scale, 3-D topography. Tidal fits across-slope velocities display instances of upward and downward phase propagation suggesting the existence of both on- and offshore propagating internal tide energy. At certain locations, turbu-
lence appears closely linked with the along-slope barotropic tide, indicating that large tidal excursions over such scale topography may play an important role in local mixing. Multiple configurations of the nonhydrostatic MIT General Circulation Model are used to (1) estimate the relative contributions of barotropic and baroclinic forcing and (2) better determine the roles of large-scale near critical slopes and small-scale 3-D roughness.

THE C-MORE EDUCATION AND OUTREACH PROGRAMS

The Center for Microbial Oceanography: Research and Education is a new (August 2006) Science and Technology Center, one of 17 extant centers funded through the NSF Office of Integrative Activities. C-MORE's mandates explicitly include ‘Integrating the research, education, and knowledge transfer components into a coherent program,’ as well as ‘Preparing educational materials designed to enhance public understanding of science, engineering, technology, and educational advances that serve society.’ We are expected to address these mandates through programs that display novelty and creativity as well as effectiveness; it is not enough to simply adopt what has worked before. C-MORE's challenges include integrating education and outreach programs across six widely separated partner institutions ranging from Hawai‘i to Massachusetts, each of which has unique local demographics that offer both opportunities and challenges. Common to all is the habitual isolation of research scientists from public education specialists. C-MORE's still-developing programs, will be described by representatives of the C-MORE senior management team and Education Office, focusing on mechanisms used to facilitate strong involvement of the research team in public education and outreach.

WHAT CLIMATE SCIENCE NEEDS FROM A SPACE-BORNE MONITORING SYSTEM

Global measurements of sea surface temperature are a critical record for quantifying and understanding global climate change. However, the problem of producing a climate-quality SST data set using space born radiometers is a challenging one. Typical requirements are for an accuracy of better than 0.1K on monthly averages over 2degree areas, and a stability on a global average of better than 0.05K/decade not only during the lifetime of a single satellite, but throughout the combined record. These requirements will be motivated from applications in climate science. To help achieve these targets, GCOS provide 20 key principles of climate monitoring, 10 of which apply specifically to the creation of climate records from satellite data. In situ measurements remain essential as a ground truth for SST analyses, but accurate measurements of SST from space can also help to characterise the in situ record.

STRATEGIES TO COUNTER ESTUARINE EUTROPHICATION IN THE MID- ATLANTIC REGION

Eutrophic conditions are worsening in many estuarine systems bordered by watersheds with increasing population and agricultural and urban land use. The conversion of natural land covers to farmlands, housing developments, and industrial sites facilitates nitrogen loading into estuarine waters, leading to cascading water quality and biotic impacts, debilitating impairments, and diminished ecosystem services. An array of Mid-Atlantic estuaries, most notably the lagoonal systems with restricted circulation and high residence times, exhibits severely stressed responses due to nutrient over-enrichment coupled to activities of a burgeoning watershed population that also exacerbates atmospheric inputs. The majority of estuaries in this region are now moderately to highly eutrophic and are ranked among the most impacted systems in the United States. Watershed management strategies to reduce nutrient loading in estuaries of this region include upgrading storm water controls, implementing low-impact development and best management practices, advancing open space preservation, and establishing total maximum daily loads (TMDLs) for nutrient limitation.

USE OF THE ENSEMBLE KALMAN FILTER IN A GLOBAL COUPLED SEASONAL PREDICTION SYSTEM

A multivariate ensemble Kalman filter (EnKF) with covariance localization is used to assimilate in situ temperature and salinity observations and remotely sensed altimetry anomalies into a global OGCM. An online bias correction algorithm is built into the system to account for the fact that the assimilation continuously alters the model climatology. Following the data assimilation, the ensemble of OGCM states is used to initialize the oceanic component of the GMAO coupled forecasting system (GCFS). The GCFS is then run in hindcast mode without any data assimilation to assess the impact of the ocean initialization on its seasonal forecasting skill. To this end, the hindcast skill of the GCFS initialized with the EnKF is compared to that of the production forecasting system in which optimal interpolation is used to initialize the OGCM prior to coupling it to the other CGFS components. Other issues addressed in this talk include (1) the effect of ensemble size on the EnKF performance, (2) the importance of online bias correction when sea surface height anomalies are assimilated, (3) whether the time-dependency of the EnKF covariance model has a measurable impact on the assimilation performance, (4) the adaptive estimation of background-covariance localization scales and (5) the adaptive deflation of distrusted error-covariance estimates.

THE VIEW FROM THE COOL ROOM: THE RUTGERS UNIVERSITY COASTAL OCEAN OBSERVATORY

The Rutgers University Coastal Ocean Observation Laboratory (RUCOOL) operates a fully integrated, real-time, research-based ocean observatory. RUCOOL provides oceanographers from around the world with a heavy instrumented, cyber-connected, sub-regional observatory for shelf-wide or embedded process experiments. Cost-effective, sustained, spatial sampling of the coastal ocean is accomplished through: 1) Local acquisition of data streams from U.S. and foreign satellites in space, 2) a network of radars deployed along the shore and 3) a fleet of robotic underwater gliders flying beneath the ocean surface. All sensor data is transmitted to and processed in the operations center in near real-time, where it is made available (via the internet) to research universities, state agencies, national agencies, educators and public users. The observatory also serves as an international proving ground for new sensor, platform and communication network development. We'll provide an overview of recently completed (LaTTE, Shallow Water 2006), current (MURI, CODAR National Network), and future (MARCOOS) research activities supported by the observatory.

EXTRA-EQUATORIAL RESPONSE TO A COMPOSITE EL NINO: INTERIOR VS WESTERN BOUNDARY TRANSPORT

A composite El Nino wind forcing constructed from 6 events during 1965 through 1998 was imposed in a linear Rossby model and an OGCM, with emphasis on the lagged response in the subtropics and the resulting interior vs. western boundary discharge and recharge. The composite identifies important features of the off-equatorial winds that are consistent among these events over 40 years. With stronger composite El Nino curl in the southern hemisphere, its anomalous subtropical currents are larger than in the north, and especially given the nearness of the western boundary in the south, the boundary transports that recharge the west Pacific warm pool following a warm event are also larger. Much of this transport signal can be diagnosed as linear Rossby waves plus a simple model of the western boundary response. Apparently the extra-equatorial component of El Nino, though often ignored, forms a significant part of the subsequent evolution.

A COLLABORATIVE APPROACH TO ASSESSING CONDITIONS IN COASTAL NATIONAL PARKS

The National Park Service (NPS) Water Resources Division (WRD) has initiated assessments of coastal water resources in 55 coastal and island Parks through the Natural Resource Challenge Watershed Condition Assessment Program. Reports from these assessments are characterizing the relative health or status of Great Lake, estuarine and marine resources in the National Park System and are revealing ecological stressors that may cause impairment. This presentation will describe the program and explore ways to strengthen partnerships among various stakeholders to produce robust and cost-effective monitoring approaches at coastal Parks. Assessing coastal water quality and habitat condition in the Parks provides a platform for cooperative monitoring and watershed management partnerships. For example, dissolved oxygen concentrations were found to be unexpectedly low in estuarine waters at Cumberland Island National Seashore during the summer, which encouraged increased monitoring for hypoxia by the State of Georgia. NPS is developing the next phase of the program to investigate resource problems and fill information gaps by forming monitoring partnerships with states, federal agencies, academia, local watershed groups and programs such as the National Coastal Assessment.

THE IMPACT OF DIURNAL WARMING ON THE ATLANTIC AIR-SEA CO2 FLUX

Quantifying the air-sea CO2 flux is important for understanding the Earth's carbon cy- cle and for climate change prediction. Here we investigate the impact of diurnal variations in sea surface temperature (SST) on the air-sea CO2 flux over the Atlantic Ocean. We use
hourly satellite data from the geostationary satellite SEVIRI to quantify diurnal variations in sea surface temperature (dSST) and long and short wave radiation. Wind data are from microwave observations (SSM/I, TMI, AMSR, QuSCAT). The gas flux is computed using a modified version of the NOAA-COARE algorithm that incorporates convectively driven gas transfer (Jeffrey et al., 2007) thus allowing flux at the low wind speeds associated with diurnal variations in SST. We compute the CO2 flux twice - first using a foundation SST and the second time using the foundation SST plus dSST. We examine the differences between these two fields over 2004-2007.

FLOW AND CONCENTRATION RELEASE THROUGH/AROUND MARINE AGGREGATES: A MATHEMATICAL MODELING

There exists a continuous fall of organic waste material from decomposing dead or dying plants or animals (detritus) in the water layer over seas and oceans. These particles coagulate to bigger aggregates, and sink with moderate velocities down to the seabed. Aggregates are considered as food source for other marine organisms. Hence, it is essential to have an estimation of the release of nutrients concentration through them. In this study, we propose the mathematical modeling of flow and concentration leakage from an arbitrarily-shaped porous medium based on the aggregation behavior of the surface waves. The challenge model is that shape of the aggregate content is varied easily, and that it can also account for variable physical properties such as porosity and permeability. After calculating the flow and concentration fields for different real conditions, the drag force experienced by aggregates has been obtained.

FAST SPINUP OF SEASONALLY-FORCED GLOBAL OCEAN BIOGEOCHEMICAL MODELS USING MATRIX-FREE NEWTON-KRYLOV

A fundamental challenge in global ocean biogeochemical modeling is the fact that many chemical and biological tracers, for example, nutrients, oxygen, toxic elements such as thorium, take several thousand years to equilibrate. Routine simulation of these tracers in coupled physical-biogeochemical models thus remains prohibitively expensive, as does any attempt to systematically understand their sensitivity to different biogeochemical parameterizations or to optimize model parameters. Here, I present a new solution to this "spinup" problem based on transforming the essentially time-dependent problem into a nonlinear algebraic equation that is solved using matrix-free Newton-Krylov (MFNK). To accelerate convergence of the Krylov solver, I have developed a multigrid preconditioner that is relatively inexpensive to compute and apply. Because of its matrix-free nature, this technique can be applied to any existing, seasonally-forced, biogeochemical model. I applied this method to a coupled biogeochemical model with several prognostic tracers, including carbon, phosphorus, and iron. MFNK reduces the spinup time by at least 2 orders of magnitude relative to conventional time-stepping.

A NEW AIRCRAFT-TOWED PLATFORM FOR AIR-SEA INTERACTION MEASUREMENTS

Direct measurements of air-sea interaction fluxes - momentum, heat, water vapor, and CO2 - are usually obtained from special fixed platforms, buoys or ships at or near the reference height of 10 m above the ocean. Research aircraft offer more mobility, but the lowest height for sustained flux patterns is usually limited to 30 m by most operators. Based on the technology of aircraft towed target drones, a new measurement platform has been developed. The Towed Atmospheric Sampling Platform (TASP) is a modified target drone 22.8 cm in diameter and 213 cm long with a hemispherical nose. It can maintain a radar reference height of 10 m above the ocean. Research aircraft offer more mobility, but the low vertical overlap makes it difficult to resolve the flow at these scales. The TASP has a hemispherical nose that is designed to limit the wind speed at which the drone detaches from the tow. The drone is controlled by a radio signal that is transmitted to the drone via a computer and received by an antenna on the aircraft. The drone is equipped with sensors that measure wind speed and direction, temperature, humidity, pressure, and air density. The data are transmitted back to the aircraft via a communication link. The aircraft is equipped with a computer that processes the data and transmits it back to the ground station via a wireless link. The TASP is designed to operate in winds up to 100 km/h and at altitudes up to 10,000 m.

MARINE AEROSOLS PRODUCED FROM BUBBLING BUBBLES: PROPERTIES, PHOTOCHEMICAL EVOLUTION, AND OCEANIC FEEDBACKS

Bursting bubbles produced in the oceans by breaking waves inject large quantities of aerosols into the atmosphere. To characterize and study the photochemical evolution of these aerosols, we designed a flow through bubbling apparatus to generate aerosols. Using Sargasso seawater, two aerosol modes were detected. The smaller mode was dominated by chlorinated organic compounds (OC), while the supernatant mode contained soluble organic material (SOM). The supernatant mode was also characterized by the presence of high levels of hydrogen peroxide and other hydroperoxides. The aerosol mode was characterized by the presence of high levels of hydroperoxides, while the supernatant mode was dominated by chlorinated organic compounds (OC).

FORMATION, SPREADING AND FATE OF LABRADOR SEA WATER

Labrador Sea Water (LSW) has been very well monitored throughout the decades concerning temporal evolution of water mass properties or variability in its formation. In recent years several persistent LSW classes have been identified which result from time-varying convection in the Labrador Sea. Since the end of the 1990s the production of LSW switched from high-density to low-density classes, associated with an overall decline of the LSW formation rate. We review the formation history of these two LSW classes for the period 1987-2007 and put particular focus on spreading pathways of LSW in the interior North Atlantic. When combing hydrographic data with time series derived from moorings we find high levels of meso-scale variability related to intense eddy activity which is overlaying an interannual evolution. Cross-frontal exchange of the boundary current with the North Atlantic Current close to Flemish Cap causes the latter to be the main distributor of LSW types into the interior western subpolar North Atlantic. The results indicate a southward spreading of LSW along the Mid-Atlantic Ridge.

EVALUATION OF ECOSYSTEM MODEL PERFORMANCE: EXPANSION OF THE REGIONAL TESTBEDS FRAMEWORK FROM THE ARABIAN SEA AND EQUATORIAL PACIFIC TO SOUTHERN OCEAN

Previous efforts to evaluate the performance of ecological models in the regional Ecosystem Modelling Testbeds Project utilized US Joint Global Ocean Flux Study (JGOFS) observations in the Arabian Sea and Equatorial Pacific, sites with very similar sea surface temperatures (SST) of 25-28°C. To further test model performance and portability, a third test site was created at 57ºS 170ºW based on the JGOFS Southern Ocean process study, a region with a mean SST of 4°C. To test this extended testbed framework, two ecosystem models were assessed: a four variable model and a more complex eight variable model. Optimizing the model parameters was performed both for each site individually as well as for all sites simultaneously. The 8 variable model was found to outperform the 4 variable model in both individual and simultaneous site tests with its improved performance improving considerably with the addition of the Southern Ocean testbed. Model performance was found to be sensitive to a combination of factors including temperature, phytoplankton physiology and ecosystem structure.

LIFT-OFF OF THE COLUMBIA RIVER OUTFLOW

Dynamics of plume lift-off in the tidally-dominated Columbia River nearfield are investigated. During more than 300 plume transects X-band radar tracked surface fronts while
highly resolved velocity, density and turbulence measurements were made. These data capture nearfield evolution and plume front structure. Lift-off represents a transition from barotropically-forced river flow to buoyant gravity current. This transition point is predicted using a Froude number criteria that depends on radial spreading, time variable estuary discharge, and topography. On longer time scales, rotation, coastal flow and sea- sonal variability of river discharge are also important.

IMPACT OF IN SITU BUOY DISTRIBUTION ON COEFFICIENT ESTIMATION FOR THE PATHFINDER SST ALGORITHM: A CASE STUDY OF NOAA-7 AND NOAA-14 USING BUOY AND SHIP MATCHUPS

The NOAA/NASA Pathfinder SST (PFST) project has the goal of creating the longest, highest resolution, and most accurately quantified SST climate data record from space. PFST extends over 2 decades from 1984-2006. Extending this data record back to 1981 by the addition of NOAA-7 should be a valuable resource. The PFST algorithm uses a statistical approach for coefficient estimation. Standard coefficients are determined monthly for two water vapor regimes using a weighted 5-month window of matchups. For NOAA-7 algorithm coefficients we investigated combining matchups from both buoy and ship observations, and various temporal periods, to minimize any adverse effects of the limited geographic availability of buoy observations during the NOAA-7 operational lifetime. The goal was to balance seasonal atmospheric effects and the need to include observations from a broad geographic range as possible. The coefficient strategy for NOAA-7 was cross-validated by sub-sampling NOAA-14 matchups of buoy and ship observations to simulate the distribution of the NOAA-7 matchups. The accuracy of retrievals from coefficients determined from combined buoy and ship matchups will be presented.

MORPHOLOGY OF TOMBOLO LIKE DEPOSITS IN THE KOKUSSAN ARCHIPELAGO, WESTERN KOREA

This study presents morphological characteristics of sedimentary deposits that connect two islands in the Kokusanzan archipelago, western Korea. These deposits consist of sand beach on the western side and muddy-sand tidal flat on the eastern side. In the tidal flat, there is an outstanding sedimentary feature, which is a wild goose shaped, gravel bar. During high tide, narrow beach and gravel bar are seen. Aerial photographs show that horizontal geometries of deposits has not significantly changed since 1978, implying that the deposits are quite stable. Since the beach is open to the northwest, it is directly affected by wintertime waves. It seems that sedimentary processes of the deposits are different from those of tombolos. Rather strong tidal currents may be more responsible for forming these tombolo-like deposits.

COMPARING COLLABORATION EXPERIENCE OF TWO PROFESSIONS: EDUCATORS AND SCIENTISTS IN COSEE GREAT LAKES

Results of baseline studies for COSEE Great Lakes attempts to facilitate collaboration between scientists and educators will be reported. The studies were aimed to characterize and compare collaboration experience between marine/aquatic sciences and primary/secondary teachers in the Great Lakes Region. Three research questions guided the studies: 1) how are K-12 teachers and scientists involved in educational collaboration, 2) what barriers may deter their involvement, and 3) which factors are related to their potential for partners in education collaboration. Comparing responses from scientists (n=94) and educators (n=194) in two baseline studies, their experience in educational collaboration were investigated. The responses of collaboration programs participants (e.g., Lake Erie RV/G Guardian and Lake Superior Exploration workshop) were also compared with those from baseline studies. Regression analyses identified predictor variables accounting for variances of scientists and educators collaboration experience.

A NUMERICAL EXPERIMENT ON THE PATH VARIATION OF TH CHANGJIANG DILUTED WATER IN SUMMER

In this study we used regional ocean modeling system (ROMS) which is fully three-dimensional, free-surface and hydrostatic primitive-equation model. It was used to simulate the circulation of the East China Sea and the Yellow Sea. We examined the effect of the wind and the discharge on the variability of the Changjiang Diluted Water (CDW) in summer by numerical model experiment using real wind field and river discharge from 1993 to 2002. Effect of wind on dispersion of CDW was evaluated by climatology condition. The domain and southern, southeastern and southwestern winds with speed of 5 m/s were assumed under climate condition. Model result shows that the CDW path change greatly according to the wind direction. Model results using realistic oceanic conditions in 1996, 1998 and 2000 when those prevailing winds are southwestern, southeastern and south- ern were selected to compare to the ideal model results. Model result implies that wind is the main force in determining the variability of CDW. The discharge of the Changjiang River might also be another important factor on the CDW variability.

THE CHARACTERISTICS OF VARIATIONS OF SURFACE LAYER ANOMALIES IN THE NORTHWESTERN PACIFIC OCEAN AFTER OCT., 1992

The northern Pacific Ocean (NPO) is to be the North Equatorial Current (NEC) and the Kuroshio Current (KC). Spatial distributions of the mean surface layer anomalies (SLA) are divided into the southwestern and northeastern regions sharply by the NEC and the KC in the NPO. The southwestern regions under the direct influence of the NEC and the KC exhibit higher amplitudes of the SLA fluctuations, while the northeastern regions are relatively smaller one. Due to the SLA after 1992, the region of the southwestern Pacific Ocean to be higher SLA is 30Â°N outside the eastern coast of the Japan with mean SLA 25 cm or more in the coastal area of the Japan, and Kuril islands, are also high in range. In the northwestern Pacific Ocean, temporal variation trends of the SLA are mostly rising, where exceedingly high region of high increasing trend of SLA represent over 4.5 cm/yr in region on mean SLA to be high. The special feature in the northwestern Pacific Ocean is on the fact that the increasing and decreasing regions appear alternately parallel to latitude along south-north direction.

THE VALIDATION OF THE OCEAN COMPONENTS OF NCEP HURRICANE COUPLED ATMOSPHERIC-OCEAN FORECAST SYSTEM

The next generation of NCEP hurricane coupled atmosphere-ocean forecast system in the Atlantic Ocean is based on the HWRF (WRF for hurricane) model and HYCOM models covering the regional ocean model, each of which is nested one-way to the NCEP global atmosphere GFS (Global Forecast System) and operational Atlantic basin RTOFS (Real-Time Ocean Forecast System), respectively. The core of the system development is the two-way coupling of the HWRF and HYCOM models. The primary objective of this study is to validate the two components of the system - model parameters and data assimilation. The coupled model is required to represent physical processes accounting for the hurricane-ocean interaction; and the nesting and data assimilation should provide realistic ocean initial and boundary conditions. The presentation focuses on the ocean contribution to hurricane forecast skill. This will be examined for storms varying in size, intensity, translation speed, etc. over a variety of relevant oceanic conditions (sea surface temperature, mixed layer depth, temperature gradient at the base of the mixed layer).

EFFECTS OF FRESHWATER INFLOW ON PELAGIC AND BENTHIC COMMUNITIES IN TEXAS ESTUARIES: A MODELING STUDY

A climatic gradient of freshwater inflow has been known to cause differences in benthic community structure and secondary production among major Texas estuaries. There have been studies to develop quantitative relationships between freshwater inflow and benthic biotic indicator variables. While some of these works were done with respect to biological process-based approach, they did not explicitly show the mechanistic relationships between benthic and pelagic ecosystem. Here we present an upgraded version of bentho-pelagic coupled ecosystem model to investigate trophic relationships among nutrients, phytoplankton, benthic flora and macrobenthic fauna in Texas estuaries. We also incorporated this ecosystem model into a box model to simulate effects of episodic flood events on freshwater inflow and subsequent changes in salinity regime. A long-term data set of nutrients, chlorophyll and macrobenthic biomass was used to calibrate and validate the model. We tried to interpret the simulated results in context of net ecosystem metabolism (NEM) that can be used to understand the relevant scales of estuarine ecosystem response to changing environmental conditions.
CLIMATE AND COASTAL ALGAL BLOOMS IN THE SOUTHERN CALIFORNIA BIGHT

Surface chlorophyll measured at the Scripps Pier in the Southern California Bight (SCB) for eighteen years (1983-2000) reveals that the spring algal bloom occurs with irregular timing and intensity from year to year. Unlike surface ice temperature (SST), which is dominated by a regular seasonal cycle. In the 1990’s, the spring blooms occurred earlier in the year and with larger amplitudes compared to those of the 1980’s. The annual mean Pier chlorophyll consequently exhibits an increasing trend with no concomitant trend evident in the Pier SST during the observation period. The interannual variation of the Pier SST and chlorophyll is not correlated with tropical EI Niño conditions over the entire observing period, but a few strong EI Niño and La Niña events have significant impacts on the Pier data. Seasonal anomalies of the SST and chlorophyll have no significant correlation with local/offshore winds, or upwelling index anomalies. Consequently, classical coastal upwelling may not be the process that drives chlorophyll variations in the SCB, perhaps because the sheltered SCB has weaker and less persistent winds and more complicated topography than the northern California Current. A

DECADE VARIATIONS OF THE CHANGJIANG DILUTED WATER AND SEAWIFS CHLOROPHYLL

It is known that the Changjiang Diluted Water (CDW), which mixed Changjiang summer freshwater discharge and Kunshan Surface Water and/or Taiwan Warm Water, spreads eastwards over the broad area of the East China Sea and reaches as far as Jeju Island to Tushima Strait. It is expected that the distribution of CDW is controlled by the Changjiang summer freshwater discharge and showed significant interannual variations. Here we analyzed the Sea-viewing Wide-field-of-view Sensor (SeaWIFS) chlorophyll-a during 1998-2006 and showed that interannual variations of the spatial distribution of high satellite chlorophyll-a (>0.9-0.4 mg m-3) was well corresponded with distribution of low salinity CDW (<30-32) and showed significant interannual variations. Here we analyzed the Sea-viewing Wide-field-of-view Sensor (SeaWIFS) chlorophyll-a during 1998-2006 and showed that interannual variations of the spatial distribution of high satellite chlorophyll-a (>0.9-0.4 mg m-3) was well corresponded with distribution of low salinity CDW (<30-32) and that interannual variation of the CDW area was associated with the interannual variation of the Changjiang summer freshwater discharge. In order to decide criteria of the higher satellite chlorophyll-a and summer freshwater discharge indicated that low salinity, high satellite chlorophyll-a CDW spread in the East China Sea after 1 to 2 months time lag of the discharge. Satellite chlorophyll-a is a good indicator of the low salinity CDW in the East China Sea.

ANISOTROPIC RESPONSE OF SURFACE CURRENTS TO THE WIND IN A COASTAL REGION

Coastal surface currents measured off the coast of San Diego are found to have an anisotropic response to wind, possibly as a result of bottom/coastline boundary effects and non-geostrophic local pressure gradients. The anisotropic response function explains approximately 20% more surface current variance in a linear regression than an isotropic wind-ocean response model. Under a steady wind, the isotropic surface current response approximately 20% more surface current variance in a linear regression than an isotropic non-geostrophic local pressure gradients. The anisotropic response function explains

SIMULATION OF SALINITY RETRIEVAL OVER OPEN OCEANS BY THE SPACEBORNE AQUARIUS INSTRUMENT

Surface salinity observations are important to understand many ocean/ climate phenomena such as the North Atlantic thermohaline circulation, ocean surface freshwater balance, surface ocean oxygenation, and climatic effect on sea level. As a part of such observations, a spaceborne L-band microwave radiometer, Aquarius, is under development by NASA for launch in 2010. The accuracy requirement of the Aquarius mission is set to 0.2 psu over 100km for monthly averaged salinity observations. To examine the feasibility of the accuracy goal, we developed a ‘end-to-end simulator incorporating surface emission model, radiative transfer model for the Earth atmosphere and cosmic background, and ionospheric model. A retrieval simulation corrects for these forward processes to estimate surface salinity. The result shows that surface salinity may be retrieved with an accuracy better than 0.2 psu rms over the global open ocean (warm ocean with surface temperature higher than 10°C, 500km away from the coast, and at 100km spatial resolution). The retrieval error increases toward colder seas. Sensitivity of the retrieval accuracy to different antenna patterns is also studied.

SIMULATION OF HYPOXIA IN UPPER CHARLOTTE HARBOR, FLORIDA

The Upper Charlotte Harbor, a shallow (-3m) estuary in Southwest Florida has suffered from reduced oxygen levels, hypoxic conditions in near-bottom layer since the late 1950’s, which is related to high primary productivity and changes in nutrient loading in the river. For example, very high nitrogen loading in the river has increased the eutrophication of the estuary. Furthermore, the 1998 Hurricane Andrew was an important factor for the hypoxia condition in the estuary.

Kim, Y. B., Seoul National University, Seoul, Republic Of Korea, ykcho@chonnam.ac.kr

VARIABILITY OF THE SEA WATER TEMPERATURE AND ITS PREDICTION IN TIDAL FLAT

The sea water temperature in subtidal zone shows high frequency variation less than one day due to the advection of warm or cold water from the tidal flat. The water temperature in subtidal zone increase during midnight low water in spring and summer. Heat supply from the heated tidal flat by the strong solar radiation during previous midday low water increase water temperature at midnight low water. In this study, we constructed the one-dimension water temperature prediction model in order to understand the effect of the tidal flat on the water temperature change. The model result represents well the characteristics of observed water temperature. The model enable us to understand quantitatively the effect of the tidal flat on the changes of sea water temperature. Furthermore, the sea water temperature change with high frequency is mainly due to the heat exchange between tidal flats and sea water during the tidal inundation.

Kim, Y. B., Seoul National University, Seoul, Republic Of Korea, ykcho@chonnam.ac.kr

OBSERVATION OF TOPOGRAPHIC ROSSBY WAVES NEAR DOKDO OF THE ULLEUNG INTERPLAIN GAP

Deep flow variability is analyzed using moored current measurements over steep bottom slope near Dokdo of the eastern Ulleung Interplain Gap (UIG), a main passageway for the deep waters exchange between the Ulleung Basin and the Japan Basin in the East/Japan Sea. The observed currents below 300 m show dominant fluctuations at periods near 20 and 40 days and bottom-intensified vertical structure at both periods, which is reasonably consistent with the theory of linear topographic Rossby waves (TRWs). The TRWs found in UIG are characterized by short wavelengths of 17-30 km primarily due to the smallness of the buoyancy frequency below 300 m. Near 20-day periods, a close relationship is observed between upper warm events and deep current fluctuations: the latter are significantly enhanced when the former develop. This indicates local coupling between upper and deep layers over the sloping bottom topography. On the other hand, the 40-day deep current fluctuations appear to be related to the variability of remote winter wind-stress curl in the northern part of the East/Japan Sea from long-term current observation over 10 years.

INTERACTIONS BETWEEN TIDAL ASYMMETRIES IN VELOCITY, NEAR-BED STRATIFICATION, AND SEDIMENT RESUSPENSION IN AN ESTUARINE TURBIDITY MAXIMUM

Sugihara, S., University of Florida, Gainesville, USA, sugihara@hpl.umces.edu; Sanford, L. P., University of Maryland Center for Environmental Science, Cambridge, USA, lsanford@hpl.umces.edu
As part of the interdisciplinary Bio-Physical Interactions in Turbidity MAXIMA (BITMAXI) study, biogeochemical transport data were collected near the center of the estuarine turbidity maximum of upper Chesapeake Bay during 2007. Rapidly sampled time series of temperature, salinity, and turbidity were collected using a vertical array of data loggers. Rapidly sampled velocity profile time series were collected using a bottom mounted RDI ADCP in Mdel 12. The moorings were in place during several week-long research cruises, each of which included a daily-anchored anchor station adjacent to the moorings during which detailed measurements of suspended particle size and settling velocity were made. The data show relatively larger near bottom stratification during flood than ebb due to advection of the salt front. The combination of the estuarine circulation and tidal velocity also caused higher bottom shear stress and thus more resuspension during flood. However, the resuspended sediments were confined within 1 m above the bed due to the strong stratification, resulting in very high suspended sediment concentrations. Additions of suspended particle characteristics in relation to these factors will be reported.

ECOMAR: ECOSSYSTEMS OF THE MID-ATLANTIC RIDGE AT THE SUB-POLEAR FRONT AND CHARLIE-GIBBS FRACTURE ZONE

ECOMAR is a 2 million GBP project aimed at understanding how physical and biogeochemical factors influence the distributions and structure of deep-sea communities, focusing on the Mid-Atlantic Ridge at 4 sites. The RRS James Cook completed the first of three voyages planned under the NERC funded project in August 2007. Long term moorings were placed at four super stations at 2500m equipped with sediment traps, current meters and ADCPs. Video and still images of the sea floor were obtained during five camera vehicle tows and ninelander deployments. Faunal samples were taken with nine mega-core, seven bottom trawls, four baited traps and eight mid-water tow tows. Fifty-eight CTD casts investigated water masses and processes across the ridge and along a TOPEX-Poseidon satellite altimeter track. EK60 acoustic surveys quantified pelagic biomass and optical remote sensing measured primary productivity the position of the sub-polar front. Seabird and cetacean observations (visual and audio) were made throughout the voyage. The ECOMAR area will be revisited by the RRS Discovery in summer 2008 and the RRS James Cook with the Iis ROV in 2009.

WANTED, MOHAWK GUY AND HIS BAND OF NEogene PLANKTIC FORAMINIFER FRIENDS FOR GAMES AGAINST CALCAREOUS NANNOFOSILS AND OTHER PHYTOPLANKTON

The study of fossil foraminifera, single-celled microorganisms, from ocean sediments retrieved through scientific ocean drilling, has revealed important paleoceanographic events throughout Earth history. From these tiny creatures, scientists can learn about the ancient environment, past climate change, plate tectonic movements, changes in ocean productivity, circulation, and much more. In this presentation, two K-12 teachers will present their work with a University foram specialist to bring these bugs to life in real and exciting ways for their students. They will share the process of working together - educators and scientists - to move from initial concept to final lessons, testing with their students, and the ways they translated high level scientific concepts into engaging geological and biological activities. The presentation will include an introduction to the use of forum bio cards and lessons that incorporate these cards to help students learn how to read and understand authentic data. The research project, the scientist, and the foraminifer species have been personalized to help students make connections between the scientific process and the people who conduct scientific research.

THE INFLUENCE OF POLICY INDUCEMENTS AND EMBEDDED RELATIONS ON THE FORMATION AND OPERATIONS OF PARTNERSHIPS

Studies of partnerships in the education (and other policy domains) have found that strong embedded relationships and strategic needs among partner organizations increase the likelihood of successful formation and operations. However, policy inducements, in the form of program grants or regulation (for example, mandated testing), have not typically been a factor of analysis. This research builds upon and contributes to partnership research by examining the influence of policy inducements upon partnership formation and the implementation of programs aimed at improving the content knowledge in math and science for teachers and administrators. Of particular interest is whether partner responsiveness to policy inducements stimulates stronger commitments to partnership operations. This study uses a multi-case study comparative design to examine the Systemic Initiative program (SI) and the Math Science Partnership program (MSP) sponsored by the National Science Foundation. Each case traces the life cycle of each grant and the influence of the inter-organizational relationships on outcomes. This work will be discussed in relationship to partnerships such as the Centers for Ocean Sciences Education Excellence (COSEE) and the Integrated Ocean Observing System (IOOS).

ON THE FLOW OF SOUTH ATLANTIC WATER INTO THE NORTHERN HEMISPHERE

The transport of South Atlantic Water (SAW) into the northern hemisphere represents the warm upper branch of the Atlantic Meridional Overturning Circulation (MOC) and thus has a direct influence on the Atlantic heat budget. Three different mechanisms are known which are responsible for the import of South Atlantic Water into the North Atlantic: (i) transport by a surface current which follows the South American coast, (ii)
transport by rings that travel northwards along the coast, and (iii) transport by so-called Subtropical Gyre Cells in the general vicinity of the Florida Current. The second mechanism is investigated: The propagation and decay of North Brazil Current Rings. Results form direct hydrographic and velocity observations from ship surveys show the presence of North Brazil Current rings at 15°N near Guadeloupe. A high-resolution ocean model, namely the 1/12° FLAME model, is used to examine the northward propagation of NBC rings and their complex interaction with the Lesser Antilles. Together with calculations of the Caribbean inflow the MOC related flow near the Lesser Antilles is discussed and an estimate for the third transport mechanism (the subtropical cells in the interior Atlantic) is given.

GROSS PRODUCTION AND UNDERWATER NET COMMUNITY PRODUCTION MEASUREMENTS IN THE EQUATORIAL PACIFIC

Primary production in the equatorial Pacific is known for its importance to the worldwide carbon cycle and connections to climate conditions. Here we present data on gross primary productivity and net community productivity (NCP) determined by Δ¹⁸O and O₂/Ar ratios, respectively, both measured from the underway flow system onboard the R/V Kilo Moana. Δ¹⁸O was sampled twice daily while O₂/Ar were measured continuously using an onboard Meso Scale Mass Spectrometric system. As Ar is subject only to physical forcings, calibration can then be made to access biological O₂ supersaturation. Using estimates of gas exchange we were then able to constrain NCP and gross photosynthetic O₂ production between 2°N and 2°S. By these measures the central and western equatorial Pacific are comparable to other biologically saturated regions. An NCP of 80 mmol C m⁻² d⁻¹, varying circa 50% over the scale of 50 to 500 km. The biological production estimates made here are considered in relation to iron measurements and other factors that might be controlling biological production in this climatically important region.

INSTABILITIES IN BUOYANCY DRIVEN FLOW OVER A SUBMARINE DELTA

A series of oceanographic cruises was conducted during spring-summer of 2004-2005 along the Texas-Louisiana coast. Field measurements show evidence of large-amplitude, shelf-scale disturbances in the distribution of hydrographic properties across the shelf. These wave-like instabilities were also seen in satellite imagery (MODIS, SeaWifs) during the cruises as well as other times of the year. The position of the meander is consistent with the location of shoals, which are remnant subaqueous deltaic features along the Louisiana shelf. Large vertical displacements of isopycnals were observed during late summer in 2004 and summer 2005. ROMS (Regional Ocean Modeling System) was used to investigate the effect of shoaling topography on the transfer of buoyancy through the oceanic water column along the Louisiana shelf. The numerical experiment was conducted in an idealized coastal domain represented as a rectangular box. The domain is bounded by coastline on the northern side and the open ocean on eastern and western edges. The influence of bottom topography, coastal slope and freshwater input on the development of the dynamic instabilities was evaluated and compared with observations of physical and biochemical parameters.

PARTICULATE NUTRIENTS AND CALCIUM CARBONATE IN THE SUBARCTIC PACIFIC OCEAN.

The subarctic Pacific is a high-nutrients, low-Chlorophyll region, where changes in interannual macronutrient concentrations are small and nitrate levels are rarely limited. But some area in the subarctic Pacific and Bering Sea are estimated to support high primary production due to deeper winter mixing and closer proximity to the Asian iron supply. Here, we analyzed particulate nutrients, calcium carbonate and Chl-a to evaluate the contributions of diatoms and coccolithophorids to chlorophyll biomass during late summer in the subarctic Pacific and its eastern counterpart. We found that we were able to categorize some areas in the subarctic Pacific by concentrations of Chl-a, particulate nutrients and calcium carbonate. The particulate Si concentrations from the diatoms, are lower than that in the eastern subarctic Pacific. The inorganic carbonate concentrations in the western and central subarctic Pacific from coccolithophorids are higher than that in the eastern subarctic Pacific. In summer to early fall of 2005, the productivity of coccolithophorids in the subarctic Pacific is relatively higher than that of diatom productivity except in the eastern subarctic Pacific.

TURBULENT MIXING ASSOCIATED WITH INTERNAL TIDE IN SURUGA BAY
Internal tides in Suruga Bay are known to be amplified by the topographic effect. Observations using turbulent profiler and ADCP were performed to clarify relation between the internal tides and turbulent mixing. R.V Seiyu-Maru was anchored at the head of Suruga Bay (about 90m depth) and measurements of turbulence were carried out by using Turbomep (Alec Electronics Co.) at about 6 minutes interval from 16:00 on 06 July to 16:20 on 07 July, 2004. We also deployed a bottom mounted ADCP near the anchored station and obtained current data from 8m depth to the bottom at 2m interval in vertical every one minute. Observational data showed details of mixing process due to internal tides. Semidiurnal temperature fluctuation associated with strong bottom current was dominantly found throughout the water column and density overturns were frequently found in the bottom layer. Relatively large energy dissipation rate were found at high stratified regions. Turbulent diffusivity coefficents due to the internal tides were estimated to be 0.07-8.3X10^-4 (m²/s).

LARVAL DISPERSION OF THE JAPANESE SARDINE INCLUDING IMPACTS OF MEO- AND DECADAL-SCALE SST VARIATIONS

The spawning ground of the Japanese Sardine is in the Pacific waters of western and central Japan. Sardine eggs are transported by the Kuroshio, and reach the nursery ground in the Kuroshio/Oyashio mixed water region. A high-resolution ocean reanalysis data was used (ICOPE, 2003-2006, 1/12 degree and 2-day average) to trace the dispersion of larvae, and the survival rate was estimated considering optimum larval growth condition (13 to 19 degrees C). The model includes realistic meso-scale variability of the Kuroshio path and the associated SST variation. In addition, to implement the decadal SST variation of the high and low catch periods, we used the February SST anomaly of the ocean hind-cast data (OEFS 1950-1999, 1/10 degree, 1 month) of which the second EOF mode well correlates with the long-term changes of the Japanese Sardine mortality rate. The result suggests that the survival rate is high (low) when the Kuroshio takes a meander path (non-meander path) and high (low) during the cooling (warming) phase of the decadal SST change. Association of this SST EOF mode to the PDO is under investigation.

SEISMIC IMAGES AND PROPERTIES OF MEDITERRANEAN OUTFLOW WATER (MOW)

Seismic reflection data images boundaries between the water masses with different physical properties. Special imaging and inversion techniques are needed to quantify physical properties across the boundaries. A feasibility study of the MOW along a seismic reflection line without simultaneous hydrographic data and a hydrographic survey without simultaneous seismic data document that the quantification by inversion of the seismic data was limited due to an inaccurate starting model for the inversion procedure. During the European funded GO Project (www.dur.ac.uk/ego), seismic data as well as hydrographic data were recorded simultaneously. These contemporaneous measurements of the Laughon phase of the decadal SST change. Association of this SST EOF mode to the PDO is under investigation.

Continental shelf water mass distribution, transformations and off-shelf transport in a sea ice-ocean model of the Ross Sea, Antarctica

A mesoscale resolution (5 km) sea-ice shelf-ocean model (ROMS-CICE) is implemented to investigate Ross Sea (RS) shelf water mass budgets and dense water production and export. Daily atmospheric forcing is ECMWF ERA-40 except winds over Terra Nova Bay (TNB) are from automated weather stations (AWS). Net High Salinity Shelf Water (HSSW) production in TNB and RS polyna areas are 0.14 and 0.64 Sv over two years of simulation. Ross Ice Shelf (RIS) is a sink for about 0.4 Sv. Low Salinity Shelf Water (LSSW) outflow from beneath RIS cavity is 0.60 Sv. Modified Shelf Water (MSW)/Antarctic Bottom Water (AABW) is abundant over the entire shelf, forming the western anticyclonic cell. net off-shelf and Modified/Lower Circumpolar Deep Water net onshore transport are 2.23 and 0.7 Sv. Using AWS winds over TNB results in a substantial decrease in polyna sea ice production, wide scale dilution of HSSW in the western depressions, disruption of northward coastal HSSW transport, and causes overall decrease in vertically averaged transport on the western RS shelf.

CARBONIC ACID ACROSS THE PELAGIC SYSTEM AND ON FISHERY RECRUITMENT

Carbon stable isotope analysis was used to infer that pelagic organisms rearing in Prince Charles Mountains waters were affected at approximately 60 degrees north latitude that is separated from the adjacent Gulf of Alaska and Pacific Ocean by a deep (>200m) and broad (>100km) wide shelf, depend in part on organic carbon subsidies of oceanic origin. Pelagic organisms at certain times may consist of more than 50% oceanic carbon. Subsidy shifts in time were systemic and systematic; for example, a strong pulse in oceanic carbon subsidies was observed across a range of species but with differences among them. Herring consistently had the greatest dependence on oceanic subsidies. Inter-annual differences in oceanic subsidies measured in juvenile pink salmon may explain approximately half of the considerable inter-annual variability in marine survival rate that results in run size differences in the tens of millions. Oceanic subsidies suggest that coastal waters may receive seeding from offshore (e.g., larval stages), providing a mechanism for explaining regional long-term shifts in marine populations.
The effects of reduced ocean pH on the growth of non-calculifying organisms are poorly known. We studied the effects of seawater pH on growth in the kelp Alaria marginata. We grew gametophytes (spatuloid stages produced from the germination of spores) at ambient temperatures and low ambient daylight in filtered, raw seawater and in seawater acidified to pH 7.8 and 7.6 by the addition of HCl and by bubbling CO2 through the medium. We measured the length of gametophytes of A. marginata after 4 days and used this as a measure of individual growth rate. We found that gametophyte growth was significantly reduced at pH 7.8 and further reduced at pH 7.6 compared with growth in ambient seawater. Although both HCl- and CO2-acidified seawater negatively affected gametophyte growth, growth rates were more sensitive to acidification by CO2 bubbling than to acidification by addition of HCl. Our results are indicative of a general response of pH among non-calcified brown algae, substantial changes in primary production by marine macrophytes and in the structure and function of nearshore ecosystems can be expected with declining ocean pH.

PARTICLE DYNAMICS ASSOCIATED WITH PATHOGEN TRANSPORT IN COASTAL LAKE MICHIGAN

Since many pathogens associate with particles, the fate and transport of particles in the coastal zone is an important process in determining the health risk associated with pathogen inputs from storm water, CSOs and river plumes. We are utilizing sediment traps, large volume (>1000 L) filtrations of suspended particulates, and ROV collections of surface sediment to quantify sediment resuspension rates, particle settling rates and particle residence times in the nearshore waters of the Milwaukee Bay - a coastal region of Lake Michigan strongly influenced by the export of materials from the Milwaukee Harbor and its highly urbanized watershed. Activities of the naturally occurring radionuclides Be-7, Pb-210 and Cs-137 have been used to determine the time scales of particle movement. Samples were collected every ~3 weeks from early March through the end of October 2007 at 4 stations from the river mouth to open Lake Michigan, including off the major metropolitan swimming beach. Radionuclide data are being used to help validate the particle dynamics modeled with a fine grid, 3-dimensional hydrodynamic model of coastal currents, temperature fields and particle transport.

THE DYNAMICS OF NON-LINEAR TIDAL MIXING NEAR TOPOGRAPHY

Elevated mixing near deep-ocean topography appears relatively ubiquitous in the world's oceans. Until recently, the dynamics of this mixing have been opaque. Here we present observations from the Hawaiian Ridge and the continental shelf of the South China Sea and compare them to numerical modeling. The observations show that the near-bottom turbulence is driven by steeply non-linear internal tides that are breaking near the topography. The generated turbulence is orders of magnitude higher than that found just a few hundred meters above, is phase-locked to the internal tide, and shows a pronounced spring-neap cycle. The model demonstrates that these non-linear features originate from hydraulic phenomena where the topographic slopes change from super- to subcritical. The turbulence observed on the supercritical slopes also appears to be directly driven by the steepness of the topography.

THE FLUX AND ISOTOPIC COMPOSITION OF REDUCED AND TOTAL NITROGEN IN BERMUDA RAIN

The concentration and isotopic composition of total nitrogen (TN) was measured in precipitation samples collected at Bermuda between January and December 2000. By correcting for nitrate, analyzed previously, the concentration and d15N of "reduced" N (i.e., ammonium + organic N + RN) was also determined. The TN precipitation flux (~0.010 to 0.019 mol N 2-yr1) was twice the nitrate precipitation flux, and the mass-weighted annual average d15N of TN ~2.3 permil was higher than the d15N of nitrate in the same samples (~4.5 permil), indicating that RN has a d15N of -0.6 permil. While neither the concentration nor the flux of RN in precipitation showed statistically significant seasonal variation, the d15N of RN did, from -2.7 permil in the warm season to 1.5 permil in the cool season, similar to seasonal nitrate trends. The low d15N of the TN flux is similar to that of N2 fixation, and could explain a significant fraction of the previously documented minimum in nitrate d15N in the Sargasso Sea thermohaline, reducing the amount of N2 fixation needed to explain this isotopic feature.

HYDRODYNAMIC, FLUVIAL, ANDTECTONIC CONTROLS ON SEDIMENT DISPERSAL AND DEPOSITION ON THE WAIAPA RIVER SHELF, NEW ZEALAND

The Waiapa River drains a small, mountainous catchment composed of easily erodible materials, and delivers an estimated 35 MTy of sediment onto the adjacent, narrow continental shelf. Accumulation of these fluvial sediments on the shelf are influenced by a variety of little-understood processes that operate over a wide range of temporal scales including flood delivery, land use changes, and subsidence. To better understand these erosion margin processes, we used a 3-D numerical model to investigate sediment transport and depositional patterns under varying oceanographic conditions and sediment loads. Suspended sediment transport and escape from the proximal shelf increased with bed shear stresses due to wind-driven currents, but decreased with wave-induced bed shear stresses because these facilitated gravity-driven transport to deeper waters. Deformation practices have produced a 4- to 7-fold increase in fluvial delivery to the shelf within the last 50 years. As load increased, wave-supported gravity flux reached capacity, increasing deposition on the shelf. Coastal morphology and actual depositional patterns implied shelf sedimentation over century time-scales was largely constrained within a subsiding Quaternary basin associated with collision margin tectonics.

BEYOND STATUS AND TRENDS OF COASTAL CHEMICAL CONTAMINATION: APRAISED BY BIOMONITORING: ACHIEVEMENTS AND CHALLENGES

The French mussel-watch program collected its first bivalve in 1979, and has been monitoring the status and trends of contaminants along the coastline ever since. Spatial and temporal resolutions are high, and have been optimized according to costs and environmental behavior of contaminants. Monitored contaminants show local, regional and temporal variations. The usefulness of this near real time monitoring program is increased by unforeseen environmental applications. Indeed, the mussel tissue samples have been archived into a collection of well characterized marine coastal environmental records which remains available for research purposes until sample exhaustion. In this presentation, we show examples of reconstruction of contamination histories that are solely possible through reanalysis of this collection. Reconstructions range from organic contaminant fingerprinting to metal stable-isotope geochemistry. Despite this biomonitoring's inherent shortcomings, the time series prove invaluable to assess legislation for ecosystems protection. Paradoxically, unintended consequences of the implementation of EU-WFD jeopardize this record in terms of its very existence, quality and continuation.

THE NATIONAL OCEAN SCIENCES BOWL AS AN INTERSECTION OF OPPORTUNITIES FOR COLLABORATION

The National Ocean Sciences Bowl (NOSB) is an academic competition for high school students. Regional NOSB competitions bring together ocean scientists from multiple institutions, agencies, and businesses with informal educators, graduate and undergraduates, and high school teachers and students for the day of the competition. The Rhode Island and Connecticut Regional Competition (Quahog Bowl), held for a decade at the University of Rhode Island, has developed a large network of partners and institutions. This presentation highlights the diversity and commitment of volunteer participants involved in the NOSB each year. There are great opportunities for networking, making connections, and for interaction with high school educators and students. However, there are also many opportunities to interact and work with the NOSB network that forms around the Regional and National Competitions throughout the year. Ocean science education programs can interact with the NOSB community in several ways, reaching new partners and a large ocean science education audience. This presentation discusses two projects that the authors have integrated into the Quahog Bowl and the NOSB over the last 5 years.

incerely are used to further examine the hydrodynamics, the bottom boundary layer processes, between fluid mud layers on the shoal during fair weather; sediment is then re-suspended, resulted in substantial changes in the fabric of bottom sediments ranging from variations interactions with bottom sediments over the heterogeneous transgressive deposit. This wind, and thus, wave conditions, created unique bottom boundary layer processes and material (fine sand) to silts and clays. The results of oceanographic deployments on the grained materials. Occasional dispersal of fine-grained sediments (silts and clays) from the with the local hydrodynamics in response to the deposition of fluvially-derived fine-
Bottom sediments on Ship Shoal, a transgressive sand body, interact in a complex way a Kuroshio, and with Kuroshio stratification but no Kuroshio current. The results are used generation and the particle amplitude of IWs. To better understand the influence of the Kuroshio on the IW genera-
ated with the Kuroshio also play an important role in modulating the generation and the amplitude of IWs. To better understand the influence of the Kuroshio on the IW gener-
a, a coupled ocean Nowcast/Forecast System (ONFS) is being used for the study. The NRL ONFS is implemented using a nested grid system. The larger grid which covers the East Asian Seas provides boundary conditions for a higher-resolution grid covering Luzon Strait and northern SCS. Tidal forcing is applied at the open boundary of the high-resolu-
tion domain. Temperature and salinity analyses generated from satellite altimeter and MCST data are assimilated into model to produce a realistic stratification with Kuroshio. Applying the NRL ONFS, numerical experiments are conducted with a Kuroshio, without a Kuroshio, and with Kuroshio stratification but no Kuroshio current. The results are used to interpret the influence of the Kuroshio on the generation of IWs in SCS.

DYNAMICS OF SEDIMENTS WITHIN THE BOTTOM BOUNDARY LAYER OVER A TRANSFRINGE SHOAL INFLUENCED BY FLUVIAL SEDIMENTS AND WINTER STORMS: SOUTH-CENTRAL LOUISIANA
Bottom sediments on Ship Shoal, a transgressive sand body, interact in a complex way with the local hydrodynamics in response to the deposition of fluvially-derived fine-ground materials. Occasional dispersal of fine-grounded sediments (silts and clays) from the Mississippi River on post-frontal northerly winds regimes in concert with river discharge, results in the textural shift of shoal bottom sediments from coarser-grounded material (fine sand) to silts and clays. The results of oceanographic deployments on the eastern flank of the shoal during spring 2006 show that the directionality of the storm-
wind, and thus, wave conditions, created unique bottom boundary layer processes and interactions with bottom sediments over the heterogeneous transgressive deposit. This resulted in substantial changes in the fabric of bottom sediments ranging from variations between fluid mud layers on the shoal during fair weather; sediment is then re-suspended, transported and re-distributed during pre-frontal and post-frontal phases. The results of additional instrument deployments scheduled for fall 2007 and ongoing numerical model-
ing are used to further examine the hydrodynamics, the bottom boundary layer processes, and associated sediment transport processes during winter storms.

WATER EXCHANGE CONTROLLED BY MIXING PROCESS AT THE MOUTH OF TOKYO BAY
We have conducted a series of field campaigns to observe mixing processes at the mouth of Tokyo Bay. A microstructure profiler (TurboM Map) was deployed to measure the intensity of turbulence. A tidal current at a different phase of tide creates a different level of water exchange through the bay mouth. Our field campaigns were made over several different tidal phases that include ebb tide and spring tide. We present the observed mixing conditions from these experiments. In order to investigate the hydrography of Tokyo Bay, we make use of a three-dimensional hydrodynamic model (GETM) that consists a single water column public domain turbulence model (GOTM). As a Lagrangian approach, following passive particles in the bay are followed to investigate water exchange rate. We present how the tidal forcing condition affects the water exchange based on both the model results and observed data.

DIGITAL SEAGRASS IMAGING MAPPING IMAGERY REVEALS KARST FEATURES AND NATURAL REEFS OF THE SPRINGS COAST REGION OF FLORIDA
This project used the Intergraph Digital Mapping Camera (DMC) to acquire high resolution imagery of seagrass beds within Florida's Springs Coast region of Florida for the first time. Although earlier aerial mapping surveys focused only on the shallow intertidal seagrasses of this region, limited data have been collected for the offshore seagrasses. Mapping projects in the 1980s and 1990s primarily relied on transect data collected over this extensive region. This paper will present the preliminary results and challenges of the 2007 mapping project. For example, the deep water seagrass edge was captured in the imagery for the southern half of the project area; however, the edge extended beyond the imagery in the northern half. Interpretation of offshore seagrass density has been challenging due to the intricacy of the beds associated with the meandering karst features and varying bottom substrates. Although seagrass coverage is the main focus of the project, digital imagery has provided new information on karst features, reefs, and rock outcrops of this little studied region. The most impressive finding is a large cluster of small reefs (< 1 ha, 2 acres) located approximately 13 km (8 miles) off the coast of northern Hernando County. This cluster of small reefs is concentrated within an 80 ha (200 acres) area. These findings indicate a larger area of natural reefs and greater diversity of benthic strata in this region of the Springs Coast than historically reported.

EFFECTS OF OCEAN ACIDIFICATION ON PHOTSYNTHETIC PROPERTIES OF MARINE PHYTOPLANKTON
By absorbing excess of anthropogenically-produced CO2, the pH in the upper ocean will decrease by up to 0.8 units within the next 300 years, possibly affecting a variety of biologically important processes such as calcification, metal speciation, and silicic solubility. Changes in ocean's pH may also modify the redox potential of photosynthetic and respiratory electron carriers, directly affecting a range of biophysical processes involved in photosynthesis, carbon assimilation, and respiration. We have grown selected species of phytoplankton and the natural phytoplankton assemblage in laboratory conditions from these experiments, sampling every two months from May through October. Cell numbers ranged from zero to a maximum of approximately 6000 cells/L, resulting in only a few shellfishery closures due to PSP. These data contrast with a 2006 study yielding much higher A. catenella cell numbers (over 50,000 cells/L at one station) and widespread closures of shellfish harvesting. Tracking catenella cell numbers at different phases of day to understand the mechanisms of blooms dynamics could serve as a useful tool for providing early warning of PSP toxicity. Integrating quantification of A. catenella cell number into existing PSP monitoring efforts may guide shellfisheries and public health agencies in their monitoring efforts.

INVASION POTENTIAL OF THE NEW ZEALAND MUD SNAIL IN LAKE TAHOE AND THE LOWER TRUCKEE RIVER (USA)
The New Zealand Mud Snail (Potamopyrgus antipodarum) is a relatively new invader in the United States. Our objective was to determine the susceptibility of the Truckee River and Lake Tahoe to an invasion by measuring survivorship and growth rates in laboratory mesocosm experiments. One experiment was conducted for each system with three treatments: (1) A high population density treatment, (2) a low population density treatment and (3) a control with no snails. All treatments included rocks with natural periphyton from the respective system. Experiments lasted for 14 days with fresh water was brought in from the respective system every three days. Snail survivorship and growth was positive but varied across ecosystems (Lake Tahoe: 5-40% with an increase in body mass in the low density treatment but a decrease in body mass in the high density treatment; Truckee River: 50-85% with a 99% increase in body mass). In order to determine if there was an influence of UV-light on the snails we conducted a separate experiment and the results of that experiment suggest that the snails do have an aversion to UV-light.

DEEP OCEAN INERTIA-GRAVITY WAVES SIMULATED IN A HIGH-RESOLUTION GLOBAL COUPLED ATMOSPHERE-OCEAN GCM
A high-resolution global coupled atmosphere-ocean simulation is carried out to investigate the deep ocean inertia-gravity waves. Large (k = 10^{-3} m^{-1}) root-mean-square vertical velocity is found in middepths. Horizontal distribution of large variability roughly corresponds to the wintertime atmospheric storm tracks and is stretched equatorward due to β-dispersion in open ocean with some “shadow regions” behind the obstacles. Frequency spectrum of vertical velocity has strong peaks at around f and 2f (f is equatorward due to β-dispersion in open ocean with some “shadow regions” behind the obstacles. Frequency spectrum of vertical velocity has strong peaks at around f and 2f (f is
examine the effects of carbon dioxide-induced pH changes on larvae, we exposed Lottia digitalis trochophores to CO2 manipulated seawater at pH 7.8, 7.6, and 7.4. We examined the resulting mortality, protoconch dimensions and overall appearance, and larval behavior. With increasing acidification, we saw significantly increased mortality, a higher incidence of malformed protoconch and behavioral differences. Some snails were malformed at lower pH. These results suggest that molluscs larvae may be particularly sensitive to ocean acidification with the potential to seriously affect their population dynamics.

ASSESSMENT OF GROUNDWATER - SURFACE WATER INTERACTION IN TSUNAMI AFFECTED AREAS

On December 26, 2004 the devastating tsunami waves cause terrible humanitarian disaster affecting thousands of kilometers of coastal belt of the Indian Ocean in SE Asia. Many coastal wetlands get affected by the large inflow of salt seawater and littoral sediment deposition during the tsunami. The longer-term effects of changes in their hydrology caused by changes to coastlines and damage to sea-defenses. Many water quality and associated problems generated by tsunami and influencing coastal environments are related to past and on-going contamination of terrestrial groundwater because this ground water is now seeping out along shorelines affected by tsunami. For example, chronic inputs of fertilizers and sewage on land over several decades has resulted in higher groundwater nitrogen which, because of slow yet persistent discharge along the coast, eventually results in coastal marine eutrophication. Such inputs contribute to the increased occurrences of coastal hypoxia, nuisance algal blooms, and associated ecosystem consequences, and significantly accelerated by tsunami as well as increasing of magnitude of saltwater intrusion. Tsunami creates an accelerating process of salt water intrusion and fresh water contaminations in affected regions that requires a drastic remediation measures. These measures be to economically feasible, environmentally sound and socially acceptable.

CENSUS OF THE THERMOHALINE ANOMALIES PROPAGATED THROUGH THE NORTIC SEAS DERIVED FROM HISTORICAL DATA 1896-2006

The thermohaline characteristics of the Atlantic water (AW) entering the Nordic Seas (NS) and flowing northward to the Eurasian Arctic are considerably modified along pathway by interacting with the atmosphere and mixing with surrounding waters. The degree of modification depends on atmospheric forcing or upper layer stratification, which determines the ratio between horizontal and vertical exchange of properties. The NS oceanographic database for 1900-2006 and objectively analyzed monthly fields were used to study the temporal-spatial pattern of large-scale temperature, salinity and density anomalies advected northward. The anomalies show event-like behavior with different duration, magnitude and penetration depth depending on upper stratification with generally colder and fresher upper layer condition after the Great Salinity Anomaly propagation. Two different regimes are obvious from the observations with weakened/enhanced downward heat/salt fluxes. Abnormal AW properties were set since the late 1990s with a more intense downwelling event in 2006, which is consistent with the increased salinity in the New Nordic Sea and in the Norwegian Sea.

A SPACEBORNE ASSESSMENT OF RIVERINE DOC FLUX INTO THE KARA SEA

The Siberian high-flowing Siberian Rivers like Oben, Yenisei, and Lena are thought to be playing an important role in terms of determining the income of carbon into the Arctic Ocean. We have undertaken a pilot satellite-based assessment of carbon flux into the Kara Sea from the Ob River. Inasmuch as the targeted waters are case II waters, we had to develop a special advanced operational algorithm (A0A) to process spaceborne data. The AOA simultaneously retrieves the concentrations of phytoplankton chl, suspended minerals (um) and dissolved carbon (doc) in the Kara Sea and in the estuary of the Ob River. Based on the surface concentrations of doc in the estuary obtained from MODIS as well as on CTD in situ data on the thermocline/ halocline depth, the doc flux into the Kara Sea was assessed. Assessed through the developed methodology, the mean annual carbon flux proved to be 4.8 ± 1012 gC/yr. This estimation is consistent with the in situ data reported in the literature (ca 3.2 ± 1012 gC/Yr). Thus, the developed bio- optical retrieval algorithm and methodological approach can be transferred to other marine and oceanic regions for operational assessment of riverine DOC fluxes.

HYDROLOGIC AND BIOGEOCHEMICAL STORM RESPONSE IN CHOPTANK BASIN HEADWATERS

During brief storm events, headwater streams transport large quantities of nutrients and sediment to estuaries, contributing to eutrophication. During 2006-07, we measured N, P and seston response at seven agriculturally dominated basins (1-26 km2) with 15-64% hydric soils, capturing 17 out of 30 storms during this period. For these storms, 3-53% of rainfall was discharged as stormflow. Nitrate and conductivity were depressed during storms while phosphate and seston peaked. When plotted against discharge, N exhibited a clockwise loop whereas P exhibited a counterclockwise loop. The volume-weighted mean of phosphate is a positive function of stormflow (r2 = 0.98). In contrast, the volume-weighted mean of nitrate is an inverse exponential function of stormflow (r2 = 0.92), decreasing from baseline nitrate (~200 um) to concentrations approaching twice that of rainfall nitrate (68 uM). Because phosphorus transport is disproportionately weighted towards brief intervals of storm runoff, it is particularly important to measure the P response during events to improve estimates of downstream P loading.

Korotin, T. S., University of California Santa Barbara, Santa Barbara, USA, tskohtech@icb.csc.ucsb.edu

STORM RESPONSE AT SEVEN AGRICULTURALLY DOMINATED BASINS (1-26 km2) WITH 15-64% NITRATE AND CONDUCTIVITY ARE DEPRESSED DURING STORMS WHILE PHOSPHATE AND SESTON PEAKED. WHEN PLOTTED AGAINST DISCHARGE, N EXHIBITED A CLOCKWISE LOOP WHEREAS P EXHIBITED A COUNTERCLOCKWISE LOOP. THE VOLUME-WEIGHTED MEAN OF PHOSPHATE IS A POSITIVE FUNCTION OF STORMFLOW (R2 = 0.98). IN CONTRAST, THE VOLUME-WEIGHTED MEAN OF NITRATE IS AN INVERSE EXPONENTIAL FUNCTION OF STORMFLOW (R2 = 0.92), DECREASING FROM BASEFLOW NITRATE (~200 UM) TO CONCENTRATIONS APPROACHING TWICE THAT OF RAINFALL NITRATE (68 UM). BECAUSE PHOSPHORUS TRANSPORT IS DISPROPORTIONATELY WEIGHTED TOWARDS BRIEF INTERVALS OF STORM RUNOFF, IT IS PARTICULARLY IMPORTANT TO MEASURE THE P RESPONSE DURING EVENTS TO IMPROVE ESTIMATES OF DOWNSTREAM P LOADING.
utilization increased from 300m to the bottom with a maximum of 2μmol/kg around 500m. Not only the property changes but also the volume flux estimated by an inverse method suggests a slow down of the deep meridional circulation. The meridional heat flux across the line is also estimated using the long term hydrography across the Kuroshio in the Okinawa Trough as well as the P3 data. The variation of the Kuroshio temperature transport agrees with the heat flux variation across the line independently estimated from the atmospheric reanalysis data and heat content change in the North Pacific.

COASTAL HYCOM MODELING IN SOUTH FLORIDA: EVALUATION OF GODAE BOUNDARY CONDITIONS, RESOLUTION AND FORCING

The South Florida (SoFLA) HYCOM (1/25 degree) and the embedded, high resolution Florida Keys (FREKSYS) HYCOM (1/100 degree) encompass a variety of coastal processes. The broad Southwest Florida shelf, the narrow Florida Keys and Southeast Florida shelf, the shallow Florida Bay and Biscayne Bay and deep regions (the Straits of Florida), including Marine Protected Areas. The presence of the strong Loop Current/Florida Current system and associated eddies connects the local and basin-wide dynamics. Different strategies of nesting to HYCOM GODAE products are evaluated, along with sensitivity to model resolution and atmospheric forcing. Simulations with boundary conditions from a regional data assimilative Gulf of Mexico model improve nested model performance along the narrow Keys shelf. Atmospheric and river forcing are important on the SW Florida shelf. Boundary conditions from the basin-wide North Atlantic HYCOM are essential in capturing Florida Current fluctuations. High resolution in FREKSYS enhances the submesoscale eddy field and the interactions between coastal and large scale flows, an essential aspect of predicting impacts of salinity changes under the Everglades Restoration Project on the fragile Florida Keys National Marine Sanctuary ecosystem.

TEMPORAL DISTRIBUTION OF BRACHYURAN CRAB LARVAE DURING A TIDAL CYCLE IN A SMALL ESTUARY IN PUERTO RICO

Semiterrestrial brachyuran crabs synchronize larval release with lunar, tidal and light-dark cycles. The influence of adult morphology to adult's tidal release pattern. The purpose of this study is to describe the volume of zoea and megalopa in a small estuary in Puerto Rico during a tidal cycle. It is expected that more larvae will be found during the night as tides goes into the estuaries. A 24 hour sampling was done in June, 2007 during full moon. Sampling was conducted with two stationary stream drift nets placed at the mouth of Roquillas Creek, Manati Puerto Rico. Water was filtered for 45 minutes every hour and volume was measured with a flow meter attached to one of the nets. Results show that density of zoea was higher during the day and lower during the night and that the density of megalopa was higher during the night and lower during the day. Tide was coming into the estuary during the night and out the estuary during the day. Identification of the larva is still ongoing. The results of this study will increase the knowledge of the life cycle of semiterrestrial brachyuran crabs which is necessary for conservation and management of these crabs/species.

INVESTIGATING TSUNAMI WAVE SCATTERING AND ENHANCEMENT USING ENERGY FLUXES

In the wake of Kuril Island tsunami of Nov., 2006, the sea level at Crescent City (CC) initially surged up to 20 cm and 2-3 hours later the highest wave of about 90 cm was recorded. Numerical experiments identified bathymetric features which scatter the tsunami wave. Results show that density of zoea was higher during the day and lower during the night and that the density of megalopa was higher during the night and lower during the day. Tide was coming into the estuary during the night and out the estuary during the day. Identification of the larva is still ongoing. The results of this study will increase the knowledge of the life cycle of semiterrestrial brachyuran crabs which is necessary for conservation and management of these crabs/species.

PIGMENT DERIVED PHYTOPLANKTON COMPOSITION ALONG THE WESTERN ANTARCTIC PENINSULA

Current bio-optical models for remote sensing of chlorophyll a are sensitive to changes in specific absorption. Variability in phytoplankton composition is tied to changes in spectral absorption; our ability to follow these changes would be enhanced by a better understanding of community composition. Examined in this study was a thirteen year span (1995-2007) of high-performance liquid chromatography (HPLC) pigments collected as part of the Palmer Long Term Ecological Research project. Phytoplankton composition was estimated using CHEMTAX analysis software, and presented here is the temporal and spatial distribution of those assemblages in surface (50% F_s) and deep euphotic zone (1% F_s) waters. Contribution to total chlorophyll a biomass and population assemblage dynamics are described. Temporal distribution of groups is discussed in terms of anomalies calculated as yearly differences from climatological means. Variability in space and time is examined using principle component analysis, and possible relationships between seasonal sea ice and phytoplankton composition, as well as phytoplankton composition and primary production are discussed. This work will provide a basis for development of a link between optics and taxonomic groups in the Bellingshausen Sea.

GEOMORPHIC CHANGES OF FINE-GRAINED SEDIMENTARY FURROWS: INSIGHT INTO SEDIMENT TRANSPORT AND DEPOSITION IN THE YORK RIVER ESTUARY

Sedimentary furrows, often seen as narrow longitudinal depressions in fine-grained sediments, have been identified in various geological settings worldwide from continental shelves to estuarine systems. Recent studies have shown that these rectilinear bedforms form parallel to the dominant direction of flow and may be initially created by helical circular circulation located at the sediment-water interface. Hourly changes of furrow morphology were monitored to determine the amount of sediment flux and transport occurring within the York River estuary. Several acoustic and geological data sets from the York River, including roulette and sidescan sonar, sediment cores, CHIRP, and multibeam bathymetry, were used to ascertain the short-term spatial and temporal patterns of these furrows in order to determine their responses to physical forcings. The rotary sonar, scanning at quarter-hour intervals, was used to investigate the seabed, allowing diurnal tidal variations to be captured. By studying furrow morphology, we were able to gain insight on the scale and processes affecting redeposition and sedimentation, as well as assess the possible relationships to underlying stratigraphy and how rapidly these features are mobilized in fine-grained estuarine environments.

DISTRIBUTIONS OF MERCURY AND METHYLMERCURY IN THE NORTH PACIFIC OCEAN

Fish harvested from the Pacific Ocean are a major contributor to population-wide mercury (Hg) exposure in the U.S. However, limited oceanic Hg data, particularly methylmercury (MeHg), has confounded our understanding of linkages between sources, methylation and attenuation, and the fate and transport of Hg in the ocean. Monitoring Hg in the coastal and open ocean is important for understanding Hg cycling and for evaluating the effects of oceanographic processes on Hg transport. The purpose of this study is to describe the volume of zoea and megalopa in a small estuary in Puerto Rico during a tidal cycle. It is expected that more larvae will be found during the night as tides goes into the estuaries. A 24 hour sampling was done in June, 2007 during full moon. Sampling was conducted with two stationary stream drift nets placed at the mouth of Roquillas Creek, Manati Puerto Rico. Water was filtered for 45 minutes every hour and volume was measured with a flow meter attached to one of the nets. Results show that density of zoea was higher during the day and lower during the night and that the density of megalopa was higher during the night and lower during the day. Tide was coming into the estuary during the night and out the estuary during the day. Identification of the larva is still ongoing. The results of this study will increase the knowledge of the life cycle of semiterrestrial brachyuran crabs which is necessary for conservation and management of these crabs/species.
Formation of mode waters is concomitant with the spring bloom in two different regions of the Atlantic. The timing of mode water formation versus the timing of the spring bloom is of primary importance.

**MODE WATER SUBDUCTION: AN EFFICIENT CARBON PUMP IN THE NORTH ATLANTIC.**

Memery, L.
Levy, M.
Kremeur, A. S.

Later in the season, EPS both contribute significantly to and, by influencing attachment/de-attachment, are left behind in the ice after algae are exported to the water column. We present compelling evidence for the role of EPS networks in the attachment and detachment of ice-algal biomass from sea ice.

**ATTACHMENT AND DETACHMENT OF ICE-ALGAL BIOMASS FROM SEA ICE.**

Juhl, A.

If integrated biogenic silica is decreasing with time at the BATS site, while the opposite is true at the GA site, statistically significant 15-year linear decrease in integrated biogenic silica (p<0.001 that slope = 0). During the same period there are increases in integrated particulate organic carbon and nitrogen, chlorophyll biomass (primarily fall and winter biomass), primary production, the abundances of dinoflagellates and prasinophytes in the upper 200 m, and in nutrient flux to 200 m. However, there is no discernable linear trend in organic matter flux to 300 m. If integrated biogenic silica is decreasing with time at the BATS site, while the opposite is occurring for other autotrophic groups, the resulting shift in phytoplankton community composition could potentially be altering the efficiency of organic matter export in the Sargasso Sea by reducing the role of diatoms in this system.

**EXOPOLYMERIC SUBSTANCES, AN IMPORTANT COMPONENT IN THE ATTACHMENT AND DETACHMENT OF ICE-ALGAL BIOMASS FROM SEA ICE.**

Biomass of sea-ice algae is generally highest in the lowermost centimeters of sea ice, the region where the microscopic habitat structure continuously re-adjusts in response to physical fluxes of heat and solutes. Mechanisms of attachment in such a fluctuating habitat play a key role in the successful colonization of sea ice by algae and other microbes, as well as in the timing of organic export fluxes from the ice to the water column. We show that significant concentrations of exopolymorphic substances (EPS) are always present in sea ice, including during freeze-up, and are therefore continuously available for microbial attachment. We present compelling evidence for the role of EPS networks in the attachment of sea-ice algae during colonization processes. A large pool of these exopolymetric networks and organic material are left behind in the ice after algae are exported to the water column. EPS both contribute significantly to and, by influencing attachment/de-attachment, play a critical role in regulating the organic export from sea ice.

**VERTICAL DISTRIBUTION OF DISSOLVED OXYGEN AND NUTRIENTS IN THE EASTERN MEDITERRANEAN.**

Gertman, I.
Kress, N.
Kress, N.

During the 1990s, influx of dense waters from the Aegean Sea, the East Mediterranean Transient (EMT), changed the deep water circulation in the Eastern Mediterranean and the vertical distribution of its physico-chemical properties. Since 2002, seasonal oceanographic surveys are performed in the easternmost part of the Levantine basin along a 50 mile transect from Israel westwards. While in 1991 there was no evidence of the EMT in the Levantine basin; prior to the EMT two minimum-nutrient layers were present: one at mid depths since 2002 this exists even at the station located 16 miles from shore. Oxygen was decreasing and nutrients decreased towards the bottom. The vertical distribution remained the same between 2002-2006. Only in 2007, more than 10 years after the EMT relaxed, there was a shallowing of the oxygen minimum/nutrient maximum layer to ca. 400m bringing water rich in nutrient closer to the photic zone. Deep winter mixing and mesoscale features may transport these nutrients to the photic zone and induce changes in productivity in this ultra-oligotrophic area.

**TESTING THE APPARENT TSUNAMIGENIC ORIGIN OF 2300 YEAR OLD HIGH ENERGY DEPOSITS FROM LONG ISLAND, NY.**

Vibracores and shallow seismic surveys of Great South Bay backbarrier lagoon reveal a variable but distinct sedimentary deposit, attributable to a high-energy source. These results, together with emerging evidence from other parts of the New York and New Jersey coasts, strongly suggest that a large tsunami struck the area 2300 yBP.

**FACtORS DETERMINING GROWTH AND SURvIVAL IN EARLY LIFE STAGES OF Cods from the North Atlantic.**

Growth and survival in the early life stages of cod are known to be affected by environmental conditions. In particular, variations in temperature and light strongly impact the
growth and feeding conditions for larval cod, creating differential survival conditions between years and between habitats. We compared the latitudinal extreme nursery grounds of larval cod on Georges Bank (42°N) in the Northwest Atlantic and Lofoten (68°N) off the coast of Norway. We applied an individual-based model (IBM) to simulate larval cod growth and survival within each nursery ground for five years. The model is forced with light, idealized prey fields, and temperatures at selected locations for selected years during the spawning season. We then analyzed the results for differences between and within ecosystems. Using our estimated larval cod growth rates from this model, we also quantified the relative roles of environmental variables and feeding environments at the Georges Bank and Lofoten sites and their relationship to field observations.

NITROGEN TRANSFORMATIONS IN SUBMARINE GROUNDWATER DISCHARGE ZONES: INSIGHTS FROM ISOTOPE PAIRING EXPERIMENTS

We are investigating nitrogen transformations and other biogeochemical processes associated with mixing of water masses within the near-shore aquifer and subterranean estuary of Waquoit Bay, Massachusetts. Where nitrate and ammonium co-occur in field settings, concentration and nutrient enrichment that is coupled to the temporal and spatial distribution of N stable isotopic data suggest substantial loss of both species through a fractionating process. Laboratory experiments employing modified isotope pairing techniques confirm N loss with mixing of nitrate and ammonium-bearing waters and suggest that loss is primarily due to denitrification, possibly coupled to oxidation of Fe(II), with minor occurrence of an anammox-type process. Other concurrent processes include: N reduction, substantial production or release of organic N, apparent ad/desorption of ammonium, and desorption or production of nitrate. Our results suggest that N is actively cycled in nearshore portions of coastal aquifers and that we need to consider a wide range of concurrent transformation pathways in submarine groundwater discharge zones. Such transformations have the potential to modify the composition of chemical species carried by SGD. Carbohydrate isotope pairing experiments are being conducted in flow-through sediment columns to simulate groundwater flow through coastal aquifer sediments.

DIFFERENT PHOTOPROTECTION AND REPAIR STRATEGIES HELP EXPLAIN SOURCES OF OCEAN-EVOLVED PLANKTON SPECIES DISTRIBUTION

Distributions of diatoms and the haptophyte Phaeocystis antarctica, correlate well with mixed layer dynamics in the Ross Sea, Antarctica, suggesting that the patterns and intensity of light available to phytoplankton may ultimately determine taxonomic composition. Differences in carbon uptake efficiency (P. antarctica takes up more than twice as much CO2 per unit PO4 than diatoms) highlight the possibility that carbon uptake dynamics is this region is not only influenced by changes in seasonal primary production, but also by the role of light in controlling species distribution using cultures of P. antarctica and the diatom, Fragilariopsis gryrius grown under two simulated mixing conditions characteristic of the Ross Sea. Fluorescence properties, photosynthetic rates, xanthophyll cycle pigment concentrations, and D1 concentration were measured in the presence and absence of lincomycin and dithiorthanol (DTT) to assess the relative importance of photoprotection and photorepair mechanisms. Results show that P. antarctica exhibits greater sensitivity than F. gryrius to lincomycin but is less sensitivity to DTT. These results suggest that P. antarctica thrives in a low and variable light environment by maximizing photosynthesis under all conditions while incurring and constantly repairing photodamage. Conversely, F. gryrius relies primarily on xanthophyll cycle-mediated photoprotection allowing this species to thrive in high, constant light conditions.

DO BIOPHYSICAL COUPLING MODELS PREDICT CARIBBEAN POPULATION CONNECTIVITY? A TEST WITH SIX GASTROPOD SPECIES THAT VARY IN DISPERSAL POTENTIAL

Biophysical coupling models have made clear predictions about gene flow, source biogeographic patterns, and dispersal pathways; however, confirming model predictions. The complex phylogeography of our focal taxa is not readily explainable by oceanographic circulation; patterns of extinction, migration and re-colonization may thus be highly idiosyncratic, even among similar species.

DESIGNING A "REEF-SAFE" SLOW RELEASE FERTILIZER FOR MANGROVE RESTORATION PROJECTS

In the waterlogged environment of mangrove ecosystems, one of the most difficult challenges young mangrove seedlings have to surmount is lack of nutrients. In order to overcome this problem, restoration efforts generally use slow release fertilizers added when planting propagules on restoration sites. However, waves, tides, and other physical forcings often cause these fertilizers to release too quickly, or wash away. We introduce and demonstrate the effectiveness of a new technique using slow release discs to encapulate fertilizer which releases slowly in a targeted fashion directly to the roots of the young mangrove tree. This novel slow-release fertilizer provides ample nutrients for young mangrove trees while reducing the risk of excess fertilizer introduction into sensitive coastal ecosystems such as coral reefs.

HYBRIDISATION OF DATA ASSIMILATION METHODS FOR APPLICATIONS IN OCEANOGRAPHY

A data assimilation method based on variational approach is presented. The novelty of the hybrid method consists in a coupling of the cost function of the variational approach with an optimal linear smoother issued from the singular evolved extended Kalman filter (SEEK). The background error covariance matrix of the usual variational framework remains unchanged. In the hybrid method, however, at each transition between the assimilation windows, it is replaced with the one provided by the smoother. The latter is updated whenever new background states are produced. It can be shown that the background states issued from an appropriately constructed variational framework and some particular optimal linear smoother are mathematically equivalent. Hence the matrix injection into the cost function is done in a consistent manner. The hybrid method has been implemented in a shallow water model which mimics a double-gyre circulation in the North Atlantic. Realistic OSSEs have been performed. Comparisons illustrate superiority of the 4D-Var-smoother hybrid over an ordinary 4D-Var on the one hand and on the other over the 4D-Var-filter hybrid.

IMPLEMENTATION OF GEOHAB CORE RESEARCH PROJECT--HARMFUL ALGAL BLOOMS IN UPWELLING SYSTEMS

The GEOHAB report on HABs in Upwelling Systems (GEOHAB, 2005) specified that GEOHAB would form a Subcommittee for the Upwelling Core Research Project, to work with scientists to ensure coordination of research using the same measurement protocols, sharing data, and contributing to model development. Four major eastern boundary current upwelling systems are represented—the Benguela, Iberian, California, and Humboldt Current—although other systems can be added. The Subcommittee developed 6 potential research projects as a priority for comparative studies including: 1. Effects of nutrients on HAB population dynamics in upwelling systems, 2. Climate and HABs in upwelling systems, 3. Genetic comparisons of HABs in upwelling systems, 4. Coastal morphology and its influence on HABs in upwelling systems, 5. Seeding strategies within upwelling systems and 6. The role of across-shelf and alongshore currents in the transport of HABs in upwelling systems. This presentation will provide an overview and rationale for the programme, and an update on progress towards a collaborative, comparative analysis of these major themes. GEOHAB 2005, Global Ecology and Oceanography of Harmful Algal Blooms, GEOHAB Core Research Project: HABs in Upwelling Systems. G. Pitcher, T. Moita, V. Trainer, R. Kudela, P. Figueiras, T. Probyn (Eds.) IOC an SCOR, Paris and Baltimore. 82 pp.
we derive coupled equations governing the vertical profiles of mean wind speed and turbulent stress, the wave height spectrum, and the length distribution of breaking wave crests. Analytic solutions are obtained for limiting cases when breaking waves support all wind stress. Numerical solutions are obtained for the full problem. The solutions indicate that breaking waves may contribute significantly to the total air-sea momentum flux. The breaking wave contribution increases for stronger, strongly forced wind waves. The model provides a new framework to estimate the air-sea momentum flux over complex surface wave fields, such as those under tropical cyclones.

GRAVITY CURRENT MIXING IN SHALLOW, WIND-DOMINATED SYSTEMS

Vertical entrainment of dense gravity currents is often studied under the presumption that the ambient fluid is weakly turbulent relative to the underflow. Under such a conceptual model, entrainment into the gravity current is the dominant mixing process. While this approximation is reasonable for oceans or coastal shelf regions, field data from Corpus Christi Bay suggests that this model does not hold for shallow, wind-driven systems. Two decades of water quality sampling, combined with other more recent studies, suggests frequent development of dense underflows leading to hypoxia in the bay. Turbulent wind-driven mixing in this shallow system (whose mean depth is 3.6 meters) is suspected to dominate over underflow-induced turbulence in governing vertical gravity current mixing, making gravity current entrainment in Corpus Christi Bay a multidirectional phenomenon. We present a new conceptual model of gravity current entrainment based on TKE transport that takes ambient turbulence into account, and thus allows for entrainment of both dense fluid into the ambient and ambient fluid into the underflow.

TEMPORAL CHANGES IN THE δ¹³C-Suess EFFECT AND ANTHROPOGENIC CO2 IN THE SUBTROPICAL SOUTH PACIFIC BETWEEN 1992 AND 2003

We measured stable carbon isotopic ratio (δ¹³C-VPD/δ) of dissolved inorganic carbon (DIC) during a re-visit cruise of WHP-P06 (BEAGLE03) along approximately 32°S in the subtropical South Pacific in August-October of 2003. The δ¹³C data obtained in 2003 were compared to those of WHP-P06 in 1992. For the comparison, we used a multi-parameter linear regression. δ¹³C changes (Δδ¹³C) in surface waters between 1992 and 2003 in the east (about −0.3 %) were lower than those in the west (−0.2 − 0.1 %) while values of depth-integrated Δδ¹³C (δ¹³C-Suess effect) in the east were higher than those in the west. Area weighted mean of the δ¹³C-Suess effect was calculated to be −14 ± 8 m year⁻¹ that is coincident with that of the anthropogenic CO2 accumulation rate (1.0 ± 0.4 m mol² year⁻¹) derived from direct comparison of DIC data according to the global mean of δ¹³C constraint ratio (Δδ¹³C / ADIC) −16 % m mol⁻¹. The observational results agree well with those from an ocean general circulation model (MOM-3).

ERROR CHARACTERIZATION OF MODIS IR SST RETRIEVALS

MODerate-resolution Imaging Spectrometers (MODIS) Terra and Aqua sensors combined have been providing infrared (IR) sea surface temperature (SST) for nearly seven years. Although SST fields from these sensors have been used regularly for a number of studies, there has not been any comprehensive validation of the MODIS SST retrieval algorithm. In this study, we have used a matchup database of MODIS SST and in-situ SST data primarily from drifting and also from radiometers to validate and estimate the error characteristics of the MODIS SST retrieval algorithm. Analysis of the SST residuals (satellite - buoy) shows a constant bias of about 0.18K and a rms of 0.5K. A number of ancillary data (wind speed, aerosols, microwave SST, etc) are used in the analysis to narrow down the main causes for the global and regional SST error fields.

BIOLOGICALLY-GENERATED TURBULENCE IN A COASTAL INLET

Bursts of elevated turbulence coinciding with the sunset asent and sunrise descent of backscattering layers in Saanich Inlet are argued to be signatures of turbulent mixing generated by vertically-migrating swarms of krill Euphausia pacifica. Saanich Inlet is highly productive, supporting dense krill swarms with concentrations of up to 10,000 individuals m⁻³. Microstructure profiles were collected every 3 minutes. Acoustic backscatter signals were monitored continuously with a shipboard 200-kHz ASL single-beam echosounder. During day and night, diffusivities are about 0.02 × 10⁻² m² s⁻¹. Though bursts of turbulence associated with krill migration last only 10-15 minutes, on days when they occur, the daily-average diffusivity in the inlet is raised by factors of 100-1000 to (4-40) × 10⁻² m² s⁻¹. Such events need only occur a few times a year in order to contribute comparable mixing in the upper pycnocline as do breaking internal waves. Their frequency of occurrence in Saanich Inlet and in the open ocean is unknown.
PERSPECTIVE ON THE SIGNIFICANCE OF CYANOBACTERIA IN WATER COLUMN VARIATION IN REMOTE SENSING SIGNAL DUE TO VERTICAL DISTRIBUTION OF CYANOBACTERIA IN WATER COLUMN

PERSISTENT ORGANIC POLLUTANTS IN SUSPENDED PARTICLES IN THE OLGOTRIGOTROPIC NORTHWEST

A field investigation was conducted in the subtropical Northwest Pacific Ocean and adjacent regions during the springtime Asian Dust Storm period in 2007 to study the possible pollution of organic pollutants in suspended particles and zooplankton. We measured persistent organic pollutants (aldrin, chlordane, DDTs, DDEs, and DDDs, HCBs etc) in different particles and found the major compounds detected were DDTs, DDEs, and DDDs etc. The results confirm that some pesticides can be transported to the open ocean from China via the Asian Dust Storm

REPRESENTER ANALYSIS IN THE COASTAL OCEAN

In one approach to variational data assimilation the optimal correction to the prior solution is constructed as a linear combination of reprenter functions. The reprenters show the trend of influence of a single observation, and can be interpreted as covariances of errors in the prior solution between the observed variable and all the model fields at all locations. We analyze reprenters computed from linear and quadratic modes for a nonlinear hydrostatic primitive equation model of coastal circulation. Error structure and evolution associated with uncertainties in initial conditions and atmospheric fluxes are assessed. The reprenters preserve dynamical consistency in the multivariable correction fields (including phytoplankton and Ekman transport). If a small decorrelation error scale is assumed in the cross-shore direction, an SSH observation contribution to corrections in the wind stress and velocities on a scale of the baroclinic Rossby radius of deformation. In contrast, the reprenter corresponding to an observation of the alongshore surface velocity provides a very local correction. Temporal evolution of the reprenters is influenced by both coastal trapped waves propagation and alongshore advection.

POPULATION CONNECTIVITY BETWEEN OCEANS IN MESO- AND BATHYPELAGIC COPEPODS OF THE FAMILY SCOLECRITICIDAE

Recent genetic analyses are progressively revealing cryptic species within zooplankton species that have been referred to as cosmopolitan or known to have ocean-wide distributions. However, most studies have focused on the epipelagic species, hence still little is known of the gene flow of populations in the meso- and bathypelagic zooplankton. We examined genetic distances based on two mitochondrial genes (mtDNA: COI and sRNA) from populations of species between the Pacific and Atlantic Oceans in the pelagic copepod family Scolecitrichidae, which is among the most species-rich families in calanoid copepods. Many species of this family, which are widely distributed throughout the world oceans, exhibit specific patterns in their vertical distribution. Mitochondrial DNA analyses showed that population gene flow between the Oceans varies with species and/or habitat depths. In particular, there was a tendency that genetic distance (KCP) between the populations from the two oceans to be higher in the meso- and bathypelagic than in the epipelagic species, the values in the former exceeding 0.15 in some species, suggesting more advanced genetic divergences in the deeper layers.

EFFECTS OF THE WIND STRESS FIELD AND STRATIFICATION ON THE KUROSHIO PATH VARIATION STUDIED BY A NESTED GRID OGCM

The wind stress field over the North Pacific subtropical gyre and stratification around Japan are considered to be deeply related to the existence of the two stable Kuroshio paths. We measured the temporal evolution of the representers which are assessed. The representers preserve dynamical consistency in the multivariate correction fields (including phytoplankton and Ekman transport). Temporal evolution of the representers is influenced by both coastal trapped waves propagation and alongshore advection.

CAN FAST REPETITION RATE FLUOROMETRY AND SATELLITE OCEAN COLOR DATA BE COMBINED TO EXAMINE GULF OF MEXICO HYPOXIA?

Summer hypoxia develops in bottom waters of the Northern Gulf of Mexico influenced by discharge from the Mississippi and Atchafalaya Rivers. These nutrient-enhanced waters stimulate phytoplankton primary production thereby increasing organic material delivery to the bottom. Fast Repetition Rate Fluorometry (FRRF) provides vertical profiles of phytoplankton photosynthetic parameters including Fv/Fm, the ratio of variable to maximum fluorescence, Sigma443, the functional cross section of PSI, and Pn, the light-saturated photosynthesis rate. Ocean color observations from satellites can be used to synoptically map chlorophyll a, CDOM, and other parameters, and these data cover the entire shelf. In 2007, FRRF profiles were collected from more than 60 stations on each of two cruises (April, August). Our investigations examined the potential for using FRRF and ocean color data together to improve our understanding of the role that phytoplankton primary production plays in developing and sustaining summer hypoxia.

MOLECULAR EVIDENCE FOR C4-TYPE C FIXATION IN DIATOMS

The propensity of diatoms to maintain maximal C fixation rates at high bloom densities, wherein CO2 can be as low as 50–150 µmol/L in the modern ocean, has a significant impact on global biogeochemical cycles. The biochemical means by which diatoms continue to grow under these conditions, given the poor substrate affinity of Rubisco for CO2, are not completely understood, butdata have emerged over the last decade or so in support of a C4-type mechanism. We conducted short term pCO2 shift experiments in pH 8.46, decreasing CO2aq from 60 to 7 µmol/L (pCO2 from 1790 to 220 ppm). Prior to and following the transition to lower pCO2, samples were collected for gene transcript analysis using Q-RT-PCR. In T. pseudonana, we observed a rapid 3-fold increase in transcript abundance for organelle-targeted malic enzyme, and a 6-fold increases in two PEPC transcripts. Cytosolic malate dehydrogenase (cytoMDH) mRNA abundance increased ~2-fold, while mitochondrial MDH did not change. Once these initial peaks, transcript abundances decreased considerably over time and were often only ~2-fold higher than pre-shift values. PEFCX transcript abundances were 1-2 orders of magnitude lower than those of PEPC, MDH or PE or regardless of pCO2. These results are consistent with an inducible C4 carbon concentrating mechanism and C fixation pathway involving malate as an initial organic acid.

VARIATION IN REMOTE SENSING SIGNAL DUE TO VERTICAL DISTRIBUTION OF CYANOBACTERIA IN WATER COLUMN

Increased intensity and potentially harmful effects of cyanobacterial blooms attract the attention of environmental agencies, water authorities and the general public worldwide. Reliable and operational monitoring methods of coastal waters, lakes and ponds are needed. Mapping of extent of cyanobacterial blooms with remote sensing is straightforward, but recognizing waters dominated by cyanobacteria and quantitative mapping of cyanobacterial biomass with remote sensing is complicated. Unlike most algae, cyanobacteria can regulate their buoyancy and move vertically in water column. We used Hydrolight 4.2 radiometric transfer model and spectral retrieval properties of three species of cyanobacteria to study impact of vertical distribution of cyanobacteria on remote sensing signal. The results show that vertical distribution of cyanobacteria in water column has significant impact on the remote sensing signal. This result indicates that developing remote sensing methods for quantitative mapping of cyanobacterial biomass is more complex than quantitative mapping of algal biomass. Moreover, the results also indicate that in situ sampling methods and strategies used for monitoring of algal biomass or calibration/validation of satellite data have to be re-designed for waters where cyanobacterial blooms may occur.
to calculate fluxes of phytoplankton to the Bay for years with strong (2002) and weak (1980) coastal upwelling. This work provides insight into the role of oceanic upwelling, a climate-driven process, in driving phytoplankton blooms in estuaries.

THE SOUTH FLORIDA ECOSYSTEM PORTFOLIO MODEL (EPM) WEB TOOL Urban development pressures in the remaining agricultural and undeveloped lands in Miami-Dade County, Florida are increasingly intense. Decisions to develop, preserve, or restore individual parcels can cumulatively affect regional ecological, environmental, and socioeconomic patterns in complex ways. These decisions ultimately lead to changes in land use/cover, with potential impacts both the Everglades and Biscayne National Park. In response, the U.S. Geological Survey has developed a prototype for a web-based geospatial information tool (the South Florida EPM) that screens future land use/cover patterns in terms of ecological (local and landscape) criteria and water quality and socio-economic indicators. The indicators are chosen to be sensitive to land use/cover, relevant to decision-makers and stakeholders, and indicative of future trends. We envision this tool being used as a web-based portal for communicating Department of the Interior priorities in South Florida’s ecologically sensitive areas that face on-going development pressure.

DETERMINATION OF SELECTED TRACE ELEMENTS IN BIOMONITORS Marine organisms, such as clams, can be employed as bio-monitors to assess the quality of the marine environment, since they can accumulate, concentrate and retain trace metals and other substances. Clams, Tivela maritima are widely used along the Venezuelan coast. The sea grass, Thalassia testudinum is very abundant in Venezuelan coastal areas and also found world-wide. In this work, we reported determination concentrations of Cd, Cr, Cu, Ni and Zn in the soft tissues of Tivela maritima and in the leaf blades and roots/rhizomes of Thalassia testudinum, which were collected at various sites along the Venezuelan coast. A Statistical analysis (one-way ANOVA) indicated that the different organisms investigated showed different degrees of bioaccumulation of the selected trace metals, thus they could be used as potential biomonitors to study the pollution levels of the selected trace elements in the marine environment. Significant spatial and temporal differences were found for the elemental concentrations of Cr, Ni and V in the soft clam tissue and for V in the sea grass. This work was partially funded by a research grant from the Venezuelan National Science and Technology Foundation (FONACIT: Proyecto de grupo 2005-000774) Mailing address: Centro de Quimica, 8424 NW 56th Street, Suite CCS-00204, Miami, FL, USA, 33166

LaCasce, J. H., University of Oslo, Oslo, Norway, jh.lacasce@geo.uio.no

THE MERGER RATE IN FREELY-DECAYING, 2-D TURBULENCE Two-dimensional turbulence has long been studied as a paradigm for nonlinear processes in the atmosphere and ocean. Numerical simulations suggest that freely-evolving turbulence is often dominated by long-lived vortices. The vortices merge, shifting energy to larger scales. What determines the merger rate however is an unresolved issue. We examine a new set of numerical experiments which employ different dissipation schemes. The merger rates differ from run to run but are successfully predicted from an empirical relation involving the mean vortex amplitude and the packing fraction. The same relation is found to apply to most previously published experimental results. Interestingly, the relation differs significantly from theoretical expectations.

WHAT CONTROLS BIOLOGICAL PRODUCTIVITY IN EASTERN BOUNDARY CURRENT SYSTEMS? The major environmental and physical factors controlling biological productivity in Eastern Boundary Current systems (EBCS) are examined through a neural network analysis based on self-organizing maps (SOMs). The method is applied to monthly observations over the period 1999-2004, consisting of remotely sensed sea surface temperature, sea level anomaly, ocean color, and wind speed and direction, in addition to a mixed layer
depth climatology SOMs show substantial differences in each of the four major EBCs and identified a continuum of classes of physical conditions favouring or inhibiting biological productivity. We found that whereas biological productivity in EBCs is enhanced mainly due to the alongshore wind-driven upwelling, it is inhibited by three factors: 1) strong eddy activity, 2) narrow continental shelf, and 3) deep mixed layer. Yet, in case of wide shelf and high upwelling strength, it was found that mixed layer shoaling reduces rather than enhances the productivity. To better understand these empirical findings, we will confront them with results from idealized EBCS setups of the ROMS model.

FIELD MEASUREMENTS OF CURRENT ATTENUATION AND VERTICAL MIXING IN THE EQUATORIAL PACIFIC

Mean velocity profiles and instantaneous turbulent velocities measured above and within two subtidal eddies (Z. marina) meadows in the San Juan Islands (Washington, USA) are consistent with the mixing-layer hydrodynamics that have been observed in submerged vegetated flows in the laboratory. Velocity profiles had a shear layer with an inflection point just above the meadow, with 50-80% attenuation of tidal currents within the meadow. Reynolds stresses <u'v'> and friction velocity u* were greatest at the top of the canopy, and instantaneous streamwise and vertical velocities above the meadow were dominated by large, low-frequency (<0.017 s-1) fluctuations which enhance vertical mixing. Friction velocity above the meadow was approximately twice that in an adjacent unvegetated region, under equivalent ambient current speeds. Drag coefficients for the meadow decreased with increasing current speed. A gaped canopy was deflected and turbulence penetrated deeper into the meadow. We are investigating the influence of this flow structure on sediment transport. Maximum blade length 1.5 m; blade front area ~3 m²; maximum tidal currents 20 cm/s at one site and 40 cm/s at the other.

IMPACT OF ASSIMILATED OCEAN COLOR SATELLITE SALINITY ON A NORTHERN GULF OF MEXICO CIRCULATION MODEL

The assimilation of real-time satellite observations into high resolution numerical models can yield more accurate forecasts of ocean currents in both open-ocean and coastal regions. We describe a capability of using MODIS and SeaWiFS ocean color spectral absorption products as an indicator of Sea Surface Salinity (SSS) for near-shore coastal waters (<35 PSU). SSS is closely associated with the fine-scale temporal and spatial variability in the coastal environment due to tidal fluctuations, river discharge (bayous, plumes), and rapidly changing topography and density structure. SSS observations are required for constraining ocean model forecast of surface and subsurface properties. Satellite observations are limited temporally and spatially, but when available can provide initialization for numerical models. We assimilate real-time MODIS SeaWiFS SSS derived from ocean color into a high resolution coastal circulation model running operationally in the northern Gulf of Mexico. The daily Nowcast/Forecast estimates of salinity up to 48 hours are derived at approximately 1.9 kilometer resolution. Modeled surface salinity estimates before and after satellite assimilation are evaluated against salinity measurements obtained from in situ observations.

ESTIMATING THE ROLE OF SALT DIVERGENCE TERMS IN THE MARINE FRESHWATER BUDGET USING ARGO DATA AS PRECURSOR TO AQUARIUS/ SAC-D SATELLITE SALINITY DATA

Surface layer salt and heat transport terms are evaluated using interpolated SSS and SST fields from Argo combined with satellite derived surface currents (OSCAR). The purpose is to (a) evaluate the importance of surface advection on large scales in the marine hydrologic balance and a precursor to studies using higher resolution SSS fields from the Aquarius/SAC-D mission (launching in 2010), and (b) describe similarities and differences between salt and heat budgets. Contrasts between the mean heat and salt divergences in the equatorial Pacific reveal that meridional advection dominates SSS divergence terms, whereas zonal advection dominates SST divergence. In mid-high latitudes, meridional advection is found to become more important as the effective temperature gradient decreases, and the subarctic gyre in the Pacific Ocean is a region of significant salt transport. In high latitudes, the formation of anti-cyclonic eddies is important for salt transport in the North Pacific. We are developing a diagnostic tool that can be used to identify regions of strong salt transport.

REMOTE SENSING OF TURBID PLUMES USING MODIS IMAGERY IN THE SOUTHERN CALIFORNIA COASTAL WATERS DURING STORM EVENTS

Water-leaving radiance data obtained from MODIS-Aqua satellite imagery at spatial resolutions of 250 m (band 1) and 500 m (band 4 at 555 nm) are used to study the spatial and temporal variability of turbid plumes in coastal waters of Southern California during strong storm events in the winter of 2004-2005. Our study is focused on the area between Point Loma and the US-Mexican border in San Diego, which is influenced by terrigenous input of particulate and dissolved materials from San Diego and Tijuana river estuaries and non-point sources along the shore. For several rainstorm events, we analyzed a correlation between the satellite-derived plume area and the amount of precipitated water accumulated during storms over the local watershed. The optimal threshold values of satellite-derived normalized water-leaving radiance at 465 nm and 555 nm were identified for distinguishing the plume from ambient ocean waters. In addition to satellite imagery and rainfall data we also use other oceanographic and meteorological data such as ocean currents, wind, and river discharge to study the plume dynamics in relation to environmental factors.

A VALIDATION EXPERIMENT OF THE NON-HYDROSTATIC FVCOM: SURFACE SOLITARY WAVES OVER FLAT AND SLOW-VARYING TOPOGRAPHY

The unstructured grid Finite Volume Coastal Ocean Model (FVCOM) has been upgraded to a non-hydrostatic version (FVCOM-NH). This new version was validated by conducting a suite of numerical experiments for homogeneous and stratified non-hydrostatic problems. The present work focuses on a detailed analysis of model results for solitary waves under an inviscid condition. In the flat bottom case, the model reproduces the constant amplitude and phase of the analytical solution, demonstrating that the second-order accurate finite-volume method implemented in FVCOM-NH is capable of ensuring both mass conservation and numerical accuracy. In the variable bathymetry case, our setup followed the experimental work of O. Madsen and C.C. Mei (1969). The evolution of the model-predicted solitary wave compared well with both theoretical and laboratory results in the flat bottom and slope regions. The model also successfully reproduced the so-called “fission phenomena”, the disintegration of a solitary wave after it enters the shallow region of constant depth. FVCOM-NH has been applied to realistic studies, including internal wave dynamics on Stelwagen Bank and on the steep slopes of the South China Sea.

SATELLITE REMOTE SENSING OF THE ROCKY INTERTIDAL USING MODIS AND ASTER SENSORS

In an era of expensive in-situ studies, satellites can provide valuable climate information in ecologically sensitive inter-tidal locations. This paper combines 5 years of thermal in situ data with remotely sensed temperature from three sensors: MODIS/Terra, MODIS/Aqua and ASTER/Terra; and two products: land surface temperature and sea surface temperature. Satellite data were found to differ from logger temperatures an average of 4.5°C (MODIS/Aqua LST), 4.1°C (MODIS/Terra LST), 4.2°C (MODIS/Terra SST) and 4.3°C (ASTER/Terra LST). ASTER was determined to have too few images per scene to be useful for an intensive habitat monitoring program. Tidal stage was found to be a strong factor in determining the logger-satellite temperature difference. Better agreement in temperatures was observed during high tide, exhibiting an average variance from logger temperatures of 4.0°C (MODIS/Aqua LST), 1.9°C (MODIS/Terra LST), and 1.6°C (MODIS/Terra SST). The satellite data have been found to be a promising source of long-term warming or cooling trends and for investigating complex patterns in the variation of biotic thermal stresses along coastal zones.

IMPACT OF A WARMING OF THE INTERMEDIATE WATER LAYER ON THE EXPORT OF PARTICULATE ORGANIC CARBON IN THE EURASIAN ARCTIC

The observed decline in Arctic ice cover is likely to increase the export of particulate organic carbon (POC) over the Arctic continental shelves. This could lead to a significant sequestration of CO2, particularly over the immense Siberian Shelves. A substantial warming of the Atlantic Water layer in the Eurasian Arctic may further affect the magnitude and nature of POC export over the Siberian Shelves. It is therefore necessary to measure POC fluxes. A reduction in ice cover could result in a significant increase in export. The said mechanisms might also affect the export of carbon into the Eurasian Basin. Long-term sediment traps were deployed in 2005-2006 in the Intermediate Water Layer of the Laptef Sea where POC fluxes reached 1.8 g C m-2 y-1 at 175 m and 3.5 g C m-2 y-1 at 840 m, with the highest fluxes occurring during summer 2006. The annual cycles of POC export will be compared to the temperatures observed in the Intermediate Water layer to determine the relationship between POC fluxes and the Atlantic Water temperature anomalies.

NORDEIC SEA OVERFLOWS AND MODELED CLIMATE

The Marginal Sea Boundary Condition (MSCB) of Price and Yang forms the basis of parameterized overflows from the Mediterranean, and Nordic Seas (PNSO) in the ocean component of the Community Climate System Model (CCSM). The numerics involved with two-way exchange between modeled seas on both sides of an overflow are discussed. In particular, the solution to the Nordic Sea case where, unlike the Mediterranean at Gibraltar, the inflow is driven by different physics than the overflow and need not occur at the same location is described. First, the mean North Atlantic tracer distributions, then centennial changes in the long term global climate are compared between solutions with and without parameterized Nordic Sea overflows.

THE UPWELLING-RELAXATION CYCLE AND ITS EFFECT ON PLANKTON PRODUCTIVITY OVER THE NORTHERN CALIFORNIA SHELF DURING WEST

During the CoOP WEST project, we explored the role of wind-driven transport in plankton productivity over the shelf off Bodega Bay, northern California. Wind forcing varies on synoptic time scales, yielding periods of upwelling interspersed with relaxation periods (weak winds). While upwelling periods are critical for nutrient delivery, relaxation periods are critical for algal bloom development over the shelf. In turn, zooplankton productivity over the shelf depends on the availability of phytoplankton and the ability to be retained in this environment. As expected, a key factor is the relative time scales of physical and biological processes. Phytoplankton blooms exhibiting strong responses to upwelling-relaxation cycles while growth of zooplankton populations depends on more than one upwelling-relaxation cycle. Results from analysis of field observations and models will be presented for the Bodega-Reyes region in 2001-2002 and compared with available results from other regions and other years.

SEASONAL AND INTER-ANNUAL VARIATION IN BIOGEOCHEMICAL PROCESSES AT THE PORCUPINE ABBYSLINE PLAIN (PAP) OBSERVATORY (49N, 16.5W)

We present a suite of multidisciplinary biogeochemical data measured in situ at the Porcupine Abyssal Plain (PAP) observatory in the North East Atlantic (49N, 16.5W) over the past 20 years. The observations cover the entire water column and the seabed beneath (4800 m). Since 2002 this includes water column measurements of temperature and salinity (to 1000 m) and biogeochemical data at 30 m (including nitrate, chlorophyll and CO2). Benthic studies have been carried out at PAP since 1989 including time-lapse photography; trawls and cores to study the benthic ecosystem and deep sediment traps to measure particle flux. This multidisciplinary data set makes the PAP site a unique surface to benthic observatory in the NE Atlantic. This substantial long-term high temporal resolution data set will be discussed in terms of coupled inter-annual variability between the pelagic and benthic environments. In addition, the importance of the PAP data set in terms of understanding regional and global change will also be addressed alongside other observational data and linked to large-scale climatic indices such as the North Atlantic Oscillation (NAO).

A VIEW TO A KILL! DEVELOPMENT OF AN IN SITU BASED METHOD FOR IDENTIFICATION OF MARINE ALGAE SPECIES AND QUANTIFICATION OF VIRAL INFECTION

In order to improve our understanding of how algae viruses influence host bloom dynamics, methods allowing the detection and quantification of hosts and infected cells are needed. Although successful identification of some phytoplankton species have been done
using molecular techniques like Fluorescence in Situ Hybridization (FISH) or CARD-FISH, metacontamination is amplified to cell phase. The metagenome signal variations make these methods difficult to apply on algae in environmental samples. Also the sensitivity of these hybridization techniques are such that they are difficult to use on low copy genes or for visualization of intracellular viruses. As an alternative we have investigated the utilization of Loop Mediated Isothermal amplification (LAMP-PCR) as a way of amplifying probe targets. The sensitivity and isothermal properties of LAMP hold many advantages compared to traditional in situ PCR and FISH based detection. We have successfully designed LAMP-PCR primers targeting the Pneumocystis Chrysonomulinae erica and co-occurring viruses CeV. These primers allow for the in situ detection and quantification of P. erica and cells infected with virus.

POTENTIAL EFFECTS OF RUNOFF, FLUVIAL SEDIMENT AND NUTRIENT DISCHARGES ON THE CORAL REEFS OF PUERTO RICO

Coral reefs have been degraded by human activity in much of the earth's tropical oceans. The potential relation between river sediment and nutrient discharges and degradation of Puerto Rico coral reefs was studied using streamflow-, suspended-sediment, and water-qual-ity monitoring. The highest daily sediment discharge is 70 % of average precipitation (1,600 mm). Annual suspended-sediment discharge from Puerto Rico into coastal waters ranges from 2.7 to 9.0 million tonnes. Storm runoff transports a substantial part of suspended sediment from uplands to the coast, eg. the highest daily sediment discharge is 1 to 3.6 times the annual suspended-sediment discharge. Hurricane Georges distributed an average of 0.8 tonne of sediment per km² of land over 12 days in 1998; a volume of 2.6 billion m³. Runoff of more than 1.0 billion m³ of water and 5 to 10 million tonnes of sediment were discharged to the coast as a result of the hurricane. N and P concentrations in river waters are as much as 10 times the pre-settlement levels. Fecal coliform and fecal strepto- cocci concentrations in many rivers are near or above regulatory limits. Unusual epilimnion and intense sediment discharge, river-borne nutrient and fecal discharge is a less-intense but chronic stressor to coral reefs found near the mouths of rivers. Negative effects of river-derived sediment and nutrient discharge on coral reefs are especially pronounced in nearshore areas of the north, southwest, and west coasts of the island.

AN INSTRUMENT FOR EXTENDING ARGO TEMPERATURE AND SALINITY MEASUREMENTS THROUGH THE SEA SURFACE

Measurement of sea surface temperature and salinity produces ground truth for satellites including the upcoming Aquarius Mission, but also affords measurements of meteorologi-cal fluxes such as evaporation versus precipitation and ocean heat flux. The SBE 41CP, installed on many ARGO floats in the world's oceans, is pumped to ensure the highest quality data. To avoid degrading the salinity accuracy by ingesting sea surface oils, the pump is turned off at 5 - 10 decibars beneath the sea surface as the ARGO float ascends. The trade-off for achieving sensor stability over the life span of the ARGO float was the forfeiture of very-near-surface temperature and salinity. To address this need, Sea-Bird Electronics has developed a free flushing sensor designed to make temperature and salinity measurements as an ARGO float passes through the sea surface. The sensor will be calibrated by the main CTD on the ARGO float each time a profile is executed. Field trials demonstrate an accuracy of +/-0.004 degrees Celsius and +/-0.002 in conductivity, yielding +/-0.02 in practical salinity.

SHORT-LIVED RADIOISOTOPE INVENTORIES AS TRACERS OF TERRESTRIAL SEDIMENT DISTRIBUTION ON A WATERSHED SCALE: ST. JOHN, US VIRGIN ISLANDS

Sediments in coastal salt ponds, and near-shore marine environments in the USVI provide a record of sediment accumulation, which reflects natural and anthropogenic activities in adjacent watershed. Sediment accumulation rates in these environments generally in-crease from 0.02-0.10 cm/yr for the last 2,000-5,000 years (based upon 14C dating) to 0.07 cm/yr to 0.20 cm/yr over the past 100 years (based upon 210Pb dating). Sites with the greatest increase in accumulation rate are located in, or adjacent to, watersheds that have undergone land use changes due to anthropogenic activities. Expanding this work to a watershed scale may be accomplished using SLRI (short-lived radioisotope, 210Pb, 137Cs, and 7Be) inventories. Sediment samples were collected in a relatively undisturbed watershed on St. John to determine the feasibility of SLRI inventory partitioning in terrestrial sediment reservoirs (watershed, coast, marine) as a means to identify/quantify locations of erosion and deposition, as well as distribution and accumulation rates. The variability of SLRI in riverine environments is expected to quantitatively describe terrestrial sediment pathways on a watershed scale and linkages between the watershed, coast, and marine environment.

MODELING NITROGEN AND PHOSPHORUS RETENTION IN THE COASTAL OCEAN AT THE GLOBAL SCALE

Human activity is leading to major increases in terrestrial nutrient inputs to the ocean and a deterioration of coastal water quality in many regions. Here, we present a spatially-explicit model of the coupled nitrogen (N) and phosphorus (P) cycles in the proximal coastal ocean that allows an assessment of the consequences of the changes in river and ground-water fluxes and nutrient transformation and retention in the coastal ocean at the global scale. Our process-based model consists of a "ribbon" of generic box models that are distributed along the entire global coast-line at a half degree resolution. Different parameter-izations for the box models are established using a global coastal typology based on hydrological, lithological, morphological and biogeochemical criteria. In our presentation, we will present results of simulations performed using spatially-explicit nutrient inputs (GlobalNEWS) and other relevant forcings (including light and temperature) and we will discuss the role of various types of near-coastal ecosystems (estuaries, fjords, lagoons, deltas and others) in retention of nutrients at the global scale.

OXYGEN CONSUMPTION IN PERMEABLE GULF COAST SEDIMENTS

Boundary layer flows and suspended matter and solutes contained within, affect granulometry, porosity, permeability, and microbial activity in near shore salt marshes. Variations in the boundary flow condition or changes in the suspended matter load result in significan-t changes in sediment compaction and permeability, which entail alterations in sediment water exchange of solutes and particulate matter. Thereby episodic events can insti-gate long lasting changes affecting life biogeochemistry at the sea floor, affecting cycles of nutrients and contaminants. Here we report investigations on oxygen consumption rates in permeable Gulf Coast sediments and its temporal and spatial variation. The consump-tion rate measurements were conducted on retrieved sediment cores over a period of one year using the percolation method described by Deleer et al. (2005). Through assessing oxygen consumption rates of the sediment we expect to achieve a better understanding of the role of the permeable sand sediments for the cycling of organic matter in the Gulf coast environment.

CAUSES AND CONSEQUENCES OF MATE LIMITATION IN THE COASTAL MARINE COPEPOD, TEMORA LONGICORNIS

Coastal marine copepods are likely to be vulnerable to mate limitation as a result of dilute population densities and their need to continuously breed in order to produce multiple fertilized clutches in their lifetime. Despite important implications for predicting copepod population growth, field surveys describing the prevalence of mate limitation in coastal copepod species are lacking. The aim of this study was to determine the preva-lence of mate limitation in the dominant marine copepod, Temora longicornis within the Damariscotta River estuary in Walpole, Maine. Clutches obtained from field-caught females were analyzed using an egg-staining technique to determine the female’s in situ fertilization status. The results of this study indicate that female T. longicornis lay un-fertil-ized eggs in substantial proportions which suggest that nauplii production may be con-strained by mate limitation within this species. This study highlights a need to incorporate fertilization/mate limitation into models describing copepod population growth.

RECENT OBSERVATIONS FROM THE GREENLAND SEA: SEASONAL TO INTERANNUAL VARIABILITY OF TEMPERATURE AND SALINITY AND IMPLICATIONS ON WATER MASS FORMATION

The Greenland Sea gyre is known for open ocean convection triggered by extreme heat loss to the atmosphere in winter. Since the late 1980’s, convection activity decreased and reached only intermediate depth. Data from ARGO floats and a profiling mooring, from 2000 to 2007, provide a hydrographic time series longer and of significantly higher temporal resolution than any timeseries discussed before that of region. It enables us to describe the typical seasonal cycle and associated interannual variabilities of temperature and salinity for the last decade. The development of heat and freshwater content of the gyre is analyzed in respect to the atmospheric forcing and lateral advection, with possible
Our analysis indicates a consistent bias towards studies on low dispersal/low latitude species. We examined estimates of dispersal in a broad range of marine species through an analysis from the time series of the upward looking sonar data by assuming that bubble clouds are the fetch is short, the penetration depth is lower and does not show a clear correlation observed and the bubble penetration depth linearly increases with the wind speed. When the wind speed exceeds about 10 m/s and the surface wave field is well developed with a long fetch, Langmuir circulations are clearly understood and used to obtain high-resolution images of internal solitary waves (ISWs) developed and used to obtain high-resolution images of internal solitary waves (ISWs). High-frequency broadband (150-600 kHz) acoustic scattering techniques have been used to determine for some of the observed scattering layers. Quantiﬁcation and reducing these atmospheric and watershed sources are important for maintaining and restoring water quality due to eutrophication. We describe the application of a watershed-based nonpoint source nitrogen loading model, previously published by the Marine Biological Laboratory, to estimate inputs of nitrogen to and from coastal watersheds. This relatively simple model can be applied easily to many estuaries so that comparisons can be made between estuaries. The model, applied to forty-nine (49) embayments along the southern New England coast, yielded nitrogen input rates to the estuaries of 21 to 3300 kg N/ha/yr (mean 224, median 67 kg N/ha/yr). A paired comparison of the model output values with the more well-known USGS SPARROW model values showed high goodness of agreement (r² = 0.73, n = 39). Application of the model for multiple estuaries can provide a means for the development of nitrogen load—ecological response models using a comparative estuary approach.

OBSERVATION OF NEAR SURFACE BUBBLE STRUCTURES USING AN UNDERWATER SONAR SYSTEM

Understanding the bubble injection process by surface breaking waves is important for improved predictions of sea spray generation and air-sea heat and gas exchanges. From January to March 2006, upward looking and sidescan sonar deployments were deployed in Narragansett Bay, RI to monitor the water column. The backscatter intensity data during high wind events were used to examine bubble cloud structures generated by breaking waves. Both the bubble injection depth and the distribution of injection events were estimated using the upward looking sonar. Organized Langmuir circulations were observed using the sidescan sonar data. When the wind speed exceeds about 10 m/s and the surface wave field is well developed with a long fetch, Langmuir circulations are clearly observed and the bubble penetration depth linearly increases with the wind speed. When the fetch is short, the penetration depth is lower and does not show a clear correlation with the wind speed. Spatial distribution of individual bubble clouds may be estimated from the time series of the upward looking sonar data by assuming that bubble clouds are advected by a current model.

GLOBAL TRENDS IN DISPERSAL AND CONNECTIVITY AMONG MARINE SPECIES

We examined estimates of dispersal in a broad range of marine species through an analysis of published values, and evaluate their applicability using indirect measures of dispersal. Our analysis indicates a consistent bias towards studies on low dispersal/low latitude species. We hypothesize that reports focusing on short distance dispersal are not representative of global trends. This hypothesis is examined using a database of indirect measures of dispersal including planktonic larval duration (PLD, 318 species) and genetic differentiation (FST, 212 species). We observed significant differences in FST (P<0.001) and PLD (P<0.001) between taxonomic groups as well as a weak association between PLD and FST (R=0.4) across groups. Within marine fish (<50% of data sets), species with demersal eggs had lower PLDs (R²=0.76, P<0.001) and higher genetic structuring (R²=0.80, P<0.001). Furthermore, significant increases in dispersal (PLD and FST) were associated with increases in latitude, adult body size, and water depth and latitude was identified as the main explanatory variable. The global trends in dispersal observed here provide a first step towards predicting species-level and regional differences in dispersal.

COMPARISON OF UPWELLING INDICES USING BLENDED WINDS (COAMPS/QUICKSCAT) AND NOAA PRESSURE FIELDS IN MONTEREY BAY, CALIFORNIA

The rich diversity and abundance of the marine life along the California coast, including Monterey Bay, is intimately linked to the coastal upwelling and the coastal upwelling index (CUI) was developed to quantify the strength and location of upwelling. The CUI is calculated using NOAA Environmental Research Division (ERD) sea surface pressure data. In this study, we examine the impact of using additional data sets to improve the CUI estimates, particularly towards the coastline. We use a Blended Wind product derived from NASA QuickSCAT and Coupled Ocean / Atmosphere Mesoscale Prediction System model outputs to compare with the NOAA CUI for the period September 2006 - July 2007. The correlation between the Blended Wind product and the ERD CUI increased positively as distance from shore decreased. While both showed expected seasonal patterns, the ERD CUI consistently displayed significantly higher variance. An enhanced understanding of upwelling mechanisms and the effects on marine life will be required to meet the demand of industry but also the sustainability of the environment.

BROADBAND ACOUSTIC SCATTERING FROM NONLINEAR INTERNAL WAVES: IDENTIFICATION OF DOMINANT SCATTERING MECHANISMS

High-frequency broadband (150-600 kHz) acoustic scattering techniques have been developed and used to obtain high-resolution images of internal solitary waves (ISWs) propagating shoreward over the New Jersey continental shelf. Multiple ISWs were tracked and imaged acoustically, while simultaneous direct microstructure measurements and relatively coincident zooplankton net samples were obtained. Multiple scattering layers were often associated with the ISWs, with the backscattering from the different layers exhibiting a consistent frequency trend. This scattering layering was observed at all frequencies at depths associated with large temperature gradients, while at the highest frequencies a deeper scattering layer was sometimes observed, not associated to large temperature or salinity gradients or high dissipation rates. The broadband spectra, together with physics-based scattering models, have allowed the dominant scattering mechanisms to be determined for some of the observed scattering layers.

MICROZOOPLANKTON DISTRIBUTION AND TROPICAL INTER ActionS DURING ANNUAL HYPOXIA IN LAKE ERIE AND THE GULF OF MEXICO

The northern Gulf of Mexico and the central basin of Lake Erie experience annual hypoxia, covering broad regions in summer and impacting their living resources. However, little is known about its effects on microbial communities. This study examined the composition, distribution, and dynamics of microzooplankton using 16S rRNA gene sequences, shipboard experiments, and real-time flow-cytometry. Examination of planktonic distribution and composition along several continuous transects in the Gulf of Mexico in August 2006-2007 revealed significant spatial heterogeneity. Heterotrophic microbes and diatoms peaked in a mid-shelf warm front and the Mississippi River plume, respectively. Their diel vertical patterns were linked to the fluctuating DO concentrations in the bottom layer, which were apparently influenced by the currents. In both systems, microzooplankton biomass in the hypoxic zone (DO < 1 mg/L) was dominated by oligotrich ciliates and gymnodinid dinoflagellates, which exhibited significant top-down pressure on pico- and nanoplankton. The results of this study indicate that microzooplankton play an important role in the pelagic food web during annual hypoxia.
NEW NITROGEN SOURCES IN THE SUBTROPICAL SOUTH-WEST PACIFIC

New nitrogen supply to the oligotrophic ocean is currently being reassessed in recognition of an increasingly important role of nitrogen fixation. To examine the relative contributions of different nitrogen supply routes, a suite of physical, biological and biogeochemical rate measurements were made during a 13-day Lagrangian study north of New Zealand, in sub-tropical waters at the southern boundary of the nitrogen fixation biome. Measurements were obtained during extreme events associated with nitrogen supply, including the transition of a tropical cyclone to a storm and the development of a surface colonial Trichodesmium bloom. The new nitrogen sources will be assessed in terms of their contribution to community primary production, and considered in the context of modelling nutrient supply in oligotrophic systems and their potential response to climate change.

THE IMPACT OF ANTENNA PATTERN DISTORTIONS ON THE ACCURACY OF HF RADAR-DERIVED NEAR-SURFACE OCEAN CURRENT RETRIEVALS: A SIMULATION-BASED ANALYSIS

We present a simulation-based analysis of errors in HF radar-derived near-surface ocean current measurements. We examine, in particular, the effects of distortions in the radar receive antenna sensitivity patterns. It is well known that pattern distortions occur to some degree with all radar installations and that the distortions have an effect on the current retrievals, particularly in the case of direction finding radar systems using compact antenna geometries, such as the CODAR Seasonde. We demonstrate a method for quantifying these distortions by a single parameter and relate this parameter to overall performance of the radar system using simulated data. Results show a high correlation between the rms errors in the retrieved radial currents and the antenna distortion parameter. We compare the results obtained when processing data using measured antenna patterns to those obtained when processing using ideal patterns. Throughout this simulation-based analysis we employ a crossed loop dipole antenna geometry, the same antenna geometry used by the CODAR Seasonde radar systems, and standard CODAR data processing software to process the simulated data.

HOTSPOTS IN THE DISTRIBUTION OF NORTHERN BLUEFIN TUNA IN THE ATLANTIC AND PACIFIC OCEANS

Northern bluefin tuna are among the most valuable fish in the sea. Effective management of their fisheries will require a detailed understanding of their seasonal movement patterns and particularly their use of hotspots. Here we apply electronic tag data to identify such hotspots in the distribution of Atlantic and Pacific bluefin tuna. We focus specifically on hotspots that consistently occur in spring to fall in the Gulf of Maine and off Baja California. By integrating track data with tag measurements of water temperature and remote sensing observations, we identify the physical features underlying these hotspots. Regional scale processes, such as upwelling and high SSTs, are considered in the context of providing real-time wave forecasts from a single high-end computer workstation.

SPATIAL PATTERNS IN FISHERIES: NEW TECHNIQUES, NEW OPPORTUNITIES FOR ECOSYSTEM-BASED MANAGEMENT

Understanding spatial distribution of fish stocks in the ocean is an important component of the information needed for ecosystem-based fisheries management. Fine-scale distributions can be used in combination with cross-scale oceanographic data to explore management patterns in relation to local and regional environmental conditions. Project CROOS (Collaborative Research on Oregon Ocean Salmon), and work in California, are fishing-industry initiatives involving the active participation of commercial salmon trolls, scientists, and state and federal agencies to develop techniques for fine-scale mapping of Chinook salmon (Oncorhynchus tshawytscha) stock-specific distributions in ocean hazards. Preliminary analysis and a rapid shift in catch patterns in September 2006 corresponded with a change in upwelling patterns and water column hydrography. Distribution differences may enable fishery managers to direct fishing effort toward abundant stocks and away from stocks of conservation concern. This is a new tool for investigating the ocean ecology of a variety of fisheries with potential application to ecosystem-based fishery management. Properly applied, these techniques can lead the fishing community and managers to a more productive relationship.

A HIGH-RESOLUTION CLOSED-REAL-TIME ATMOSPHERE/WAVE FORECAST SYSTEM FOR THE COASTAL ZONE

Early results are presented from a NOAA funded project involving the configuration of a short-term high resolution wave and atmospheric model forecast system. The coupled modeling system is designed for eventual transition to National Weather Service Forecast Offices in an effort to extend the current open ocean wave forecasts provided operationally by the NOAA/NCEP WaveWatch (WW) model into the coastal zone (i.e., within 100 km of the shoreline). Results from sensitivity tests with the Weather Research and Forecast (WRF) model involving grid resolution, nesting and data assimilation (scatterometer and radial winds) will be presented. Output from embedded high resolution hydrodynamic and wave propagation models will be compared to both buoy and extrapolated WW forecasts. Because the system is intended for operational applications, results are considered in the context of providing real-time wave forecasts from a single high-end linux workstation.

OPERATIONAL SST BIAS CORRECTION USING AATSR DATA

The operational SST retrieval algorithms often show regional biases of a few tenths of Kelvin, induced by defects in the atmospheric correction techniques that are currently used. These regional biases vary from a data set to another and often lead to data consistency problems for users. A preprocessing step, including a bias correction aiming to homogenize the data sources is thus essential before ingestion of the data in analyses, assimilation in models and more generally before every applications using multiple southern boundary of the nitrogen fixation biome. Measurements were made during a 13-day Lagrangian study north of New Zealand, in sub-tropical waters at the southern boundary of the nitrogen fixation biome. Measurements were obtained during extreme events associated with nitrogen supply, including the transition of a tropical cyclone to a storm and the development of a surface colonial Trichodesmium bloom. The new nitrogen sources will be assessed in terms of their contribution to community primary production, and considered in the context of modelling nutrient supply in oligotrophic systems and their potential response to climate change.

DYNAMICAL AND STOCHASTIC MODELLING FOR THE EVALUATION OF COASTAL OBSERVATIONAL NETWORKS IN THE BAY OF BISCAY

The exchange processes between continental shelves and the deep ocean involve energetic processes such as slope current variability, eddies and filaments. Unfortunately, these processes exhibit short time and space scales and are therefore difficult to observe. Our objective is to evaluate observational networks in the Bay of Biscay by a stochastic modeling method. A baroclinic coastal ocean model is set up there during summer 2004. Two experiments of simulations are carried out, one with perturbations of the wind stress, and another one with perturbations of the density field. The ensemble spread is considered to provide a good proxy for the model error, given error assumptions such as the ones adopted here. The corresponding model error subspaces are explored, in order to specify their space and time characteristics. Then, several observation networks are defined and their performances are evaluated by studying the eigenvalue spectra and corresponding eigenvectors of the scaled representer matrix.

SPECIES-SPECIFIC SILIFICATION RATES USING A NEW FLUORESCENT PROBE (PDMPO) IN THE SUB-ANTARCTIC AND POLAR FRONT ZONES (OF THE SOUTHERN OCEAN)

During the SAZ-SENSE cruise, conducted during the austral summer of 2007, we investigated the origin of the high autotrophic biomass accumulation regularly observed in the SAZ (Sub-Antarctic) south-east of Tasmania compared to the relatively poorer waters south-west of the island. As diatoms are an inordinate role in the Si biogeochemical cycle was fully characterised during this cruise, with measurements of siliceous biomass, Si uptake and dissolution rates, and diatom taxonomic diversity. Complimentary to taxonomic identification, particular emphasis was put on the activity of key species in the silification process. The recent development of new molecular markers (fluorescent hybridization methods) have made it possible to visualize important biogeochemical processes such as biogenic silica production down to the level of individual cells. The new PDMPO-marker methodology allows quantification of the relative contribution of each cell or diatom species against total Si uptake rates by using image analysis in epifluorescence microscopy. The first results of this new combined isotopic and fluorescent probe labelling will be presented here and will give fresh insights into who does what within the diatom community.

TOPOGRAPHIC-CHANGE ANALYSIS OF SANDY HOOK, NEW JERSEY, BASED ON LIDAR DATA

Three lidar surveys at Sandy Hook, New Jersey, acquired in October 2002, April 2004, and May 2005, were used to identify areas that had undergone significant topographic change. The first analytical step calibrated the third lidar datasets to ensure that vertical-elevation values did not change in areas where change was known not to have occurred, such as in parking lots, on tennis courts, and on roofs of flat buildings. Next, elevation-difference maps were created, and areas with vertical change greater than 1 m were analyzed on a smaller scale. The large elevation changes were mostly observed on the beach face along dunes, which were further analyzed for change in volume and surface area. The elevation-difference map between the 2002 and 2005 surveys showed change that occurred because of erosion. The comparison between the 2005 and 2007 surveys revealed a period of depositional change. Although there was erosion in the northeastern section, in the 2002 to 2005 and the 2005 to 2007 survey comparisons, the difference map between the 2007 and 2002 surveys showed the overall trend was depositional throughout the region.

TEACHING RAPID CLIMATE CHANGE USING EXAMPLES FROM THE GEOLGIC RECORD - A DISCOVRY-BASED LEARNING MODULE FOR THE PALEOECO-EOCENE THERMAL MAXIMUM

Science educators are increasingly incorporating aspects of climate change into primary and secondary school curricula, but teaching about climate change requires context from the geologic record. How has the Earth’s climate varied in the past, and how does the current rate of climate change compare to ancient events? We have created an inquiry-based learning module focused on the Paleocene-Eocene Thermal Maximum (PETM), one of the most prominent and relevant examples of rapid global warming known in the geologic record. The PETM occurred 55 million years ago and was characterized by global warming, significant changes in the carbon and hydrologic cycles, and a myriad of biotic responses. Our learning module is based on two types of primary data - the ‘shipboard data’ collected during Ocean Drilling Program drilling operations aboard the JOIDES Resolution, as well as “shore-based” analyses. The progression of the exercise allows students to experience the initial discovery of the signature of the PETM in deep-sea sediments and then compile data collected from 9 deep-sea drill sites into a global picture to reconstruct the magnitude and scope of the event.

PARTICULATE ORGANIC MATTER AND BALLAST FLUXES MEASURED USING TIME- SERIES AND SETTLING VELOCITY SEDIMENT TRAPS IN THE NORTHWESTERN MEDITERRANEAN SEA

Gravitational sinking of particulate organic carbon determines most of the rate at which the ocean absorbs CO2 from the atmosphere and sequesters it in the deep ocean. Prompted by suggestions that POC flux into deep water is influenced by ballast mineral
model combines Z-grid and sigma-grid in the vertical direction. Following the UnTRIM model, this new model solves the 3D equations of motion in the unstructured grid using the Eulerian Lagrangian Method without mode-splitting. The model was applied to simulate estuarine/coastal circulation during normal conditions and extreme events, i.e., storm surge and inundation during hurricanes in 2004/2005. While the Z-grid model and sigma-grid model yielded similar results during normal conditions (tides for GOM), simulated storm surge and currents in shallow coastal regions from the Z-grid and sigma-grid models differ significantly. During periods with significant water level fluctuation, sigma-grid model yielded much more accurate water level and currents than the z-grid model, due to the inability of Z-grid to resolve the near-surface layer.

WAVE EFFECTS ON SEDIMENT TRANSPORT ON THE TIDAL FLAT, GANGWHA, KOREA

Tidal flats of Incheon, Korea are located off the coast of the Han River mouth. The extensive macrotidal mud flats, for which tidal range exceeds 9 m, are unique in that freshwater discharge during the summer wet season influences the region, while strong waves dominate resuspension and transport processes during winter. A field campaign initiated to better understand imparting influences of these processes and a benchtop pod was deployed in a tidal channel in Southern Gangwha tidal flats during November, 2006 and September-October, 2007. Instrumentation on the pod includes one Acoustic Doppler Velocimeter, one Acoustic Backscatter System, and two Optical Backscatter Sensors. Sediment suspension mainly occurred during the accelerating phase of flood and ebb. On the other hand, deposition occurred during the slack after flood when waves were relatively weak. When waves reduced, shear appeared to support sediment suspension even during the slack after the flood. This phenomenon has an important ramification on sediment budget on the upper reach of tidal flat.

INTERNAL TIDAL CURRENTS IN THE KAOPING SUBMARINE CANYON

Data from five comprehensive field experiments during years 2000-2006 were used to study the internal tidal flow pattern in the Kaoping Submarine Canyon (KPS), Taiwan. The internal tides are large with interface displacements of about 200 m and maxima velocities of over 100 cm/s. They are characterized by a first-mode velocity structure with zero crossing at about 100 m depth. In the lower layer, the currents increase with increasing depth. Vertical phase shift is apparent, especially in the upper layer. Also, the density reaches the maximum at about the end of the flood currents, indicating a predominant standing wave pattern.

MODELING OF WIND-DRIVEN INTERACTIONS AT THE ESTUARY/OCEAN TRANSITION

This study focuses on the reciprocal influence that an estuary and its adjacent shelf exert under the influence of wind forcing. In particular, the bathymetric effects on the wind-driven circulation at the transition between an idealized estuary and the adjacent ocean are studied with the Regional Ocean Modeling System (ROMS). Distinct simulations are performed to compare wind-driven patterns resulting over flat bottom, under various wind velocities, to those over bathymetry. The effects of density gradients are added to the patterns that arise for wind-driven flow over bathymetry. Finally, the effects of tidal forcing are assessed. The relative contribution of wind and density gradients is described in terms of the non-dimensional Wedderburn number, whereas the competition between tidal forcing and density gradients is depicted in terms of the vertical Ekman number. Results suggest that under most cases of Wedderburn and Ekman numbers tested, the flow is mildly affected by bathymetry. The greatest bathymetric effects are observed at Ekman numbers of order 1, regardless of the Wedderburn number.

AN UNSTRUCTURED-GRID 3D HYDRODYNAMIC MODEL FOR SIMULATING ESTUARINE AND COASTAL HYDRODYNAMICS DURING NORMAL AND EXTREME EVENTS

An unstructured-grid hydrodynamic model is developed and applied to simulate estuarine and coastal circulation during normal conditions and extreme events. The model was developed using combined finite difference and finite volume methods for unstructured grids (both triangular and quadrilateral). While finite volume method is naturally applicable to unstructured grids, finite difference method is more efficient. In addition, this

ENSO TELECONNECTION TO THE TROPICAL NORTH ATLANTIC
Studies have shown that the existence of El-Niño in boreal winter does not always guarantee
a warmer-than-normal tropical North Atlantic (TNA) condition the following spring-
summer. In this part, it is due to instances where an interfering positive North Atlantic
Oscillation (NAO) pattern strengthens the North Atlantic sub-tropical high (NASH) and
increases the evaporative cooling over TNA, thus counteracting the opposite tendency
emanating from the Pacific. Other potentially important factors include the changes in
El-Niño and its teleconnection patterns in response to the decadal- to multidecadal climate
fluctuations that modulate the background mean state. In this study, we explore the ENSO
teleconnection to TNA under the influence of decadal-multidecadal (global and regional)
climate fluctuations by a simplified linear model (LBM) and the NOAA Community
Atmospheric Model (CAM) coupled to a slab mixed layer ocean model.
Several sets of model experiments are performed by prescribing the global SSTs while
using the slab ocean model to simulate the SSTs in the TNA region.

CARBON AND NITROGEN UPTAKE RATES OF PHYTOPLANKTON FROM IN SITU INCURBATIONS UNDERS THE SEA ICE IN THE CANADIAN ARCTIC
Although ongoing changes in climate and ice conditions are expected to alter the carbon
and nitrogen uptake rates of phytoplankton as primary producers in the Arctic Ocean,
recently a few measurements have been done in the Canada Basin. The expedition in 2005
allowed us to provide a valuable data for the uptake rates of phytoplankton under the sea
ice from in situ incubations, compare them with the 2002 data under different environ-
mental conditions in the same basin, and form a backbone for any future discussion of impacts
global warming on the primary productivity in the region. The patterns of nutrient
concentrations were similar, whereas the surface water temperature patterns were quite
different between the two data sets in 2002 and 2005. Since stronger light intensity through
the sea ice reached to the ice bottom in 2005, the carbon and nitrogen uptake rates of phyto-
plankton under the sea ice were higher in 2005 than in 2002. The mean f-ratio from this study in 2005 was 0.31 (±0.12) which is within the range in the Arctic Ocean.

DECADAL VARIABILITY IN THE INDO-PACIFIC OCEAN INFERRED FROM SATELLITE DATA AND ECCO ASSIMILATION
The nearly one-and-a-half decades of coincident satellite observations of sea surface
height (SSH) and vector wind are used to describe the decadal variability of the Indo-
Pacific region along with and an ECCO ocean assimilation product (http://ecco-group.
org). A near-coherent phase change of decadal SSH and wind is found out over much of the
Indo-Pacific region. The changes in the tropical Pacific tend to lead those in other areas.
The trade winds in the Pacific and Indian Oceans are anti-correlated to each other. Associated
with this is the anti-correlated variability in the strength of the shallow meridi-
onal overturning cells in the two oceans (the subtropical Oceans). Horizontal gyre circula-
tions in the subtropical and subpolar regions also experience near-coherent variation in
their strengths. Atmospheric and oceanic linkages of these variations are discussed.

HYPOXIA IN LONG ISLAND SOUND: ANTHROPGENIC OR CLIMATE INDUCED?
The factors controlling bottom dissolved oxygen (DO) in Long Island Sound (LIS) exhibit
temporal and spatial changes. For non-summer seasons, the bottom DO is mainly driven by
solubility. During summer, however, intensified stratification under weak wind condi-
tions leads to the depletion of bottom DO from the saturation level. Stratification plays a
role in the variability of the bottom DO for the westernmost and shallow (<15 m) stations,
but its importance diminishes at deep stations (>20 m). The bottom DO tends to reach
its minimum concentration when bottom temperature is around 19~20 °C, although the
importance diminishes at deep stations (>20 m). The bottom DO tends to reach
its minimum concentration when bottom temperature is around 19~20 °C, although the
importance diminishes at deep stations (>20 m). The bottom DO tends to reach
its minimum concentration when bottom temperature is around 19~20 °C, although the
importance diminishes at deep stations (>20 m). The bottom DO tends to reach
its minimum concentration when bottom temperature is around 19~20 °C, although the
importance diminishes at deep stations (>20 m). The bottom DO tends to reach
its minimum concentration when bottom temperature is around 19~20 °C, although the
importance diminishes at deep stations (>20 m). The bottom DO tends to reach
its minimum concentration when bottom temperature is around 19~20 °C, although the
importance diminishes at deep stations (>20 m). The bottom DO tends to reach
its minimum concentration when bottom temperature is around 19~20 °C, although the
importance diminishes at deep stations (>20 m).
cent-chance annual storms can generate elevated water levels on the order of 4 m in the Florida Keys and of order 1.5 m on overland wave propagation. For situations where the maximum elevation of an island is below the 1% SWEL elevation, the parameter of interest governing overland wave propagation is vegetation rather than topography, with regard to the specification of velocity hazard zones. Land-use practices, including the clearing of vegetation, may have an effect on coastal flooding. Wave damping, static set-up and the extent of overland wave propagation as a function of the damping effects of vegetation was examined both spatially and temporally. Velocity hazard delineations were mapped using FEMA’s CHAMP model as a framework to examine changes in zones with respect to the spatial scale of a mangrove stand as well as with temporal changes in mangrove coverage. Linear wave theory was applied to illustrate the effects of the additional damping force on overland wave propagation.

PRIMARY PRODUCTION OF DISSOLVED AND PARTICULATE ORGANIC CARBON IN OCEANS

Total net primary production (FT) of marine phytoplankton includes recently fixed carbon in both particulate (PP) and dissolved (PD) components (PT=PP+PD). In the absence of PT or PD measurements, publications often assume that PD is negligible, particularly in eutrophic systems, or use the frequently-cited constant value PD/PT=+13%, or select values that seem appropriate within the range of field observations (PD/PT=5 to 40%). A growing number of observations suggest PD/PT=+0%, or compute it from concurrent measurements of FT and PP. Common methods (mainly variants of the C-14 method used to measure PP) reflect a combination of direct release from intact phytoplankton, cell lysis, protoplasm osmotrophy, grazing and excretion, and bacterial osmotrophy and excretion. Community composition and incubation conditions (light, temperature, nutrients and duration) may affect the overall and relative importance of these processes. In addition, filters used to separate particulate and dissolved matter may affect PP and PD. We present a meta-analysis of >1000 published field values from contrasting marine ecosystems, recommend best methodological practices, and discuss the importance of PD in oceans and its biological and environmental controls.

INTERNAL HYDRAULIC JUMPS GENERATED BY TIDAL FLOW OVER A TALL STEEP RIDGE

The interaction between tidal currents and oceanic topography is known to provide a mechanism for transferring tidal energy into baroclinic motion. This mechanism is hypothesized to provide a significant fraction of the energy needed for deep mixing in the ocean. A subject of ongoing investigation is the partitioning of that baroclinic energy into motions likely to lead to mixing local to the topography and radiating internal waves which ultimately cause mixing elsewhere. Here we examine one process which may lead to local mixing, namely the generation of transient internal hydraulic jumps. These tidally-driven jumps are predicted to occur when the vertical tidal excursion is large, which is shown to occur over a variety of pressures and durations. The vertical length-scale of the jumps is predicted to depend on the flow speed such that the jump Froude number is of order unity. A series of numerical simulations explores the parameter space of topographic slope, barotropic velocity, stratification and forcing frequency. Results agree with the theoretical predictions, with finite amplitude internal hydraulic jumps and overturning forming during strong offshore tidal flow over steep slopes.

MICROCYSTIS IN THE SAN FRANCISCO ESTUARY

The impact of the recently developed CHAB Microcystis on the San Francisco Estuarine food web is unknown. It is hypothesized that Microcystis contributed to a recent decline in fishery production directly through its toxicity or indirectly through its impact on the structure of the food web. To initially evaluate these hypotheses, phytoplankton, zooplankton and fish were collected bivweekly at 10 stations throughout the estuary in 2005. Microcystis in algal and animal tissue were measured by protein phosphate inhibition method. Microcystins were present at low concentrations throughout the food web. Higher microcystins were associated with different cyanobacteria across the estuary in the surface layer and different phytoplankton communities at depth. Thus, even at low density Microcystis may influence fishery production.

AEROCBR RESPIRATION AND HYPOXIA IN THE LOWER SI. L. W. ESTUARY: CONSTRAINTS FROM STABLE ISOTOPE RATIOS OF DISSOLVED OXYGEN IN THE WATER COLUMN

Along the Laurentian Channel, a large-volume water body displays persistent hypoxic conditions, with deep-water oxygen (DO) concentrations as low as 51 nmol/L. The present DO deficiency is part of an ongoing trend that persists for at least the last seven decades and can partly be ascribed to an increase in organic particle flux to the sea floor and enhanced bacterial respiration rates. The relative role of the benthic versus the deep pelagic environment as sites of DO consumption, however, remains uncertain. We report concentration and stable isotope measurements of dissolved oxygen in the estuary and the Gulf of St. Lawrence water column, which show a significant increase in the 18O:16O ratio with progressive DO depletion. We discuss the observed net O-isotope effect for community respiration in the deep layer of the estuary in terms of the relative importance of benthic versus water column respiration, and we will compare the findings based on the O-isotope approach with direct bacterial production measurements in the water column and reported estimates on benthic O2 fluxes for the St Lawrence system.

A BIO-OPTICAL PRODUCT FROM A COUPLED BIO-PHYSICAL OCEAN CIRCULATION MODEL OF THE WESTERN NORTH ATLANTIC

Autonomous observation platforms supply information on the biological, physical and chemical state of the ocean that lends itself to validation of and assimilation into coupled bio-physical circulation models. However, conversions are necessary to relate observed quantities to modeled variables. Traditionally, this conversion is done to observations, for instance, relating the ratio of blue and green light intensity to chlorophyll concentration in the water. We implemented a coupled bio-physical Regional Ocean Model (ROMS) with bio-physical equations to produce fields directly comparable to routine observations from optical sensors on moorings, gliders, floats and satellites. We contrast modeled fields of water leaving radiance at standard wavelengths to corresponding fields from satellite sensors.

WIND FIELD AND SEA STATE DERIVED FROM TERRASAR X IMAGES

TerraSAR-X is a new X-band radar satellite launched on June 15, 2007. In this mission an operational, space-borne synthetic aperture radar (SAR) system with very high spatial resolution is acquiring imaging modes like Stripmap, Spotlight and ScanSAR. The spacecraft is equipped with a phased array X-band SAR, which can operate in different polarisations and has furthermore beam steering capabilities. Due to its polarimetric and interferometric capabilities as well as the high spatial resolution of up to 1 m, the TerraSAR-X sensor is an interesting tool for coastal oceanography. An overview of several marine applications is given, e.g., current and ocean wave measurements, monitoring of morpho-dynamical processes and high resolution wind field retrieval. A combination of theoretical investigations adapting C-band algorithms and the use of existing experimental data acquired by both airborne and ground based X-band radar is used to derive a new X-band wind field algorithm. Case studies of wind and ocean wave parameter retrievals will be presented, e.g., based on TerraSAR-X scenes taken over the English channel and the coast of Florida.

SEDIMENT METABOLISM ON THE LOUISIANA CONTINENTAL SHELF

Rates of aerobic and anaerobic sediment metabolism were measured on the Louisiana Continental Shelf during 5 cruises in 2006 and 2007. On each cruise, 3-4 stations were occupied in regions of the shelf that experience summer-bottom water hypoxia. Net DIC, O2, N2, and nutrient fluxes across the sediment-water interface were measured in static core incubations. Sulfate and iron reduction rates were measured in vertical core sections. Sediment cores were also exposed to varying levels of light to assess the photosynthetic potential of benthic microalgae. Whole sediment metabolism was estimated via
a sediment diagenesis model. DIC fluxes did not vary greatly across the shelf with a range of 133 to 5 mole m⁻² d⁻¹, and N₂ fluxes ranged from 0 to -29 and 0 to 1.9 molmes ⁻² d⁻¹, respectively. Experimental and modeling results indicated sulfate and iron reduction were important carbon remineralization pathways. Surface sediments exposed to 0.5 to 1.0% ambient light showed rapid increases in O₂ indicating the potential for benthic photosynthesis. Sediment metabolism will be compared with rates of water-column metabolism measured at the same stations.

CONDUCTING OCEAN FERTILIZATION IN A RESPONSIBLE WAY

The ocean science community, NGOs, government and the private sector are considering issues related to the potential of ocean fertilization to sequester CO₂. Most issues are scientific and concern the efficacy or the side effects of ocean fertilization. Uncertainty about how commercial ocean fertilization would be conducted has led to additional concern over the types and standards of measurement, independent verification, management of side effects, the availability of data from commercial fertilization projects, deployment in sensitive marine areas, and other issues. Ocean fertilization is likely to take place on the high seas beyond national jurisdictions. There is as yet no clear international regulatory frameworks that apply directly to this activity. This implies that a voluntary code of conduct might be helpful in identifying the standards of responsible behavior. Other fields, like nanotechnology, have dealt with issues of ethics and responsibility in commercialization of scientific ideas. Drawing on such examples, we propose elements that could be included in a code of conduct for responsible ocean fertilization experiments and activities related to commercialization.

SEASONAL TO PENTADAL CARBON CYCLING IN SANTA MONICA BAY, CA

Time-series measurements of inorganic carbon, nutrients, and physical parameters were initiated in 2003 on a bi-weekly basis in the upper 300m at a coastal site in Santa Monica Bay, CA. Our nearly 5 years of DIC measurements reveal a complex seasonal pattern with a tendency for a maximum in late winter to late spring and a minimum in early summer. The spring time DIC maxima are associated with episodic and short-lived upwelling events that are in general followed by a short period with a moderate to strong decrease in DIC due to both CO₂ outgassing and DIC uptake by phytoplankton, mainly diatoms. Our record also reveals a number of strong drawn-down events that occur in summer and fall, when nitrate is completely exhausted, for reasons not yet fully understood. Over the annual cycle, Santa Monica Bay is mostly undersaturated with respect to atmospheric CO₂, constituting a net sink of the order of 0.5 mol C m⁻² yr⁻¹. Interannual variability in the time-series record is controlled by the frequency and strength of the spring-time upwelling events.

SIGNALS OF LANDSCAPE DESTABILIZATION ON CONTINENTAL MARGINS—COMPARISONS OF ORGANIC GEOCHEMICAL RECORDS FROM THE EEL AND WAIAPOA SHELVES

The sedimentary and geochemical signals of landscape destabilization are transmitted through small mountainous watersheds to the continental margins with particular efficiency, largely because such systems typically have little capacity for sediment storage. On the continental shelves offshore from both the Del River in northern California and the Waiapoa River on the North Island of New Zealand, for example, historical deforestation is recorded by shifts in the concentration, age and isotopic composition of discrete plant fragments and organic matter bound to mineral grains. These changes likely reflect perturbations in the residence time of OC within the watersheds and the surface mixed layer of the seabed, as well as the relative importance of the key processes of sediment production: bedrock incision, shallow landsliding, and bank failure. Preliminary results indicate that the signals of earlier episodes of landscape destabilization are similarly preserved throughout the Holocene record of the Waiapoa margin.

INTERNAL TIDE GENERATION BY SURFACE-TIDE/EDDY INTERACTIONS

Internal tide generation by the interaction of surface (barotropic) tidal currents with bottom topography is familiar and well-studied. Internal tides can also be generated by the interaction of surface tidal currents with baroclinic geostrophic eddies. Using a wave-tri-ad approach, it is found that resonant generation of internal tides occurs if the eddy aspect ratio is comparable to that of a semidiurnal internal wave as is the case near 45 degree latitude. The baroclinic tide will become of comparable energy to the barotropic tide in a time of order the inverse geostrophic shear V¹. Analytic solutions are complemented with results from a numerical model.

ENSO IN THE IPCC-AR4 MODELS: A MULTI-VARIABLE APPROACH

In a pilot study, the sea surface temperature (SST) of the equatorial Pacific was used to characterize the ENSO spatial signature in the models simulating the “Climate of the 20th century” (from IPCC-AR4). Using an original methodology based on self-organizing maps, which allows for intercomparison of all the models, common biases were identified between groups of models in the ENSO variability and during key-phases of El Niño and La Niña (peak, and transition). In the present study, a multi-variable approach (SST, precipitation and winds) is adopted to further identify the physical mechanisms explaining the similarities and differences in the ENSO characteristics simulated, both spatially and temporally, for the pre-industrial conditions (picntr) by the IPCC-AR4 models.

UTILIZATION OF THE BOTTOM STATIONED OCEAN PROFILER FOR COASTAL OBSERVING APPLICATIONS ON THE WEST FLORIDA SHELF

The Bottom Stationing Ocean Profiler (BSOP) is an autonomous, freely drifting, vertically profiling vehicle designed for applications on the continental shelf. By parking on the bottom in between profiles, BSOP tends to maintain station under typical continental shelf conditions. Designed and developed by the University of South Florida's Center for Ocean Technology, BSOP carries sensors, collects, stores, and transmits data via a bi-directional satellite link, and may be reprogrammed in situ to alter mission objectives. During the past several years, extensive offshore use in a multitude of deployment scenarios has demonstrated the operational uses and limitations of the platform. BSOP performance characteristics and reliability illustrate the utility and potential importance of profiling vehicles for continental shelf applications as part of coastal ocean observing systems.

A KARENIA ODYSSEY: MODEL IMPLICATIONS FOR CURRENT AND FUTURE UNDERSTANDING

Arrival of iron-rich Saharan dust on the outer West Florida shelf each summer interrupts the normal seasonal succession of phytoplankton, from diatoms to microflagellates, of temperate and subtropical shelves. Instead, iron-starved diazotrophs fix the ubiquitous dinitrogen gas, passing this "new nitrogen" in the form of dissolved organic matter of reduced carbon content to the euphotic zone. Observations of the seasonal succession through time have demonstrated the operational uses and limitations of the platform. BSOP performance characteristics and reliability illustrate the utility and potential importance of profiling vehicles for continental shelf applications as part of coastal ocean observing systems.

Lengaigne, M., LCEO-FRSL, Paris, France, langaigne@ocean.iupagene.fr
perature in the upper ocean are used to estimate eddy fluxes of heat and momentum in the surface layer of Drake Passage. Fluxes are ensemble averaged along mean streamlines to improve statistical significance. The acceleration/deceleration due to the eddy momentum flux divergence coincides with the merging/diverging filaments of the ACC fronts. Significant along-stream eddy heat fluxes are observed in the Polar Front. The observations are compared to output from a tenth-degree, 40-level simulation of the Parallel Ocean Program (POP) model. Preliminary calculations show that the model has a similar distribution of eddy kinetic energy to the observations, although the absolute values are somewhat smaller.

Lentz, S. J., Woods Hole Oceanographic Institution, Woods Hole, USA, slentz@whoi.edu
A BRIEF OVERVIEW OF INNER SHELF CIRCULATION AND DYNAMICS

Recent progress in our understanding of the inner shelf circulation and dynamics is reviewed. The inner shelf is the region between the surf zone, dominated by surface gravity waves, and the mid shelf, dominated by wind forcing (water depths of ~5 - 50 m). The inner-shelf circulation is central to a wide range of interdisciplinary processes, including coastal upwelling of nutrients, the movement of organisms between estuarine or intertidal waters and the mid shelf during different life cycle stages, the off-shore movement of sediment, the offshore dispersal of pollutants, and the deposition of contaminants such as oil spills onto beaches. Previous studies have focused on along-shelf wind stress as the primary forcing mechanism of inner-shelf cross-shelf circulation. However, recent studies indicate the inner-shelf cross-shelf circulation is forced primarily by surface gravity waves (undertow) and cross-shelf wind stresses, not along-shelf wind stresses. The vertical structure of the wave-driven circulation over the inner shelf is different from the surf zone due to the earth's rotation. Stratification enhances the wind and wave-driven exchange flow but the dynamics of the stratified response are unclear.

RATING CAGE IN THE UNGAUCED CAQUETA BASIN COMBINING ALTIMETER-DERIVED WATER STAGES AND DISCHARGE PROPAGATED FROM REMOTE STATIONS

Provide distributed discharges is a major task of hydrological monitoring. However, fewer and fewer in-situ measurements are collected each year wherever over the world. From the last two years, virtual gauges have been proposed to increase the density of the river monitoring network in Amazon basin (Leon et al. 2006). In spatial hydrology a virtual station is considered as any crossing of water body surface (i.e., large rivers) by radar altimeter satellite Tracks. We present rating curves obtained for thirteen virtual gauge stations at the main stream of Caqueta Basin, a poorly gauged basin in the Colombian Amazon basin. Water stages have been derived from satellite altimetry (T/P and ENVISAT). Discharges were propagated at the location of the satellite tracks from remote gauging stations using a 1D Muskingum-Cunge model. Validation has been conducted by comparing the results with stages and discharges measured at five in-situ gauges available on the Caqueta main stream. Outflow errors range from 10% to 20% between the upper basin and the lower basin respectively. The method proposed by Leon et al. (2006) to deduce zero flow depth at virtual stations was applied and its allows to find mean absolute differences less than 1.1 m estimated and measured zero flow depth. Finally, a 1.2 x 10-4 m.m-1 mean bottom slope has been obtained for the 730 km long reach of the considered stream.

A SNAP-SHOT LOOK AT THE 210PO-210PB BALANCE IN WESTERN LONG ISLAND SOUND

We measured Lead-210 and Polonium-210 as well as physical water quality parameters during a 6-day cruise in late June, 2006 between Oyster Bay and Throgs Neck Bridge in the Narrows of Western Long Island Sound. Preliminary results indicate a well mixed water column with high levels of re-suspended sediment carrying excess lead-210. One significant hydrological feature observed was a well-defined border between two distinct water masses north of Hempstead Harbor, in the area of the Hempstead Sill. The western mass was dominated by a high sediment load and low fluorescence, whereas the eastern counterpart displayed higher biological productivity. Elemental analysis is underway to confirm this observation. This study is an attempt to expand on previous observations on estuarine circulation using natural radionuclides conducted during the 1970’s in Eastern Long Island Sound.

OBSERVATIONS OF PLANT FLOW INTERACTIONS IN THE RIDGE AND SLOUGH LANDSCAPE OF EVERGLADES NATIONAL PARK

Standing biomass exerts considerable control over flow dynamics on the surfaces of coastal wetlands. This presentation will examine surface hydrodynamics and plant flow interactions in the freshwater wetlands of Everglades National Park. During the wet seasons between 2002 and 2007, we routinely measured all 3 velocity components at slough and ridge sites located in upper Shark River Slough. Flow velocities were usually less than 2 cm/s with higher velocities typically occurring in the sloughs compared to the sawgrass ridges (0.50 cm/s and 0.34 cm/s, respectively). In both settings, flow characteristics were strongly affected by the distribution of biomass in the water column; particularly in the slough where both emergent and submerged vegetation were present. Vertical flow profiles and series of clearing experiments showed that flow speeds can increase by as much as three times when submerged biovolume (e.g. utricularia spp. and periphyton) is removed. Interestingly, the presence of emergent stems, did not appreciably affect mean flow speed. These results suggest that both seasonal changes in water level and biovolume control flow in the Everglades.

ASSESSING THE ISOTROPY OF TURBIDITY USING BROADBAND ACOUSTICS

Acoustic backscatter returns from turbulent oceanic microstructure have the potential to remotely describe temperature and salinity variations and identify turbulent dissipation rates. Oceanic turbulence models that relate acoustic backscatter levels to turbulence parameters generally assume that turbulence is isotropic, and there is a lack of experimental verification or dispute on isotropy or anisotropy is crucial to refining turbulence models and advancing reliable acoustic detection of turbulence. Broadband (150-600kHz) acoustic scattering measurements were performed over the New Jersey continental shelf, observing the passage of internal waves and their turbulent wakes. To address this anisotropy, the instrument collected data in both horizontal (longitudinal) and vertical looking modes while tracking a wave train. In most locations, the acoustic spectra are generally flat or increasing with frequency, and are not consistent with scattering dominated by temperature microstructure. Some locations, however, do show an expected spectral roll-off for turbulent scattering. Preliminary comparisons between vertical and horizontal data show similar spectral levels and frequency dependence, suggesting that if the scattering is due to turbulence, the turbulence is isotropic.

PHYSIOLOGICAL RESPONSES AND PRODUCTION OF PHYTOPLANKTON DETERMINED FROM VARIABLE FLUORESCENCE QUANTUM YIELD

Biological processes of phytoplankton in the ocean play a dominant role in controlling the global carbon cycle. Understanding the variability in the physiological characteristics of phytoplankton could enhance the ability in predicting productivity, and thus lead to a better understanding in the influence of phytoplankton on global cycling. The present study examined the variability in physiology and productivity of phytoplankton in Sagami Bay, Japan using the fast repetition rate fluorimeter (FRRF), and investigated the possible causes of the variations in these parameters. Diel variations in the functional absorption cross-section (SPS2), photochemical quantum efficiency (Fv/Fm) and productivity were observed. FRRF profiles also showed distinct near-surface quenching. These observations can be viewed as a strategy on balancing carbon fixation and light absorption. Moreover, light availability was shown to be an important factor contributing to the varying Fv/Fm and SPS2. The varying productivity observed could be a result of the Fv/Fm and SPS2 gradients observed. The effect of environmental conditions on phytoplankton physiology observed using the FRRF technique could narrow the gap in our ability to estimate and predict primary productivity.

SELL DYNAMICS AND FJORD DEEP WATER RENEWAL: IDEALIZED MODELING STUDY

Fjord exchange circulation and its response to abrupt changes in forcing is examined by means of an idealized modeling experiment. Puget Sound, a fjord-type estuary in western North America (State of Washington), is the main context for this study. Parameters of the idealized model are representative of the entrance sill at Admiralty Inlet and the Main basin of the Sound. Sensitivity to some of the model parameters relevant to a 3D realistic model is discussed. An idealized tidal forcing with fortnightly modulation drives a qualitatively realistic cyclic of exchange circulation while the other boundary conditions are kept fixed in time. The cycle is characterized by anisotropy of cloudiness with a sharp front at the leading edge and reversed circulation cells below the sill depth developing between the intrusions. This basic state is then perturbed and response of the circulation to abrupt changes in oceanic salinity and river discharge is examined. Sudden increase in river discharge is shown to prevent onset of the intrusions.
The influence of the Columbia river plume on patterns of phytoplankton growth, grazing and chlorophyll

EXAMINATION OF ORGANIC MATTER IN SEDIMENT CORES TO ELUCIDATE ANTHROPOGENIC IMPACTS WITHIN THE SACRAMENTO-SAN JOAQUIN RIVER DELTA, CA

Sediment core records of organic biomarkers and stable and radio carbon isotopes provide high time-resolution of anthropogenic activities have altered the sources, amount and "ages" of organic carbon within ecosystems. Anthropogenic impacts including changing land-use practices have impacted systems like the San Francisco Bay and its associated Delta. For this study, sediment cores were collected within the San Joaquin and Sacramento Rivers as well as reference sites representing marsh and agricultural tracts. Dwncore profiles of organic biomarkers and stable isotopes were used to elucidate changes in organic matter sources over time. Radiocarbon (14C, 26O) and organic pesticides (bromodiphenyl ethers (BDE) and DDE (a degradation product of DDT) were used to estimate sediment accumulation. Together, biomarkers and anthropogenic organic compounds document shifts in the relative abundance of carbon from aquatic, terrigenous and anthropogenic sources in response to changes in land use and human activities over historical timescales. By examining sediment records we can better understand how anthropogenic activities impact carbon cycling within coastal ecosystems.

THE TIME-DEPENDENT SECONDARY CIRCULATION IN A STRAIGHT, PARTIALLY STRATIFIED ESTUARY

Observations are analyzed to quantify the structure of the cross-channel (secondary) circulation in the Hudson River estuary and its dependence on tidal amplitude and fresh-water discharge, at a cross-section where forcing due to curvature is insignificant. For all conditions, the secondary circulation is asymmetric, with strong flows (~20 cm/s) during weak tides and weak flows (~2 cm/s) during strong tides. The structure of the flow is independent of discharge, but dependent on tidal amplitude. During weak tides (strong stratification), secondary flow has a mode-one structure during flood. Fluid flows to the channel from the western flank at the top of the bottom boundary layer and returns to the flank at the surface and the bottom. During strong tides (weak stratification), secondary flow has a mode-two structure during flood. Fluid flows to the channel from the western flank at the top of the bottom boundary layer and returns to the flank at the surface and the bottom. During weak tides, the fluid flow boundary layer reaches the surface, secondary flow has a mode-one structure, with surface flow towards the channel and bottom flow towards the flank. Advection due to secondary flow is a significant term in the along-estuary momentum budget during strong tides, but not during weak tides. However, cross-channel advection is a significant term in the salt balance for both strong and weak tides. In particular, during weak tides, vigorous mixing of stratified fluid occurs where the pycnocline intersects the bottom boundary layer on the flank. This mixed water is injected into the channel interior below the pycnocline. Bottom and sur

SCIENTIFIC AND OPERATIONAL OCEAN MODELING AND DATA ASSIMILATION

The impacts of human activities on the ocean are increasingly global. To successfully coexist with the ocean and utilize marine resources, our civilization needs to monitor and predict the impacts of our activities, and to develop efficient ocean observing systems. Better scientific understanding and better forecasting of environmental impacts requires synergies between ocean predictions and observations. Important feedbacks include models that learn from and adapt to data, and sampling plans that learn from and adapt to model estimates. Such integrated ocean observing and prediction systems consist of a large set of coupled components, from the data utilized to the numerical schemes, and from the methods employed to the scientific approach of the modeller. All of these components can have a large impact on the outcomes. Examples and results will be provided for physical, biogeochemical and acoustic ocean dynamics and processes in eastern and western coastal US regions, from tidal scales and sub-mesoscales to mesoscales. Recent technical results in adaptive data assimilation, uncertainty estimations, bias corrections, model comparisons and multi-model fusions will be illustrated.

Levett, E. W., NOAA/Laboratory for Satellite Altimetry, Silver Spring, USA, Eric. Levett@noaa.gov

INTERPRETING THE SEA LEVEL RISE RECORD FROM SATELLITE ALTIMETRY

The TOPEX/Poseidon, Envisat, and Jason-1 satellite altimeter missions provide a 15-year record of global sea level rise, which shows a rate of 3.2 ± 0.4 mm/year with significant interannual variability. Despite evidence of the accelerated melt of continental glaciers, the rate of sea level rise since mid-2004 has been much lower, 1.5 to 2.0 mm/yr, close to the 20th century rate determined by tide gauges. We present a new error analysis of the sea level record and calibration using a tide gauge network. An important goal of climate studies is to determine the relative contribution of steric (heating and salinity) and eustatic (melting ice, runoff, etc.) sea level rise and to understand how and why these contributions vary. Concurrent measurements from the Argo array of profiling floats and the GRACE gravity mission, which respectively measure steric and eustatic changes, provide an independent check. The accuracy of satellite gravity measurements varies significantly with spatial wavelengths. We present a spectral analysis of recent altimetry, hydrographic, and satellite gravity measurements and compare these results to output from GFDL and ECCO models. We also comment on the consistent with a reduction in the rate of ocean heat storage.

DORVILLEAIDAE AT METHANE SEEP S: A MODEL FOR UNDERSTANDING DIVERSITY ON THE CONTINENTAL MARGIN

Much of the faunal diversity on continental margins is associated with relatively small-scale habitat patches that have varying abiotic and biotic conditions. Methane seeps are one example of highly sulfidic habitat patches on the margin. Dorvilleid polychaetes have a predilection for these sulfidic settings and multiple species in the genera Ophryotrocha, Parogia and Exallopus co-occur at Pacific methane seeps. We combine ecological, geo-
chemical, physiological and phylogenetic approaches to explore the role of sulfide in driv-
ing terms of niche partitioning and evolutionary relatedness. Dorvilleid abundance and dis-
tribution, stable isotope values, environmental sulfide concentrations, and settlement preferences reveal partitioning of species based on geography, water depth, habitat (clam bed, microbial mat), diet, sulfide tolerance, and dispersal ability. Colonization patterns determined from short-term colonization tray deployments with manipulated sulfide levels reflect local habitat composition. Dorvilleid species at seeps are represented by several distinct evolutionary clades. Clades reflect geographic distributions, habitat affini-
ties, and/or reproductive constraints but not uniform sulfide tolerances; instead congeners exhibit divergent trophic and sulfide preferences.

CYCLE BACTERIALLY DRIVEN DIURNAL CHANGES IN THE UPPER OCEAN SULFUR CYCLE

The contribution of the internal tide to shelf circulation is discussed. 

temporal variability of the broader semidiurnal tidal band (including both M2 and S2) was 

with the modeled M2 barotropic tide derived from the Topex/Poseidon altimeter. The long 

interaction of the barotropic tide with topography, such as the steep and rough continental 

the potential activity of the bacterial DMS cleavage enzyme with peak activities occur-

ring in the 6 hours after sunset. This analysis suggests that, in the Sargasso Sea, changes in 

DMS and DMSP concentrations on diurnal timescales may be driven by changes in bacte-

rial DMS production rather than by phytoplankton productivity.

Levy, M., L. OCEAN-IPSIL-CNRS, Paris, France, marina@lode.jussieu.fr

THE MODULATION OF BIOLOGICAL PRODUCTION BY OCEANIC SUBMESOSCALE TURBULENCE

Submesoscale dynamics modulate biogeochemical budgets in a number of ways. I will re-

view some of these processes, with a focus on mid-latitudes open ocean. First, I will show 

that submesoscale dynamics induce both intense upwelling of nutrients and subduction of 

phytoplankton. Then, I will show some examples of horizontal stirring of phytoplankton 

and discuss the importance of stirring with respect to biogeochemical budgets. Finally, I 

will emphasize that submesoscale dynamics have a strong impact on productivity through 

their influence on the stratification of the surface of the ocean. These processes will be 

illustrated by high-resolution in-situ observations and by high-resolution process-oriented 

model studies. These processes have in common that they concern the short-term, local 

effect of oceanic turbulence on biogeochemistry. Recent modelling efforts to get a com-

plete picture, which also include the far-field long-term effect of eddies, will be presented.

MICROBIAL FUEL CELLS - FROM LABORATORY STUDIES TO APPLICATIONS

This paper presents results from the deployment of Microbial Fuel Cells (MFCs) in the sea 

and in rivers. Our goal is to use MFCs to power chemical sensors and telemetry systems in 

marine environment and in freshwater aquifers. Direct use of energy generated by (MFCs) 

is obstructed by several factors, of which the low cell potential, low power density and 

fluctuating environmental factors are the most obvious. We have designed a probe, which 

uses energy generated by MFCs and is equipped with power management circuitry and 

microprocessors to control the operation and to decide when and how much energy needs 

to be accumulated and when and how much energy needs to be used for the specific 

tasks - powering the sensors and the telemetry system. All electrical circuits of the probe 

are powered by the energy generated by the MFC. The probe was deployed and tested 

in the sea water - in Newport, Oregon - and in fresh water - in Hayle Creek, Bozeman, 

Montana and in Palouse Creek, Pullman Washington, and in our laboratories.

VARIABILITY OF THE NORTH ATLANTIC CIRCULATION MEASURED BY THE OVIDE PROJECT

The Ovide (A25) hydrological section extends from Cape Farewell (Greenland) to Lisbon (Portugal), crossing perpendicularly three major currents of the North Atlantic: the east Greenland Current, the Deep Western Boundary Current and the North Atlantic Current. The section, close to the 1997 FourEx section, was performed three times in 2002, 2004 and 2006, collecting physical and biogeochemical measurements at a hundred stations. The significative variability observed in both the estimated transports and the measured water mass properties will be discussed. Establishing a transport budget between the Greenland-Scotland sills and the section, it is possible to calculate the diapycnal transport between the North Atlantic Deep Water and the layer above. A proxy of the Atlantic Meridional Overturning Circulation across the Ovide section is proposed, leading to a discussion on the timescale of its variability and on its connection with the horizontal circulation and the poleward heat transport.

DEVELOPMENT OF AN AUTOMATED UNMANNED BOAT FOR MEASUREMENTS IN TIDAL PASSES

Three automated unmanned boats (A-Boat) are constructed at the Coastal Studies Institute, Department of Oceanography and Coastal Sciences, School of the Coast and Environment, Louisiana State University. With Visual BASIC, a controlling program is designed to run the remotely controllable boat for round-the-clock repeated sampling in tidally dominated channels. These boats, made with aluminum, plastic, and fiberglass, respectively, have been developed ranging from 10 to 12 ft in length, equipped with electric motors, a high-resolution GPS (60 Hz accuracy), and a windows-based computer system. The A-Boat is monitored on land while the A-Boat does preprogrammed tasks. This is accomplished by a wireless communication that can work for up to 10 km. As an initial test, we have used RD Instruments 600 and 1200 KHz Workhorse Monitor acoustic
Doppler current profilers (ADCP) mounted in one of the two wells on the boat and conducted continuous surveys across several tidal channels on the southeastern Louisiana coast. In this paper, we present some preliminary survey results at the Southwest Pass of the Vermilion Bay. Flow convergence and three-dimensional eddies are observed during the survey.

**MEAN FLOW EFFECTS ON THE PROPAGATION PATHWAYS OF EDDIES**

In the past we have shown that the large anticyclonic eddies generated south of Hawaii propagates along paths that are difficult to reconcile with existing theory. It was hypothesized that this was due to interactions with the mean flow. This work, however, only tracked a limited number of eddies and used only TOPEX/Poseidon altimeter data. Because of these limitations we were not able to address this hypothesis conclusively. We have since tracked a much larger number of eddies using data from all available satellite altimeters and we are also attempting to make estimates of the evolution of kinetic energy, potential energy and relative vorticity as the eddies propagate away from Hawaii. We will first show the results for this greatly extended set of eddies and show that the problem of unusual paths noted in the earlier work is still present; i.e., it was not an artifact of the small number of eddies and the single altimeter analysis. Second, we will present an evaluation of the mean flow interaction hypothesis posed in the earlier work.

**LARGE EDDY SIMULATIONS OF ESTUARINE MIXING PROCESSES**

We have developed and validated a new finite-volume Large Eddy Simulation (LES) model for oceanographic applications and used it to investigate mixing processes in stratified estuarine flows. Recent observations have shown that stratification and turbulent mixing exhibit a flood-ebb tidal asymmetry in estuaries and continental shelf regions affected by horizontal density gradients. However, several key questions on the tidal asymmetry remained unanswered. Is the mixing asymmetry caused by the flood-ebb asymmetry in the bed stress or due to tidal straining of the density field? What is the role of the strain-induced buoyancy flux which is stabilizing on ebbs but destabilizing during floods? Can the turbulent transport term supply turbulent kinetic energy (TKE) from the bottom boundary to the pycnocline? We use the LES model to investigate the penetration of relatively driven bottom boundary layer into stratified water in the presence of a horizontal density gradient. By analyzing turbulence fields and comparing the terms in the TKE budget, we examine how different factors affect estuarine mixing under various stratification and tidal current conditions.

**NUMERICAL MODELING STUDY ON COASTAL OCEAN BIOPHYSICAL RESPONSES TO HURRICANES**

A regional-scale coupled bio-physical model is used to hindcast the circulation and plankton distribution in the Gulf of Mexico (GOM) and South Atlantic Bight (SAB) during the periods of Hurricane Isabel, Ivan and Katrina. The physical model is based on the Regional Ocean Modeling System (ROMS), and the biological model is a nitrogen-based NPZD model. Surface forcing conditions are from the North American Regional Reanalysis (NARR), and the open boundary conditions are obtained through the one-way nesting with the North Atlantic data assimilative Hybrid Coordinate Ocean Model (HYCOM) solutions. Our regional model results are gauged against in-situ mooring observations and satellite remote sensing data. Based on time and space continuous model realizations, we diagnose variability of coastal currents, temperature and salinity fields during the passages of strong hurricanes. We also report our analyses on the relative importance of ocean advection, mixing and local upwelling in determining plankton distributions in the GOM and SAB.

**NUMERICAL MODELLING OF SEAED DISTURBANCE AND SEDIMENT MOBILITY, AND IMPLICATIONS TO MORPHODYNAMICS ON THE STORM-DOMINATED SABLE ISLAND BANK, SCOTIAN SHELF**

Waves, tidal currents, wind-driven and circulation currents, and sediment mobility were modelled for one full year over the storm-dominated Sable Island Bank (SIB), Scotian Shelf. The mean shear velocity of tidal current and that of the wind-driven and circulation currents are less than 2 cm/s, but the peak mean wave and combined wave current shear velocities reach 4 and 4.5 cm/s respectively. Comparison between the model-predicted shear velocity and bedload threshold suggests that the circulation and wind-driven currents cause minimum sediment mobility on SIB. Tidal current and waves can each cause sediment mobility at least once a year over 36% and 71% of the bank area respectively, while the combined wave-current shear can cause sediment mobility over 93% of the bank area. Calculated time percentages of sediment mobility caused by various processes indicate that wave or wave-dominant disturbance is most important and occurs over >50% of the bank area, while mixed disturbance is also significant and occurs over ~ 30% of the bank area. Tide or tide-dominant disturbance occurs over only 10% of the bank area. Several parameters are proposed as universal indices for quantifying seabed disturbance and sediment mobility for coastal and shelf environments.

**THE EFFECT OF A ROUGH SEA SURFACE ON INVERTED ECHO SOUNDER PERFORMANCE**

The Inverted Echo Sounder (IES) is designed to measure the round-trip travel time of sound from the sea floor to the sea surface, from which changes in thermal stratification can be inferred. Our application of this technology for the measurement of nonlinear internal waves has motivated an examination of the effect of a rough sea surface on instrument performance. The IES emits a pulse width of duration of a few nanoseconds at a frequency of 12kHz, and detects the backscattered signal using a hard-limiter and threshold-detection circuitry. The primary contribution to short period signal variability is scattering from the rough sea surface. A numerical simulation, which incorporates a representation of the sea surface, underwater acoustic propagation and backscattering, and the analog circuit within the instrument, is implemented so as to identify the extent of surface roughness effects. Pierson-Moskowitz spectra were used to represent a fully-developed sea state, corresponding to different wind speeds. The parabolic equation acoustic model is used to gain an understanding of propagation and backscattering of the IES signal. The calculated acoustic signal is then processed using the simulation of the instrument so as to determine predicted variability in the time series measurement. The probability distribution of travel times is then compared with that observed during deployments in the South China Sea. The instrument performance using alternative surface wave spectra is also explored.

**VALIDATION OF SUB-KILOMETER SAR WIND PRODUCTS FOR THE NOAA ALASKA SAR DEMONSTRATION**

RADARSAT-1 ENVISAT and ALOS SAR data have been routinely obtained for the NOAA Alaska SAR Demonstration (AKDEMO) project. The AKDEMO is a multi-year demonstration of the production and the use of SAR quantitative and qualitative products in a pre-operational environment. Sub-kilometer ocean surface SAR wind products are generated in near real-time and provided to the National Weather Service for weather analysis and forecasting. Different SAR wind algorithms have been used to derive the wind field. SAR measures the variation in Normalized Radar Cross Section, which is a function of wind velocity and direction. SAR imagery has only one azimuth viewing angle; therefore, to derive the wind velocity, one must obtain the wind direction independently from another source. In this study, we systematically evaluate the AKDEMO SAR wind retrieval accuracy by comparing the SAR wind retrievals with in-situ measurements. SAR wind retrievals with different algorithms and different wind direction inputs, i.e. model or buoy, are compared with the moored buoy winds that match closest in time. SAR wind retrieval consistency is evaluated for different sized area averages of SAR wind measurements.

**A FAST NEWTON-KRYLOV SOLVER FOR SEASONALLY VARYING GLOBAL OCEAN BIOGEOCHEMISTRY MODELS SUITABLE FOR AUTOMATIC PARAMETER OPTIMIZATION**

We present a computationally-efficient method for obtaining the fully spun-up state of a seasonally-varying global ocean biogeochemistry model. The solver uses a Newton-Krylov method to find the fixed points of the map that assigns to an initial state the value of the model state at the end of a one-year run. Apart from the preconditioner, which we describe in the paper, the method relies on a black-box public-domain Newton-Krylov solver that does not require the explicit construction of the model’s Jacobian matrix. Applied to the PO5.45 plus DOP cycle of an OGCM2.6 model, the solver is more than an order of magnitude faster than the traditional time-stepping approach for spinning up the model. The efficiency of the solver is illustrated by using the seasonally varying globally-gridded PO5.45 climatology to objectively optimize the parameters that control the mean lifetime of semi-labile DOP and the fraction of new production allocated to DOP. The optimization study demonstrates that the information in the seasonal variations of PO5.45 do not provide a significantly stronger constraint than the annually averaged data used in previous optimization studies.
APPLICATIONS OF QUANTARNY AMINE SURFACTANTS AS BIOGEOCHEMICAL TRACERS IN ESTUARINE, COASTAL, AND DEEPWATER SYSTEMS.

Cationic surfactants such as dialkyl(dimethyl)ammonium chlorides (DADMACs) find widespread use as fabric softeners. Other hydrophobic quaternary amine compounds (QACs) are used as disinfectants, and in a wide range of personal care products. Cationic surfactants are very tightly bound to suspended particle and sediment surfaces, and many of them are very persistent in marine waters. New extraction and HPLC-MS detection methods allow for sub-ng/g concentrations to be determined in < 100 mg samples, trace amounts in comparison to concentrations of individual DADMAC homologs that can exceed mg/kg in the most sewage affected harbor sediments. Initial applications of QAC analyses in urban estuarine settings include: tracing sources of organic matter and other superhydrophobic contaminants; constraining estuarine sediment transport; and understanding the persistence in sediments of other organic compounds that share a municipal wastewater source. Given the very high concentrations of DADMACs in sewage sludge, they serve as especially powerful tracers of sludge disposal and deposition at the Deep Water Dump Site (DWD-106). Additional applications of QACs as tracers of sediment age and cross shelf/slope transport will be discussed.

TEMPORAL VARIABILITY OF OXIDANT AND REDUCTANT SUPPLY TO THE REDOX INTERFACE IN THE CARACAO BASIN AND CONTROLS ON CHEMOAUTOTROPHY.

Rates of chemosynthesis are persistently high in the suboxic interface and upper anoxic zone in the Caracao Basin. Since 1996, we have been making monthly measurements of oxygen and nutrients and two or three profiles per year of chemosynthesis at the CARACAO time series site. In this paper we will present calculations of the vertical fluxes of oxidant and reductant over time and compare them to the chemosynthetic rates and information on the physics of the basin. In general vertical fluxes can only explain a small fraction (less than 10%) of the measured chemosynthesis suggesting that lateral sources of these compounds (and especially of oxidant) probably by Ekman transport, are most important.

EFFECT OF BENTHIC MICROALGAE ON NUTRIENT BUDGET OF A SHALLOW WATER SYSTEM: A NUMERICAL MODELING STUDY.

Analyzing the nutrient budget of an estuarine ecosystem is important for understanding nutrient inputs, their transformation and ultimate fate. In a shallow water system, the light can reach the bottom, which allows benthic microalgae to perform photosynthesis directly. This activity profoundly influences sediment biogeochemical processes, and thus the nutrient budget. In order to examine the role played by the benthic microalgal, an unstructured grid hydrodynamic model UnTRIM was coupled with the eutrophication model CE-QUAL-IAM and applied to a shallow water system, Lynnhaven River in Virginia. The nutrient budget was analyzed from the well-calibrated models that include a newly constructed benthic microalgal module. Based on the results, it was shown that the major external source for nitrogen and phosphorus was from nonpoint source loadings (91% of the total nitrogen and 95% of the total phosphorus). There were three comparable sinks: (1) export to the Bay (32% for nitrogen and 26% for phosphorus), (2) burial in the deep sediment (31% for nitrogen and 74% for phosphorus), and (3) denitrification in the case of nitrogen (37%). Sensitivity tests showed that, due to benthic microalgae's presence, internal recycling was enhanced, denitrification rate in the sediment increased, and overall export to the Bay was significantly decreased.

Both local and remote winds generate currents in an estuary, which can be as important as gravitational circulation in transporting nutrients and contaminants. Previous investigations based on simple analytical models and statistical analyses of sea-level and current-meter data at monitoring stations have suggested that the remote wind affects sea level and volume transport but the local wind dominates the generation of currents. Using outputs from a 3D hydrodynamic model validated against observations, we conducted EOF analysis to separate the two modes of wind-driven currents in Chesapeake Bay. In the along channel section, we found two dominant EOF modes. The first mode shows one-layer flow correlating with sea-level change rate at the estuary mouth and explains 58% of total current variability. The second mode shows two-layer flow correlating with local wind forcing and explains 20% of the total variability. In cross-channel section, both vertically sheared two-layer flows and horizontally sheared three-layer flows (upwind in the deep channel and downwind in shallow shoals) but no significant EOF modes.

A THREE-DIMENSIONAL VARIATIONAL DATA ASSIMILATION SCHEME IN SUPPORT OF COASTAL OCEAN OBSERVING SYSTEMS.

A three-dimensional variational data assimilation (3DVAR) system (ROMS3DVAR) has been developed for the Regional Ocean Modeling System (ROMS). This system provides a capability of predicting meso- to small-scale variations with temporal scales from hours to days in coastal oceans. Novel strategies are implemented, including the implementation of three-dimensional anisotropic and inhomogeneous error correlations, application of particular weak dynamic constraints, and implementation of efficient and reliable algorithms for minimizing the cost function.

KUROSHIO IN THE LUZON STRAIT.

Three ADCP were deployed in the central Luzon Strait (LS) to monitor current velocity. The observed current velocity indicated that the Kuroshio consistently flowed into the South China Sea (SCS). Further information was provided by the composite shipboard ADCP data that the Kuroshio intruded into the LS through the deepest channels (~20.5°N). Most of the intruded components made a loop and flowed out of the northern LS while a branch of Kuroshio intruded into the SCS. The MICOM model forced by the monthly wind provided by the ECMWF was used to interpret the observed current velocity. The model results validated by the ADCP data were capable of explaining the annual and interannual variations in the LS and the northern sector of the SCS. The annual transport across the LS is primarily westward. The eastward transport was occasionally found in summer during certain years. Furthermore, the variation in zonal transport was caused by the Sea Surface Height (SSH) variation occurring west of northern Luzon. Wind stress curl is responsible for this SSH variation. The Ekman transport, driven by the monsoonal winds, and Kuroshio strength off LS had little impact on the intrusion since the intrusion itself could be a variation.

IN-SITU PIV MEASUREMENT OF TURBULENT FLOW STRUCTURES OVER A MUSSEL-COVERED BED IN LAKE MICHIGAN.

A low-cost non-tethered submersible PIV system has been developed to measure small-scale flow structures in turbulent environmental flows. The system consists of a CW DPSS laser (532 nm), a scanning mirror (galvanometer), a CCD camera with GIGE interface, an ultra-compact PC for data acquisition and a USB signal-generating device that controls and synchronizes all components. All the components are battery-powered and can be fitted into a small underwater housing. The capability of the underwater PIV system has been demonstrated through a couple of field deployments in Lake Michigan. 2D turbulent velocity field (~20 by 20 cm) is resolved on a plane perpendicular to the lake bottom, which is covered by Dreissena mussels. Measurement results, including the vertical profiles of mean velocity, Reynolds stress, dissipation rate and the turbulent flux of particles (phyto-plankton and sediment particles), will be presented and discussed.
horizontally across material surfaces within fixed coherent eddies. This non-Lagrangian distribution functions of subsurface RAFOS float displacements from several different primarily responsible for the 'long tails', hence non-Gaussianity, observed in probability Lilly, J.

through emergent marsh areas. occupied only 2-8% of the total cell width, but they played a large role in transport through LIBERTY SCIENCE CENTER to develop RTD lessons using an interactive wall display. Effective data translation must overcome technical, cognitive, and aesthetic challenges and is best facilitated by a team approach. Ocean observatories and their real-time data, provide an excellent means to engage students and the public in environmental research with compelling and relevant stories. Liefjd, I. D., Dauphin Island Sea Lab, Dauphin Island, USA, iliefjd@dil.org.

MATCH AND TEMPORAL VARIABILITY IN ABUNDANCE OF THE DIATOM PSEUDONITZSCHIA SP. IN COASTAL ALABAMA WATERS The potentially-toxic diatom Pseudo-nitzschia is common in the northern Gulf of Mexico. In coastal Alabama, its abundance is monitored by the departments of Public Health (ADPH) and Environmental Management (ADEM) and the Dauphin Island Sea Lab. Seven sites along the Alabama Gulf Coast are monitored weekly to bi-weekly for potentially-toxic microalgae in the BEACH program. Pseudo-nitzschia was detected at densities up to 10^6 per liter in 380 of 606 routine samples (63%) taken between November, 2003, and May, 2007. A cluster analysis of the frequency distributions of abundance at the sites showed that the site of Little Lagoon Pass had a strong dissimilarity compared to other sites. This was due to a higher frequency of bloom densities and a lower frequency of absences, indicating that it is a regional 'hot-spot' for Pseudo-nitzschia. Distributions showed no apparent relationship with temperature, over the range 10 -34 C. There was a weak positive relationship between salinity and abundance, over the range 3 - 35 PSU. Pseudo-nitzschia was absent more frequently from brackish sites. Peaks in abundance occurred in April-May, with secondary peaks in fall. Lightbsey, A. F., St. Anthony Falls Laboratory, University of Minnesota, Minneapolis, USA, aniel@gwcmn.edu.

MEASURING AND MODELING FLOW THROUGH SPATIALLY HETEROGENEOUS VEGETATION There is increasing interest in the internal circulation of both natural and constructed wetlands to better understand and model their ecology, nutrient and pollutant removal, and water storage abilities. Models for the marsh regions within wetland systems often assume uniform vegetation, which is represented by uniform hydraulic roughness. However, velocity heterogeneity is nearly always present and alters the distribution of the chemical and biological transformations that occur within a wetland. Therefore, the identification of fast flowpaths is an important step in understanding overall system function. Here, we describe field work within a 145-ha constructed treatment wetland in EUROPHYPHO BOOSTERS IN THE WESTERN NORTH PACIFIC OCEAN With increased observations of devastating category-5 cyclones, such as Hurricane Katrina (2005) and Supertyphoon Maemi (2003) found to intensify on warm ocean features detect ed by satellite altimeters), there are great interests in investigating the role ocean features play in the intensification of category-5 cyclones. Based on 13 years of satellite altimeter data, in situ and climatological upper ocean thermal structure data, best track typhoon data of the US Joint Typhoon Warning Center, together with an ocean mixed layer model, 30 western North Pacific category-5 super Typhoons occurred from 1993 to 2005 are systematically examined in this study. It is found that warm ocean features act as ‘booster’ to super Typhoons. In regions where the background climatological warm upper ocean layer is too shallow (typically with the depth of the 26C, C isotherm 26C, 60m) to support intensification to the fifth category, the presence of boosters can effectively deepen the warm ocean layer by as much as 70% (i.e., the depth of the 26C, C isotherm reaching 100m). As such, the critical negative feedback to intensity due to typhoon self-induced sea surface temperature cooling can be effectively suppressed so that intensification to the fifth (i.e., the highest) category becomes possible. It is found that in the western North Pacific, 33% (i.e., 10 out of the 30 cases) of the typhoons reached this highest category due to the fuel of boosters. ASSESSING MITOCHONDRIAL CYTOCHROME B FOR DNA BARCODING IN DINOFLAGELATES
DNA barcoding can be a powerful tool for unraveling biodiversity of dinoflagellates in natural environments. Earlier studies suggest that the conventional DNA barcoding gene mitochondrial cox1 does not provide as good taxon resolution as mitochondrial cox1 in dinoflagellates but systematic evaluation has not been done. In this study, cox1 barcode region was compared with cob for utility in DNA barcoding. Surveying over 30 dinoflagellate species strains in cox1 sequences reveals that a 382-bp fragment of cob is easy to PCR amplify and its resolving power in phylogenetic analysis is equivalent to cob whole gene (~1kb) and surpasses cox1 barcode region. With this cox1 barcode primer set, we analyzed dinoflagellate diversity in Long Island Sound (LIS). Dinoflagellates from orders of Gymnodiniales, Prorocentrales, Gonyaulacales, Suctoriales (Symbiodinium-like), and Peridiniales (including Pteridium-like organisms) were detected, with the highest Shannon-Weaver diversity index occurring in the summer at the western LIS and the lowest in winter. Gymnodiniales were consistently dominant the dinoflagellate assemblages. Pteridium- and Symbiodinium-related taxa were also found. The results demonstrate that cob is a promising DNA barcoding marker for uncovering dinoflagellate biodiversity.
